Mine Design for Silopi Üçkardeşler Asphaltite Vein
Silopi Üçkardeşler Asfaltit Filonu İşletmeTasarımı

S.G. Erçelebi, C.A. Öztürk, İ.E. Önsel, M. Özkan
Istanbul Technical University, Mining Engineering Department, Istanbul

ABSTRACT In this study, Silopi Üçkardeşler asphaltite vein is introduced and geology of the area is explained as a part of project carried out at ITU Mining Engineering Department. The experimental results for the geo-mechanical properties of the geological formations and the asphaltite itself are also presented. Silopi vein has total 39,662,238 tons of reserve with average lower calorific value of 5,216 Kcal/kg. The minable reserve for the vein by means of open pit and underground mining is calculated as to be 19,836,377 tons. Open pit and underground mine design studies are performed in order to exploit the asphaltite vein in optimum economical way. Open pit optimum depth is found to be around 885 meters which will result of 13 years of 425,000 tons yearly production. After reaching final depth of pit, a 50 m pillar is going to be left and underground production will commence. Produced asphaltite will be sent to a power plant.

Keywords: Silopi Üçkardeşler asphaltite, mine design, reserve estimation

ÖZET Bu çalışmanın amacı, Silopi Üçkardeşler asfaltit filonunu tanıtmak ve İTÜ Maden Mühendisliği Bölümünde yapılan tasarım çalışmaları hakkında bilgiler vermektir. Aynı zamanda jeolojik formasyonlar ve asfaltit numuneleri üzerinde jeo-mekanik deneyler yapılmış ve sonuçlar özetlenmiştir. Filon rezervi ortalama 5,216 Kcal/kg alt ısıl değere sahip 39,662,238 ton olarak hesaplanmıştır. Bu jeolojik rezervin 19,836,377 tonunu açık ve yeraltı işletme yöntemleri ile üretebilmek için tasarımlar yapılmıştır. Açık işletme optimum derinliği 885 m. kotu olarak 13 yıl boyunca yılda 425,000 ton cevher üretebilecek şekilde bulunmuştur. Bu derinlikten sonra işletme yer altı üretimine geçecektir. Açık işletme ve yer altı işletmesi arasında 50 metre kalınlığında bir asfaltit üretilmeden topuk olarak bırakılacaktır. Üretilecek asfaltit kurulacak termik santralde yakılarak elektrik üretilecektir.

Anahtar Kelimeler: Silopi Üçkardeşler asfaltit, maden tasarımı, rezerv tahmini

1 INTRODUCTION

Lebküchner (1969) describes asphaltic substances as all natural residues of asphaltic petroleum, disregarding whether they were found in primary or secondary deposits, associated with mineral substance or not, chemically altered or not. Lebküchner's study is one of the earliest studies among asphaltite veins occurring in South East of Turkey. Asphaltite veins (or vein-like substances) are important energy source for South-East. There are 12 economical asphaltite veins in the south of Şırnak and in Silopi. Total reserve is about 82 millions of tons (Dicle Kalkınma Ajansı 2010).

Among 12 veins, only Harbul vein which is owned by Park Elektrik Üretim Madencilik Sanayi ve Tic. A.Ş., burns asphaltite in a power plant to produce electricity. Most of the other veins already reached to open pit limit and abondened. Üçkardeşler Asphaltite vein has a high calorific value (5216 Kcal/kg) and has a potential of producing 1x135 MW electricity for 50 years or 2x135 MW electricity for 25 years.).

As now, there is no asphaltite underground mine, but known asphaltite veins go deeper and presents a great potential for underground mining. When Üçkardeşler asphaltite vein reaches its limit for open pit mining in 13 years, an underground mine will be in operation and will serve as an example to other remaining veins.

Üçkardeşler vein is investigated by General Directorate of Mineral Research and Exploration (MTA) first time between 1980-84. MTA drilled vertical and incline total 54 drills between 1980-84 and 5 inclined holes in 1985-86. 4 more holes are drilled by Şırnak Enerji A.Ş. in 2011-2012.

2 STUDY AREA AND GEOLOGY OF THE SITE

The studied area is located in the north of Gitta (Çalışkan), Besbin (Görgülü), Beşiri (Koyun Ören) villages in Silopi town in Şırnak. Silopi town covering the studied area has been neighbor to Syria (20 Km) to the southwest, Iraq (51 Km) to the southeast and Cizre town (11 Km) to the west, Şırnak city (33 Km) to the north and Uludere town (11 Km) to the northeast. E-24 highway goes through the Silopi town and reaches to Habur border. In Silopi, the way between Habur border reaches to Besbin village in the studied area. Üç Kardeşler Vein which is the main subject of the study is 2.5 km far from the Besbin village (Fig.1).

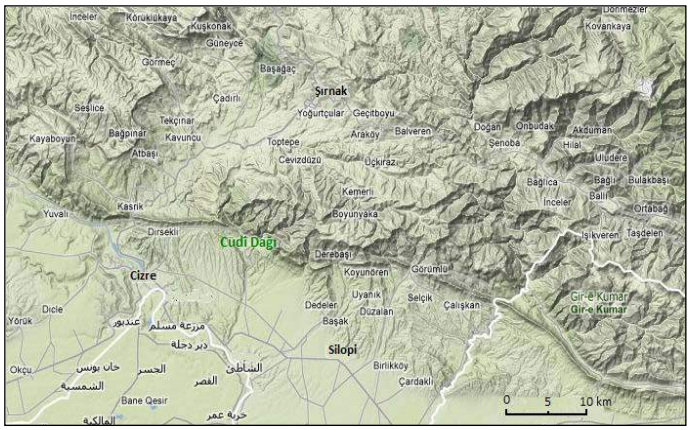

Figure 1. Location Map (Google)

A geological cross-section of the study area is given in Figure 2 to show the main geological formations in open pit mine and dump site.

Within the region, rocks deposited in the upper Paleozoic – upper cenezoic period of the time, extend roughly east-west direction. Paleozoic rocks are represented by the Permian limestone. Mesozoic rocks consist of lower-middle Triassic (Goyan Group), the upper Triassic-Jurassic-Cretaceous limestone and dolomitic limestone (the Cudi Group).

In the study area, there is the slope debris which is common and thick, affect the work of the mining. The slope debris formed coarse gravel and blocks locate near of Üçkardeşler vein.

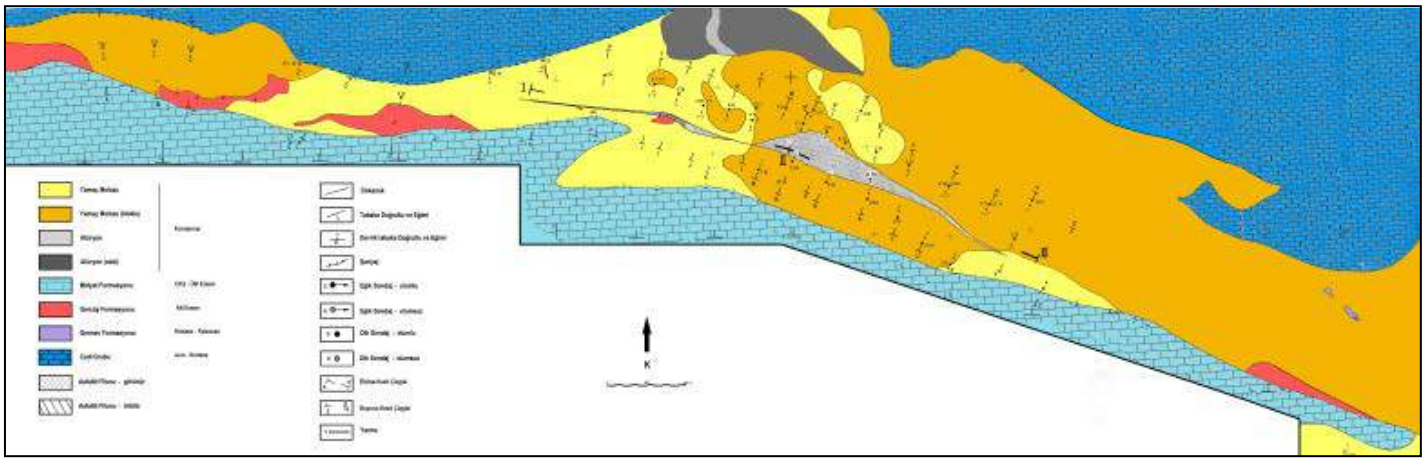

Figure 2. Geological map of the area

3 GEOTECHNICAL PROPERTIES OF FORMATIONS

Core samples for Gercüş and Midyat Formations and asphaltite were taken from Inclined boreholes drilled for the purpose of taking samples for testing. After investigation of geotechnical logs of boreholes, it was found out that sandstone, mudstone and siltstone were the main rocks of Gercüş Formation and these materials vary between themselves. Midyat formation consists of strong limestone, clay limestone and altered and clayed limestone. Material in this formation can be considered as very strong, strong and low strength. In order to determine mechanical and physical properties of rocks belonging to Gercüş and Midyat Formations and asphaltite cores are taken to rock mechanics labs of ITU Mining Engineering Department. Uniaxial compressive strength tests (σ_c), point load tests (I_s), triaxial compressive strength tests, shear strength tests were performed physical properties were determined on rocks classified. Triaxial compressive strength, uniaxial compressive strength and point load index, elasticity modulus (E_m), cohesion (c), internal friction angle (ϕ), and unit volume weight (γ) were determined after tests. Contentious tests were performed to increase reliability of results.

Average strength and density of asphaltite were found to be 17.82 MPa and 1.41 gr/ cm^3 respectively. Rock strength Parameters are given in Table 1.

Table 1. Material strength parameters (ITU Technical Report, 2012).

Rock mass	Material	σ_c (MPa)	I_s (MPa)	E_m (MPa)	c (MPa)	ϕ (^{0})	γ (kN/m^3)
Gercus formation	Gray and green sandstone containing few clay and silt	25.26	1.07	4,743.3	4.70	51.10	23.9
	Red–brown clay stone and sandstone containing sand and silt	22.97	1.05	3,529.1	5.50	45.00	25.0
	Red–brown clay stone containing silt and filled with gypsum	18.55	0.92	3,781.2	n/a	n/a	17.2
Midyat formation	Limestone	139.9	6.80	31,200	40	44.00	24.2
Uckardesler asphaltite vein	Asphaltite	17.8	0.54	599.8	4.40	37.60	14.1

4 RESERVE CALCULATIONS

In order to construct the geometry and 3 dimensional solid model of the asphaltite vein, the drill hole data obtained from MTA is used and given below. In addition 4 new holes were drilled by Şırnak Enerji. The length of Üçkardeşler vein is 1265 meters. The width of the vein is between 2 to 75 meters. Depending on the width, the vein is divided into 3 parts.

Part I (West Part)

The length of this part is 605 meters. Except the 130 meters part which is on the East of K-K' cross section, there is no overburden. On the eastern part, the vein is covered with 20-50 meters of slope rubble. The width of the vein in this section is between 2 to 40 meters. Vein is inclined 80^0-87^0 from South (1100 m) to North (900 m). Between 900 and 850 m high it becomes vertical and 85^0-80^0 inclined in lower parts. Drill holes E2B-E8, E3-E9, show that, mineralization is not continuous from one side to other. Under 950 meters, mudstone and clay wedges interfere the asphaltite.

Part II (Middle Part)

This part is 560 meters long. The width of the vein is between 5 to 75 meters. Vein is vertical until 700 m, and then 85^0-80^0 inclined to South.

Part III (East Part)

The vein is 100 meters long in this part. Vertical at the top, and 85-80 inclined to South under 850 meters. In the Eastern part there is a clay wedge. At the end of the vein clay and mudstone wedges are common.

By using all drillhole data mentioned above, 3 dimensional solid model of the vein is constructed by the help of Micromine software. Drill holes locations and solid model, with proven and probable reserves, are shown in Figure 3, 4 and 5. When calculating the proven reserve, the influence of the drill hole is taken as 100 meters, and for probable reserve calculation, influence distance is taken as 200 meters.

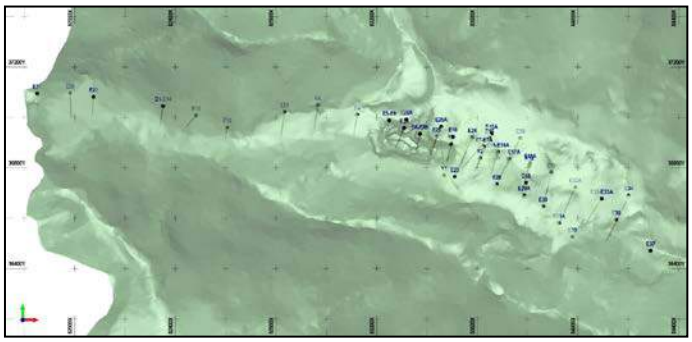

Figure 3. Topography and drillholes.

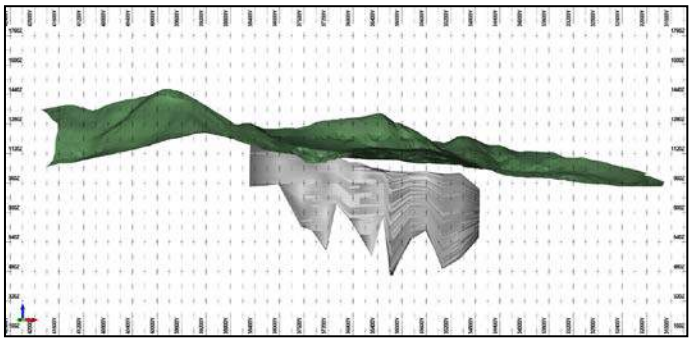

Figure 4. Proven reserve

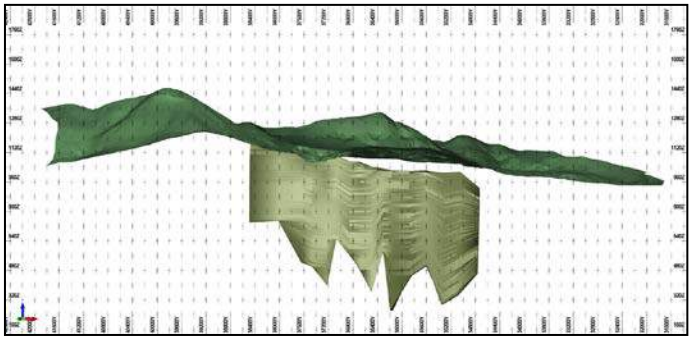

Figure 5. Proven and probable reserve

Table 2. Üçkardeşler aphaltite vein reserves.

Reserve Type	Reserve (m^3)	Reserve (Ton)
Proven Reserve	15,925,088	22,454,374
Probable Reserve	12,204,159	17,207,864
Total Reserve	28,129,247	39,662,238

Result of tests carried out to obtain the properties of the asphaltite show that the moisture content of original asphaltite is %3.52, ash content is %37.59, volatile matter is %46.66, fixed carbon is %14.10, total sculpture is %7.50, and combustible sulphure is % 7.25, low calorific value is 5,216 Kcal/Kg, and high calorific value is 5,487 Kcal/Kg.

5 OPEN PIT DESIGN AND PLANNING

5.1 Slope Stability

In this study, the minimum Factor of Safety value is taken as 1.30 for the design of open pit slopes. Factor of safety (F) has vital importance for the design of slopes that can be simply defined as the ratio of forces against sliding to driving forces. Limit equilibrium condition is defined while F=1. This is because F must be higher than 1.0 for the design of slopes against sliding.

Slide v:6.005 software was used to analyze the stability of slopes. These analyses were carried out on the cross-sections taken from the plan view of the final open pit design as given in Figure 8.1. Firstly geological information was processed to the cross-sections taken from 4 different sections of the open pit as the most vertical overall slope angle. After that, cohesion, internal friction angle, and unit volume weights of each formation were given as input parameters. Underground water table level (UGWT) was drawn as nearly close to the surface for Gercüş formation and relatively deeper for Midyat formation which is strong rock mass. Stability analyses were carried out by using Bishop multiple slipping and

Janbu multiple slipping surface analyses and the model giving the least value of F is accepted so as to be in safe side of the design.

As an example from the stability analyses Cross section 1-1' is given in Figure 6.

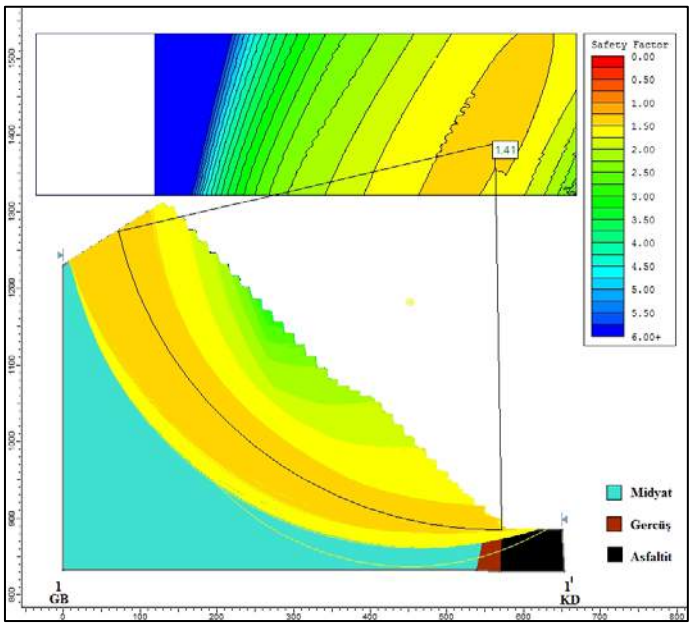

Figure 6. 1-1' Cross-section stability analysis, F=1.41; overall slope angle: 44^0

The analyses show that the overall slope angle can be designed as $37\text{-}38^0$ for Gercüş formation and 44^0 for Midyat formation both for exploitation and final overall slopes.

Bench Geometry

According to slope stability analysis results, bench heights as 15 meters, bench widths as 15 meters for production benches, 10 meters for final benches, road widths as 15 meters and road inclination as 8^0 are chosen. Bench angles are 75^0 for Midyat formation, 60^0 for Gercüş formation, 75^0 for asphaltite and 45^0 for slope debris. Overall slope angle for the pit is 36.5^0 for North slopes (Gercüş formation), 44^0 for South slopes (Midyat formation), 37^0 for East slopes and 39^0 for West slopes.

5.2 Surface Mine Design

5.2.1 Optimum pit limit

Optimum pit limit is determined by using Lersh-Grossman Algorithm implemented in Micromine software. Optimum pit depth is found to be around 885 meters. In addition, East and West end of the vein is where asphaltite becomes very thin, under 2 meters, and it is not economical to mine these parts.

5.2.2 Surface mine planning

Annual production of 425,000 tons of asphaltite of average 5216 kcal/kg is going to be used at a 1x135 MW coal firing power plant. Until reaching to the optimum pit depth it will be possible to operate open pit for 13 years. After 13^{th} year underground mine will be in operation alone.

According to slope stability analysis and the slope geometry given in previous section 5 and 10 years surface mines are planned by using Micromine software. At the end of first period (first 5 years), surface mine will be around 960 m altitude, entire asphaltite over 975 m elevation inside the economic pit, and some of the asphaltite from the 860-975m bench will be produced. The plan at the end of the first period is given in Figure 7 and 3-D shape is given in Figure 8.

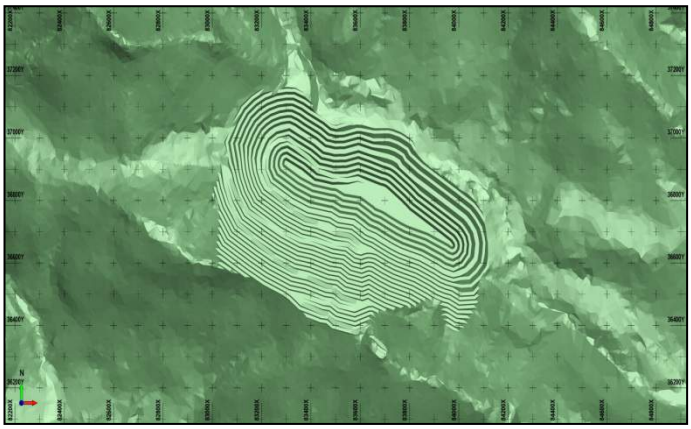

Figure 7. Surface mine plan after I^{st} period

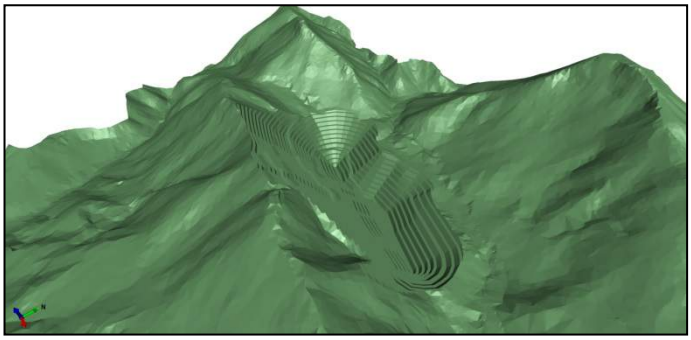

Figure 8. 3-D view of surface mine after I^{st} period (Looking from S-E direction).

Plan of the surface mine at the end of IInd Period (5-10 years) is given in Figure 9 Figure 10 shows 3-D shape. Figure 11 and 12 shows 2 period production together. Asphaltite production, overburden removal and stripping ratios for two periods are given in Table 3. For the Ist Period, stripping ratio is 16.6, for the IIth Period, it is 13.2 averaging 14.8 as total.

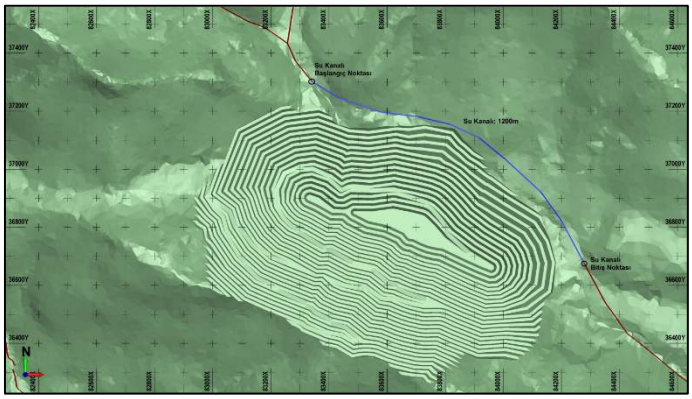

Figure 9. Surface mine plant after IInd period

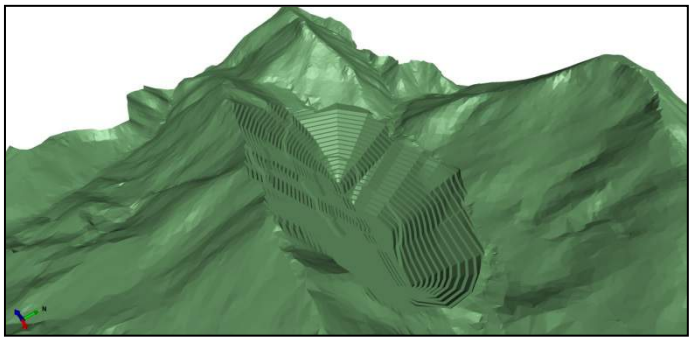

Figure 10. 3-D Surface mine after Ist period (Looking S-E).

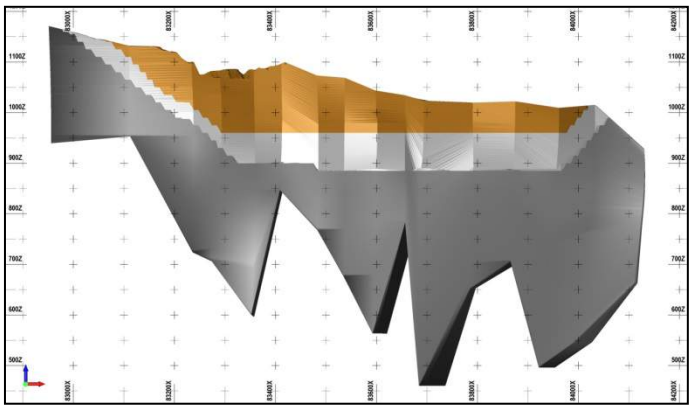

Figure 11. Surface mine example cross section showing I and IInd period

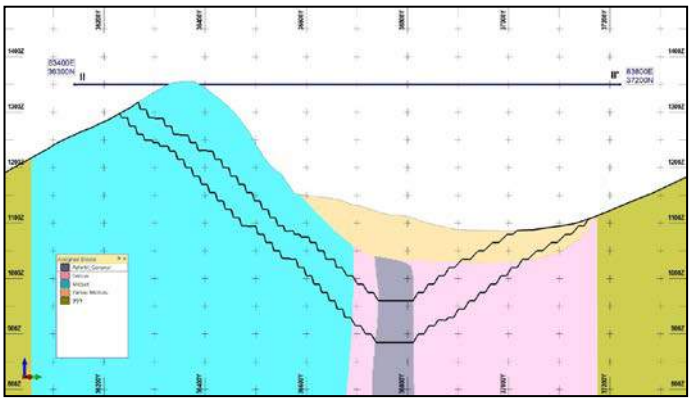

Figure 12. I and IInd period asphaltite production

Table 3. Ist and IInd period production summary of surface mine.

	Asphaltite (ton)	**Overburden (m^3)**	**Strip Ratio**
Ist Period	2,567,115	42,671,042	16.6
IInd Period	2,940,680	38,873,443	13.2
Total	**5,507,795**	**81,544,485**	**14.8**

5.2.3 Dump site

The opposite side of the Kalender Hill to the surface mine is selected as dump site. This site the most appropriate area for the dump site when considering high mountainous regional feature of the mine area. Overburden haulage will take place from a 400 meters long tunnel which will be constructed on the west of the surface mine. Another alternative is the going around Kalender hill by means of 700 meters long haulage way. Both alternatives with the local coordinates are shown in Figure 13.

It is expected that overburden material will compose 30 degree dumping slopes. In this project a slope stability study is not carried out for the dump site. Dump site slope stability study is important in terms of environmental issues and safety considerations and dump slopes should be constructed in a way that slope failures are avoided.

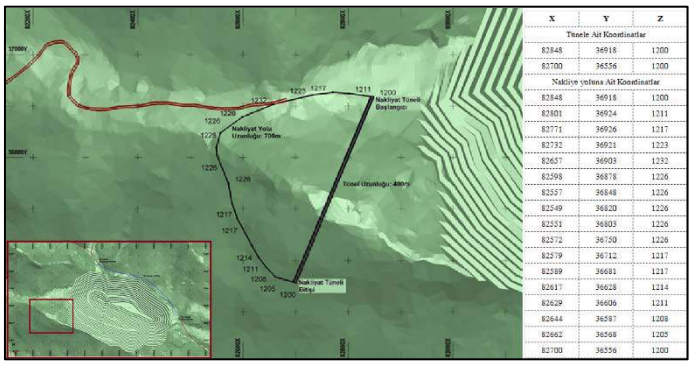

Figure 13. Surface mine to dump site haulage way alternatives

5.2.4 Open pit equipment selection

Equipment selected in open pit mine are given below with their capacity.

Equipment	Capacity	Quantity
Drill	10.16 cm(4")	3
Excavator	5 m^3	6
Truck	30 ton	28
Loader	4 m^3	1
Dozer	335 HP	3
Grader	165 HP	1
Repair equipment	10 ton	2
Sprinkler	10 ton	1
ANFO truck	10 ton	1
Equipment truck	10 ton	1
Fuel Truck	10 ton	1

6. UNDERGROUND MINE DESIGN

As can be seen from section 4, Üçkardeşler asphaltite vein has 22,454,374 ton proven reserve and proven+probable 39,662,238 ton reserve. Plan, design and cost study related to underground mine have been carried out according to proven reserve estimation.

In Section 5 amount of ore which will be produced by open pit mine is determined. To prevent the underground mine interfering the open pit mine and to prevent slides, a pillar has to be left between underground and open pit mine. The study about the height of the pillar is given in this chapter at the following part "Support of the Underground Spaces". At Table 4 ore reserves of underground, open-pit and pillar is given.

Table 4. Üçkardeşler asphaltite vein production and pillar reserves.

No	Definition	Amount (Ton)
1	Open Pit Mine Production	5,507,795
2	Underground Mine Production	14,328,582
3	Pillar	2,617,997
4	Total	22,454,374

From the table above it can be seen that proven reserve which can be produced by underground mine is 14,328,582 ton. In Figure 14 parts of the ore body which are going to produced by open pit, underground mine and pillar between them is given.

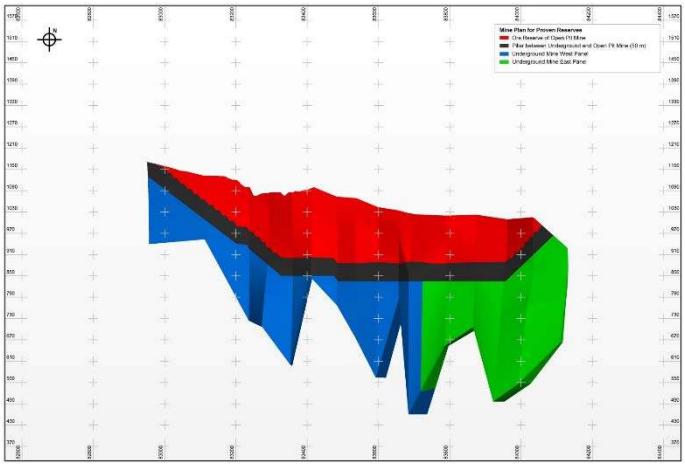

Figure 14. 3D view of Üçkardeşler asphaltite vein underground and open pit proven reserves and pillar.

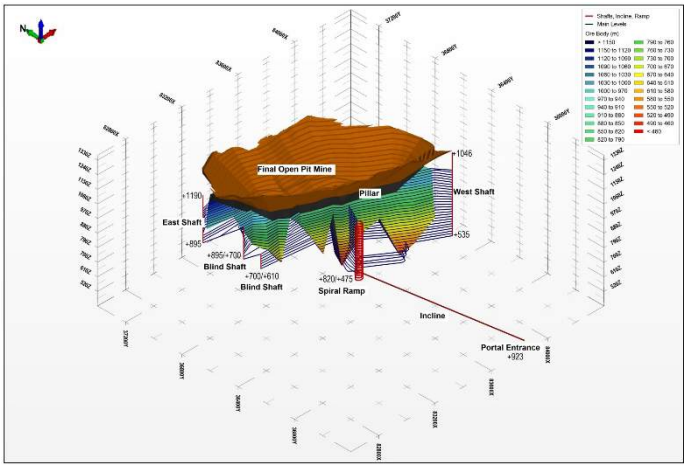

Figure 15. Underground mine development project – North East 3D view.

Details of underground mine design is given elsewhere (Ozturk, 2014) and will not be repeated here. Figure 15 shows underground mine design.

7. CONCLUSION

Asphaltite veins are only energy resources in southeastern part of Turkey. In this study, the summary of findings for Üçkardeşler asphaltite vein in Silopi region is presented. Using existing drillhole data, proved and probable reserve of the vein is calculated as 39,662,238 tons. In the study 19,836,377 tons of this reserve is estimated to be produced by means of open pit and underground mining method to feed a power plant. Open pit mine will be operated 13 years and after that underground mine will commence.

For open pit mine the slope stability analyses show that the overall slope angle should be designed as $37\text{-}38^0$ for Gercüş formation and 44^0 for Midyat formation both for exploitation and final overall slopes. Open pit mine will produce 425,000 tons of asphaltite per year to feed a 1x135 MW power plant. Also an alternative of the 2x135 MW capacity and 850,000 ton/year asphaltite production is considered. In both alternatives yearly production rate of 425,000 ton can serve the power plant in all 13 year. Underground mining operations will start after 13 years in case the 1x135 MW is used and production will be 425,000 ton/year throughout the mine life. In case 2x135 MW capacity power plant in operation underground mining operations will start in the sixth year and will serve the power plant for 20 years.

The Future of Mega Data in Virtual Reality Environments in Mining Practice

F.T. Suorineni
UNSW Australia, Sydney, Australia

ABSTRACT At the mine feasibility stage data is collected from several sources. This data may be multi-dimensional. Space and time are examples of the multi-dimensionality of data. At the operational stages data is also collected from various sources to ensure the mine is operating optimally, economically and safely. Mines are therefore dealing with mega data from multiple sources and dimensions at any given time. Understanding mega data from multiple sources and dimensions calls for new thinking. The extreme power of computers coupled with virtual reality technology and scientific visualization provides a way for dealing with and understanding multidimensional mega data from multiple sources. The concept of Big Data has recently emerged. This paper argues Big Data application in mining should be approached cautiously and discusses the benefits and future of virtual reality and scientific visualization in dealing with multi-dimensional mega data from multiple sources in mining practice with case examples.

Keywords: Mega data, Virtual reality, Multi-dimensional data

1 INTRODUCTION

1.1 Stages in the Mining Process

The development of a mine starts from discovery of the orebody and continues through various stages to production and closure. The critical stages in the mining process are summarized in Figure 1.

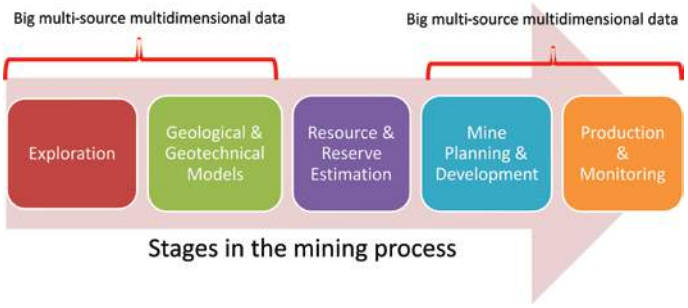

Figure 1. Stages in the mining process.

In Figure 1 the exploration stage usually involves the collection of data by multidisciplinary teams in:
– Geophysics
– Geochemistry
– Geologists
– Geotechnical, and
– Other information.

The data involved in each discipline may be several gigabytes and multidimensional – space, time and cost for example.

Several exploratory drill holes (Figure 2) would have been used to collect data from cores including grades, rock quality, structure and definition of lithologies. Geotechnical data such as rock strengths, RQD among others will also be collected at this stage.

The data from different experts from multiple sources do not sometimes correlate and are often in conflict when integrated. It is difficult resolving such data conflicts as each expert will often insists on being right.

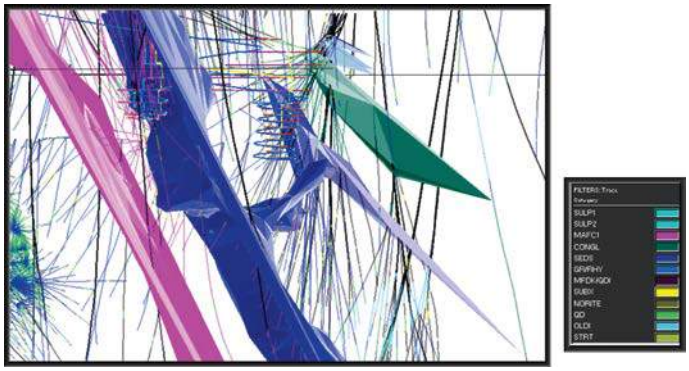

Figure 2. Several boreholes for different multi-dimensional data extraction for multiple purposes – Example of Mega Data in mining.

The next stage in the mine development process is to understand the geology of the

deposit as deciphered from Stage 1. At this stage, all data from the various sources and disciplines must be integrated to construct the geology of the deposit – the geological model. Here, the use of virtual reality and scientific visualization is critical as explained later in this paper.

Understanding the geomechanics at the exploration stage is also critical for deciding on the mining method and strategy later in the mine development. This is also achieved through integration of the various geotechbnical and geological data – the geomechanical model.

The geological model forms the basis for the ore resource and reserve estimations. Both the geotechnical and geological models provide guidelines on the mining method selection and development strategies (Fig.1).

The mining method selection stage is critical as some methods such as block caving, once selected and developed cannot be reversed. Such methods are inflexible methods as opposed to flexible ones, and must be selected with all the due care and caution necessary.

When developed, mine geometries are complex (Figure 3) and can be compared with major city infrastructures – streets, buildings, underground and above ground infrastructure – pipe and electrical networks and subways.

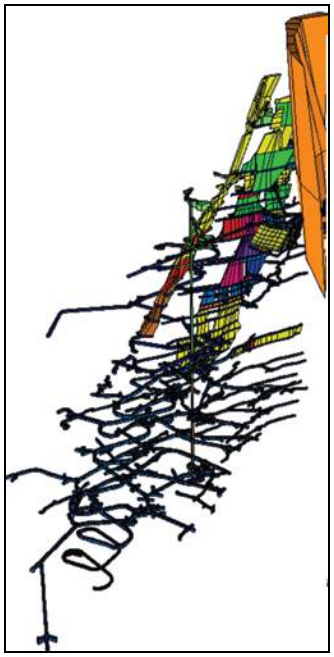

Figure 3. Complexity of underground mine infrastructure.

The complexity of a mine is more pronounced when it is in production. Optimum production and enhanced safety of workers and equipment is required at this stage. Both optimum production and enhanced safety require monitoring of various kinds.

In reality, for a producing mine large multi-dimensional datasets from multiple sources including the following:

- Geology
- Rock properties
- Different excavation types and geometries
- Monitoring data of various types and volumes such as seismicity
- Damage locations
- Support types and locations
- Production levels
- Ore grades
- Dilution levels, and
- Ventilation data and many more.

The size/volume and dimensionality of data from mines can be so overwhelming that it is difficult for the best mind to process and understand. It is not uncommon therefore, to frequently hear that mines collect so much data but never analyse that data even though understanding the data could unlock the secrets to enhanced productivity and safety.

1.2 The Big / Mega Data Phenomenon

1.2.1 Big data

The origin of the term “Big Data” may still be a matter of debate. However, it is established that the first usage of the phrase with a technical connotation to not just a lot of data, but different types of data handled in new ways in the computing context is John R Mashey in 1998 (Lohr, 2013).

Intel (www.intel.com.au/BigData) defines Big data as any collection of data sets so large and complex that it becomes difficult to process using traditional data processing applications. It lists the challenges in dealing with “Big Data” as:

– Analysis
– Capture
– Curation
– Search
– Sharing
– Storage
– Transfer
– Visualization, and
– Privacy violations.

Clearly, what is considered "Big Data" will vary from one institution / company to another depending on the capabilities of the organization and on the capabilities of the applications that are used to process and analyze the data. Big Data is also technology dependent as what is considered to be "Big" today will not be so in the future with advances in technology – Computer power.

1.2.2 Trends and challenges in big data applications

1.2.1.1 Trends

The key drivers of Big Data can be grouped into
– Business
– Technical
– Financial, and
– Intelligence / security

Businesses are using Big Data to discover new insights that drive competitive advantage from data that is increasingly everywhere and in various forms at manageable cost. Here is where “Big Data” is now a buzz word in the mining industry, where the survival of companies in finding innovative ways to reduce cost to meet low market prices is a challenge in today’s fluid mineral market prices.

According to a an article in the Generation of New Technology (GNT) (GNT, 2010) webzine, worldwide spending on hardware, software, and services for 3D visualization, simulation, and training in the defense and government segment will reach $16.5 billion in 2010 and grow to $20 billion by 2015. This foretells that the paradigm change will happen in all industries in the near future since many technological advances and innovations come from advanced defense research. The fact that we are discussing the use of this phenomenon in mining today is confirmation of this prediction coming true.

1.2.1.2 Challenges

Just as previous trendy words and phrases like “Sustainability” and “Innovation” have not resulted in their expected impacts on the mining industry, caution is required in the rush of the industry to adapt the “Big Data” phenomenon with the expectation that it will result in a paradigm shift to make it more efficient. There are challenges to overcome for the adoption of Big Data phenomenon in the mining industry to be beneficial.

The potential challenges in Big Data application include skill training and having the appropriate technologies. New skills are required for the human elements to make sense of large data and new tools are needed to help with data analysis. In the required new skills, judgment and intuition will be absolutely essential to making use of needed tools.

The technological challenges in Big Data applications are summarized in Mitchell (2014) and presented as follows:
– Big Data lakes:
– More predictive analytics
– Need for high-end data scientists
– Need for NoSQL
– Deep learning, and
– In-memory analytics

With Big Data traditional databases which require that you design the data set (Structured database) before entering any data are of little use. In place of database theory are data lakes, also called enterprise data lakes or enterprise data hubs. With data

lakes all data from all sources are dumped into a big Hadoop repository and what is required are tools for people to analyze the data, along with a high-level definition of what data exists in the lake. The challenge here is that people who use the tools to analyse data lakes in the traditional sense must be highly skilled.

With unstructured databases that suits Big Data, Structured Query Language (SQL) is of limited use and Not Only SQL (NoSQL) come into play. NoSQL tools are still in their infancy of development and until then, querying of data lakes of Big Data will remain a challenge and require skilled programmers.

An approach to overcome the SQL challenge is "Deep learning". Deep learning enables computers to recognize items of interest in large quantities of unstructured and binary data, and to deduce relationships without needing specific models or programming instructions. Like NoSQL, deep learning is also still evolving.

With Big Data, analysts have not only more data to work with, but will also require the processing power to handle the large numbers of records with many attributes. Foroohar (2013) noted that given the rise of social media, Big Data and other technical trends we should not expect boost in efficiency and productivity. This negative forecast is attributed to the declining prices of software, computers and networking technology that have potential to slow down gains in the power of technology. Simply put, slower tech-price declines and slower gains in computer power imply that pace of innovation in the short term will be sluggish. This poses a potential challenge to the benefits of Big Data in the production industries, including mining.

1.3 Virtual Reality and Scientific Visualisation

The evolution of virtual reality (VR) technology is summarized in Kaiser et al. (2005). The VR system projects dynamic stereo images onto a curved screen, providing several people with the sense of full data immersion. Subsurface excavations, infrastructure, geology, hydrology, geochemistry, geomechanics, cost and time can all be combined to provide a holistic overview of a mine property.

Inherent complexities of three-dimensional data can be viewed with a true sense of depth and spatial relationship in the VR. The scale of the screen, combined with the depth perception provides an immersion that increases the participants' overall understanding of spatially complex data relationships and accelerates data comprehension as well as transfer of experience and knowledge.

The power of VR environments lies in the illusion of being in a virtual world and individuals can see and feel their data as being part of it. The large size and extent of images combined with the depth perception in VR centres allow interpreters to see details without losing the broader perspective. In the VR, data and images can be rotated in any direction, magnified to various scales and sliced in arbitrary directions for detailed viewing, analysis and interpretation.

The human eye's ability to quickly detect and understand patterns and anomalies is unsurpassed by technology. The benefits of developing advanced visualization applications are clearly highlighted in the National Science Foundation (NSF) review of visualization technologies for science (Munzner et al., 2006). NSF notes that scientific visualisation is essentially a means of quickly identifying trends and anomalies and relies on the human's visual analysis capability as the most effective means of doing so. It is therefore a means of maximising the use of human perception and pattern recognition and thus enables better insight by all for enhanced strategic and tactical decision making.

Vasak and Suorineni (2010) differentiate between 3D modeling software visualization capabilities and scientific visualization. Proper use of VR and scientific visualization represents a fundamental paradigm shift in how we collect, store, process and interpret

multi-terabyte datasets, formerly the domain of enterprise database managers.

3D Modeling software visualization is limited to space while scientific visualization uses the geometric (easting, northing, elevation) data as a structural support for thematic (property) data. The goals between the modeling visualization and scientific visualization are also different; the former is used to create data and information, whereas the latter is used to explore datasets to find new trends and develop new knowledge. Most scientific visualization software relies on the concept of filters being applied to a dataset to extract or highlight knowledge. These filters can be connected into a visualization pipeline which, once correctly defined, can be applied to any number of datasets. This approach is particularly well suited when integrating data from multiple sources or when having to review multitudes of similar datasets.

Scientific Visualization relies more on the exploration of datasets that have been generated by simulation software whereas mining tends to rely on inferred datasets based on observational data. Examples of this type of inferred data are most exploration datasets where large volumes of space must be "defined" based on limited drill hole (or geophysical) datasets.

Another key difference lies in the use of time as a fourth dimension. While many scientific fields of study model the change in a process or object over time, the modeling of time still remains rather limited in mining. Despite these fundamental differences both disciplines require a means of quickly identifying trends and anomalies.

2 BIG / MEGA DATA AND SCIENTIFIC VISUALISATION IN MININING

2.1 Big Data in Mining

The mining industry is characterized by occasional "trendy" phrases or words to mark paradigm shifts and emphasise transformational change. Examples of these trendy words include "Sustainability" and "Innovation". Regrettably, such words end up being used so vaguely they lose meaning. The intended supposed transformational changes are now seen and the words and phrases get lost. New terms are then invented and adapted. This trend is cyclic.

Lately, the buzz phrase in the mining industry is "Big Data" that has swallowed the previous – Sustainability and Innovation. This paper cautions that to make progress with Big Data in mining we must understand what Big Data is in that industry.

Big Data in the mining industry is not the Big Data in sales business and security where the emphasis is on volume but rather on unstructured data as in Figure 4. More importantly, in the mining industry data is often deposited in hard copies, soft copies or in both forms if one is lucky. The data is also deposited not in a single repository but in different departments in individual possessions, with the risk that losing employees often imply losing critical data!

Vasak and Suorineni (2011) observed that although mining has large datasets, the lack of structure and data standards creates obstacles to integrated evaluation. It also makes it difficult to discover and establish relationships. Understanding mine data remains important for increased productivity and safety in mines.

Figure 4. The nature of Big Data in mining – Data lake, multiple sources, and different repositories: Garbage dumps.

The RAND report on the critical technologies for the mining industry

recognises that it is the knowledge management benefits of new IT technology that will provide the greatest benefit to the industry (Peterson et al., 2001). Although mine operations are generating more data, such information is rarely well utilized for reasons discussed in this paper.

The major challenge in understanding the unstructured mine data is first how to separate the important information and correct information. An often cited solution for simplifying complex data interpretation (at least currently) is the use of simple graphical interfaces that are easy to comprehend by all levels of mine personnel, since data is not as interesting as insight (Peterson et al., 2001). It is these underlying principles that form the basis for new scientific and engineering visualization techniques in mining.

2.2 Virtual Reality and Scientific Visualization In Mining

Big Data interpretation currently poses a challenge as most of the means of interpretation are still in their infancy of development. These challenges were presented in Section 1.2.1.2. The source of the challenges is defining relationships from data lakes.

Virtual reality and scientific visualization provides an alternative to defining statistical relationships / trends in Big Data data lakes and requires no expert special skills in programming. This is based on the unchallenged view that the human eye's ability to quickly detect and understand patterns and anomalies is unsurpassed by technology – "Seeing is believing".

Burgess (2012) observed that it is unlikely there will be major changes to the mechanics of mining and processing but that the use of cleverer technology and automation of equipment is an attractive alternative.

The combination of Big Data and computer power combined with virtual reality and scientific visualization will allow analysts qualitatively explore new behavioral data in real time in mines. The following sections provide case history examples of the application of virtual reality and scientific visualization in mining to understand phenomena and parameter relationships we never understood before.

The first case study is an example of application of Big/Mega Data and virtual reality scientific visualization at the exploration stage of the mineral resource while the last two are examples of the application of the technologies at the mine operation stage.

2.2.1 Case study 1: Exploration

Vasak and Suorineni (2010) noted that finding an orebody using geophysical and probing (drilling) methods is analogous to finding a tumor in a human body by using various scanning technologies and recreating a fully 3-dimensional representation that surgeons can use to operate precisely.

The exploration stage in mining was discussed in Figure 2. Figure 5 presents how the concept of "Big/Mega Data" combined with virtual reality and scientific visualization is beneficial in achieving value from data. By integrating the mapping, geophysics (surface and inversion model), drilling and the resource model, the full potential of the deposit was readily grasped using stereoscopic virtual reality. Figure 5 shows two views of the prospect property.

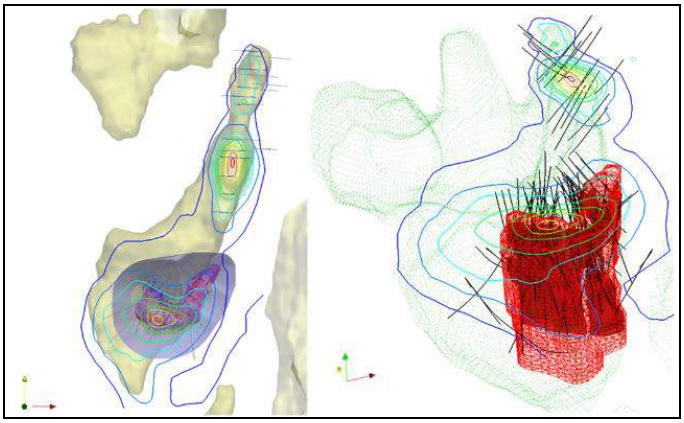

Figure 5. Example of use of Big/Mega Data in the exploration stage (Vasak and Suorineni, 2010).

Figure 6 shows the measured resource from the block model is at the highest existing drillhole concentration. To improve the bankable resource, the gaps highlighted as

inferred (yellow surface) must be strategically drilled to maximize the benefit while minimizing the drilling costs, e.g., the number of drillholes and the total footage drilled. The red drillholes are laid out in an optimized pattern that uses the exiting layout and maximizes the volume of influence (e.g., the surfaces shown on the middle four planned drillholes) to capture the largest possible volume of inferred resource.

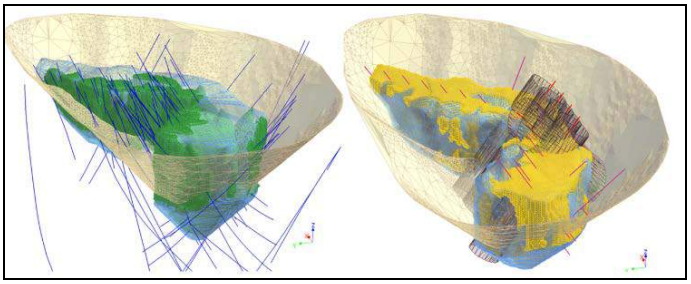

Figure 6. Benefits of Big Data and virtual reality scientific visualization at the mineral exploration stage – Optimisation of resource and reserve (Vasak and Suorineni, 2010).

2.2.2 Case study 2: Understanding rockbursts

Kaiser et al. (2005) discuss the use of VR and scientific visualization for the interpretation of seismic data that is summarized here.

Seismic and microseismic data patterns are complex, come from various sources and in large volumes from several years of seismicity monitoring, with each event involving more than a dozen measured or interpreted parameters (seismic moment, stress drop, source size, location in space and time, etc.). Seismic and microseismic data therefore have all the characteristics of "Big Data" in the mining sense (Figure 7).

Data fusion provides a "new" view of existing data and enhances the identification of hidden relationships or discovery and explanation of complex data interdependencies such as seismic and microseismic data.

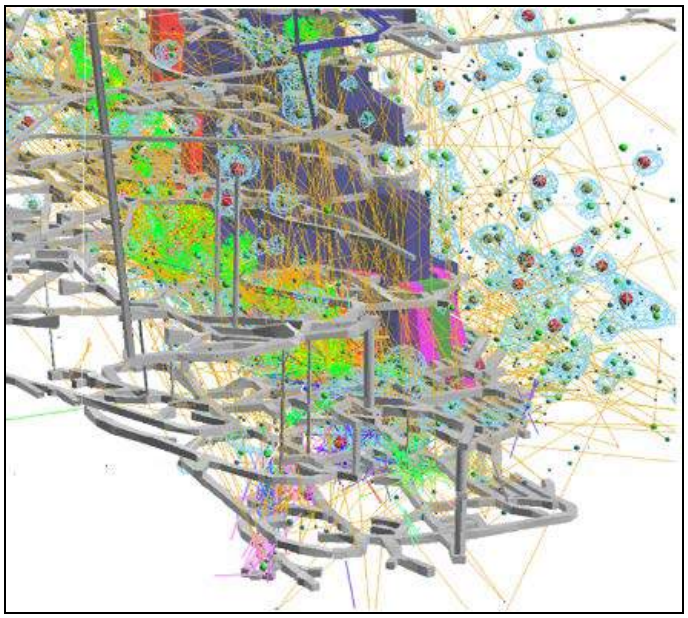

Figure 7. Use of Big/Mega Data and scientific visualization for the understanding of mine seismicity. The figure shows timelinks (lines), source parameter relationships (colour/size) and the complex mine infrastructure (Vasak and Suorineni, 2011).

The interpretation of seismic data constitutes one of the most complex forms of mining data and requires an integrated approach to data interpretation. Because of the complex nature of seismic data a multidisciplinary approach is necessary for its proper interpretation. Such an approach will bring together experts with vastly different backgrounds and expertise, including experts from seismology, geology and structural geology, geomechanics, (geo-) statistics and mining engineering.

Collaborative, immersive VR lends itself ideally for seismic data interpretation and is a good example of how Big/Mega Data combined with VR and scientific visualization is extremely vital in mining. Figure 7 is translated to a practical application (Figure 8) of in mining. In Figure 8 zones of different risk levels are identified and can help in support optimization and mine planning.

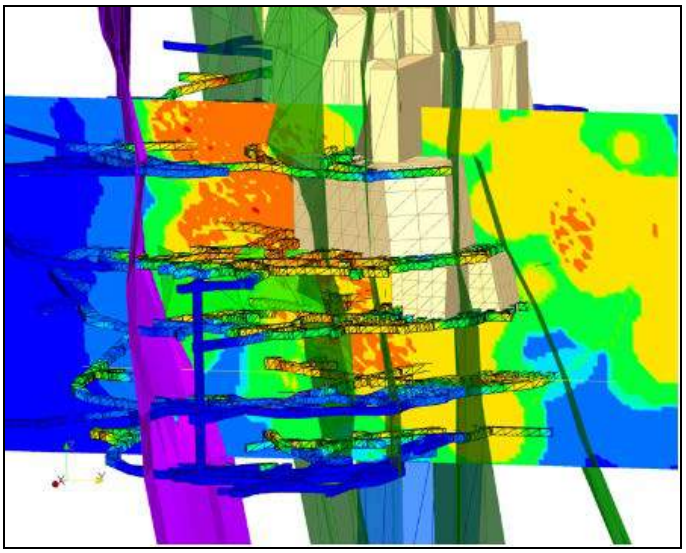

Figure 8. Seismic Excavation Hazard Map showing a section through an active region of the mine and hazard projected onto mine excavations (Vasak and Suorineni, 2011).

2.2.3 Case study 3: Understanding block caving performance

Block caving is an underground mining method which is becoming increasingly important due to its associated low operating costs. The process of block caving is extremely complex and although it is increasing in popularity because of its low operating cost, it is still the least understood of the underground mining methods.

As block caving is employed in increasingly difficult environments with; higher stresses, stronger orebodies, larger cave heights, bigger footprints and increased production rates, it is important to enhance our understanding of the geomechanics within the BCMS.

A major obstacle in the understanding of block cave mining is the lack of access to the cave. An alternative to direct access to the cave is the use of the virtual reality environment.

Block caving is a system that requires analysis as a whole, rather than looking at individual factors. Laubscher (1994) identified 25 primary factors that must be optimized for an ideal block caving mine. Independent optimization of these factors, instead optimizing them as a system, will often result in adverse offsets of others. Big Data and scientific visualization offer an opportunity for the optimisation of block caving operations as systems, as well providing virtual access to understand the in cave fragmentation process. Figure 9 is an example of this approach applied to a block caving mine.

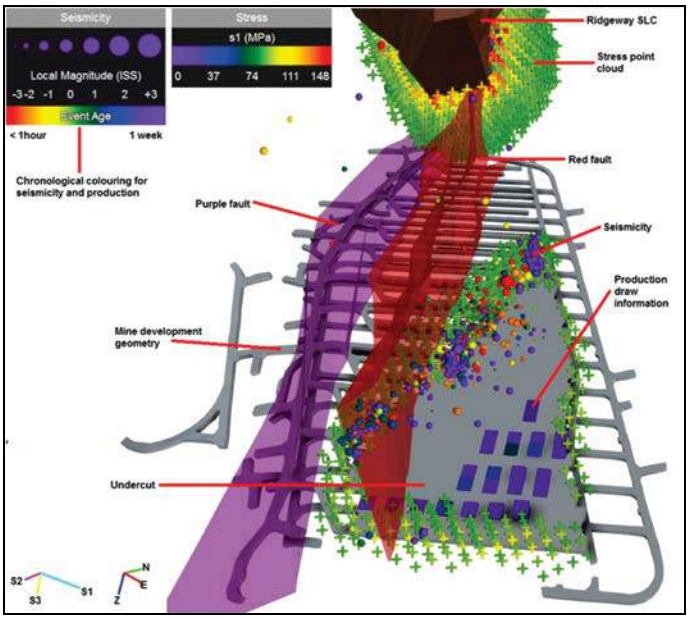

Figure 9. Use of the BCMS Visualiser for VRSV assessment of undercutting performance from a stage of development of Newcrest's Ridgeway Deeps operation. Incorporating; seismic information, stress modelling results, geological structures and production draw information along with the mine's geometrical changes, which enables a systematic investigation into undercutting performance (Tibbett et al., 2014).

3 THE FUTURE OF BIG DATA AND MNING

The ability to visualise the mining system as a whole and view the information as it occurs in real time is crucial to expanding our understanding of mining operations and in particular, block cave mining systems.

The ability to draw personnel from different backgrounds into the one environment such as a "Strategic Management Decision Making Room (SMDMR)" is a key feature of VRSV and Big Data in mining applications in the future. Collaborative assessment will form the backbone of analysing our increasingly complex mining systems in the future for

enhanced safety and productivity in the fluid economic times.

4 CONCLUSIONS AND RECOMMENDATIONS

This paper sought to examine the Big Data phenomenon in mining with particular emphasis on its future. The paper has explored what Big Data is, what it means in mining and its benefits when combined with virtual reality scientific visualisation. It then went further to explain virtual realization and scientific visualization and how by combining Big data and scientific visualization is going to be more beneficial to the mining industry.

The paper concludes that in order for Big data not to disappear like other previous trendy words/phrases that periodically captivate the industry such “Sustainability” and “Innovation” without achieving its expected transformational benefits the mining industry must first understand what Big Data means to the industry, identify potential obstacles and develop the appropriate strategies and tools to overcome such obstacles.

Ultimately, the full benefits of Big/Mega Data combined with virtual reality scientific visualization in mining will be achieved when these can be used to visualise mining processes in real time to optimize mine safety and productivity.

It is recommended that mining companies need to invest in skill training, development of tools to overcome potential obstacles in the interpretation of data in data lakes and start to develop a culture of common data repositories and continuous dialogue within and departs and inter-departments.

ACKNOWLEDGEMENTS

The author acknowledges the contributions of past colleagues and current Ph.D. students. In particular, the case examples used in this paper are derived from work with Mr. Vasak. The support of colleagues in the School of Mining Engineering at UNSW Australia is also acknowledged.

The Issue of Abandoned Mining Exploitations in Albania

G. Muka, V. Jorgji, T. Korini, R. Balla
Faculty of Geology and Mining, Tirana, Albania

ABSTRACT In cases of open stoping mining some of the key issues of abandoned mining exploitations are: identifying the impact of the exploitation area, qualitative and quantitative computation of this impact, risk quantification of the impact on the sector and taking measures to reduce damage or avoidance of mining. In Albania the use of open stoping mining is carried out mainly in deposits of chromium, copper and iron. The overall stability of openings o at these mines is assured using different variants of mining methods like cut and fill stoping (for copper deposits) or methods wherein the roof can be allowed or forced to collapse (iron deposits) or be abandoned for a delayed collapse (chrome mines).

In terms of effectiveness must be said that the mineral losses were about 15-20% in copper and chromium and about 20-30% in iron ore. In some cases these previously abandoned reserves are subject of the reactivation for exploitation, especially in chrome (the mines of Bulqiza, Krasta, Kam, Kalimash, etc.). This paper presents some of the problems associated with the design of mining exploitations in such conditions and the difficulties of the exploitation of the remaining pillars. A detailed study of all factors influencing the exploitation in such conditions is necessary for implementing rational projects and improving the mining safety.

Keywords: Abandoned mines, existing workings, designed workings, rock mass stability, abandoned pillars, tectonics and reactivation

1 ABANDONED MINING EXPLOITATIONS IN ALBANIA

The exploitation of mineral resources in Albania, with few exceptions, has started after 1945. During a period of approximately 50 years it became the main activity of the domestic economy. The request, in the framework of planned economy, was to increase the production of chrome, copper and iron-nickel minerals. The destination of this gross output, except for copper ore, up to 70's was the export. It was around the end of 70's to begin processing chrome and iron-nickel in the country with the establishment of the metallurgical plant for iron-nickel in Elbasan (1978) and the ferrochrome factory for chrome in Burrel (1979).

Under these terms, the demand for increased mining production was rapidly grown considering that gross output as well as processed minerals were the backbone of the economy. Thus, during 1985-1990, the production of chrome ore reached 1.3 million tons per year (Figs. 1, 2). It was these demands to cause intensive exploitation of mineral resources by failing to implement the opening and preparation of new exploitation fields. This intensive exploitation has evolved regardless the correct application and monitoring of the appropriate mining methods, leading to problems concerning the management of mining pressures and the recovery ratio of resources.

Taking notice of the chrome industry trend (as other minerals had even worse performance) it is concluded that mining fields were abandoned immediately after favourable geological and mining condition resources were exploited, while other less desirable resources (tiny ore body thickness, dip less than 45^0, tectonic developed sectors, etc.) were not only abandoned but further risked with the impossibility to effectively being exploited in the future. They were classified as losses at around 15-20% (Ceci

& Borici, 1986; Gurra, 2011). Under these circumstances, we can talk about abandoned exploitations, in terms of the necessity to perform an exploitation plan, ignoring the technical and technological discipline of the process (Gurra, 2011; Muka, 2013).

Another aspect relates to the thorough abandoned exploitations after 90s, when political changes conditioned economic development activities in the framework of a market economy. Since mineral resources were owned by the centralized state, weakening of it made mineral production activity fall drastically. So for chrome, (as seen in Figures 1, 2) from about 1.3 million tons, produced in 1990, production drops to about 200,000 tons in 1992. A small production increase in the period 1993-1996 (up to about 300,000 tons) is explained by the necessity to keep the miners at work, because their unemployment would lead to growing social tensions.

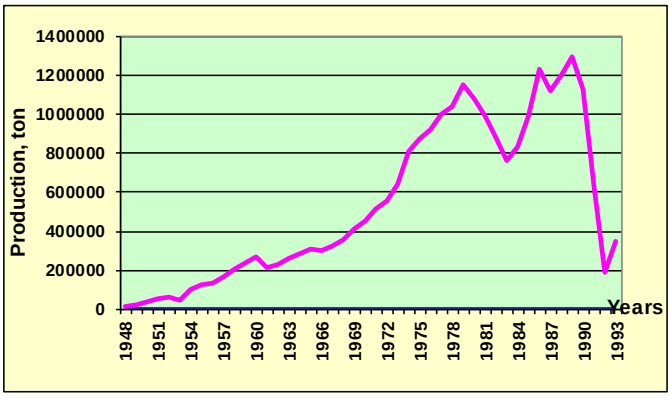

Figure 1. Chrome production during 1948-1993.

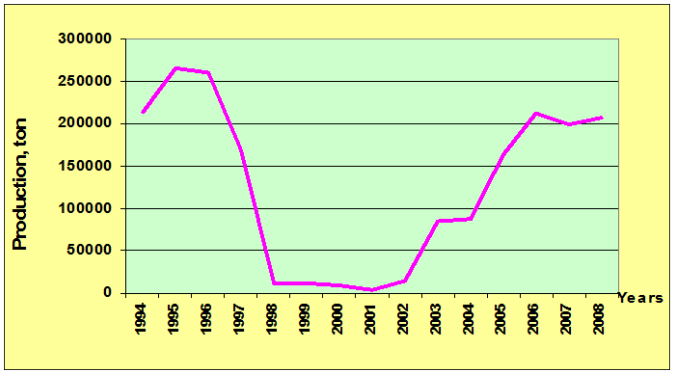

Figure 2. Chrome production rate during 1994-2008.

In 1997, Albania experienced a very difficult politico-economic period, what caused the mineral production to fall in a very low level. The consequence of this decrease, which lasted until 2003, was the creation of abandoned exploitations in all mines of the country.

Both forms of abandonment were due to "amnesia" about:

- The clear identification of the balance of mineral reserve exploitation.
- The exact presentation of opened spaces and exploitation workings.
- Technical and technological approach towards opening of preparation workings.
- Defining measures to prevent the access to the open spaces created during the old exploitations.
- The withdrawal planning of recyclable materials such as rail carriages, etc.
- Compacting and final classification of graphic documentation, etc.

2 REACTIVATION OF EXPLOITATION IN THE "ABANDONED AREAS"

In the market economy conditions the entrepreneurs' attention focuses on the market study. Even entrepreneurs in Albania, both domestic and foreign, became very active in the minerals resources market study. In this activity, they found that there was a considerable interest for minerals such as chrome, copper and iron nickel. This interest was made known to political decision-makers who were committed to create a favourable legislation for investors in the mineral exploitation sector (Goskolli 2011).

Private activity of mineral resource exploitation in Albania started in 1995, through concessions, mainly for those mines that were considered as abandoned exploitations (Goskolli, 2011).

Since the beginning, the new concessionaries faced the following problems:

- The total lack of geological and surveying documentation.
- The lack of knowledge about the current situation and the dynamics of mining pressures development.

- The inaccuracy in the balance of reserves.

Avoiding these problems required, first of all, the completion of geological and surveying documentation. For this purpose they used the archives of state entities such as "Institute of Mineral Extraction and Processing Technology " and "Albanian Geological Service". These archival materials, although not so relevant, served as the basis for fulfilling and updating the documentation.

In order to perform the ore production in abandoned exploitations, one must:

a. Define the margins of concession permits, in plan and altitude, since within a single sector, more than one permission, was granted.
b. Identify the entrances of all opening workings and inspect their situation, both in geometric and technical-mining terms.
c. Verify their stability condition and stabilize them, if necessary.
d. Check and correct the excavations' position, in plan and altitude.
e. Specify the geometry and amount of remaining reserves, to design their further exploration.
f. Fulfil the exploitation design, taking into consideration:
   - The position of remaining reserves.
   - Their geological and hydrogeological conditions.
   - Mining pressures state and their management ways.

The solution to these problems include all chromium, iron-nickel and copper permits, about 325 permits (Goskolli, 2011).

Figures 3, 4 and 5 show the distribution of chrome exploitation permits.

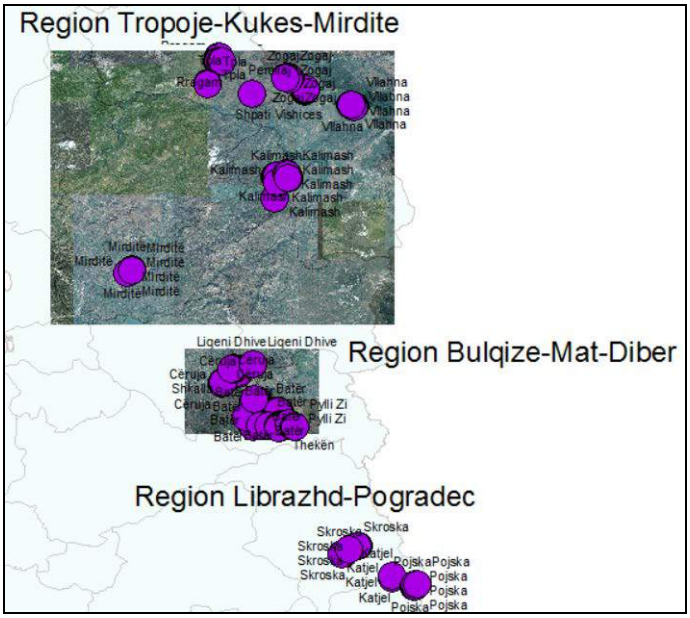

Figure 3. The distribution of chrome mining permits in Albania.

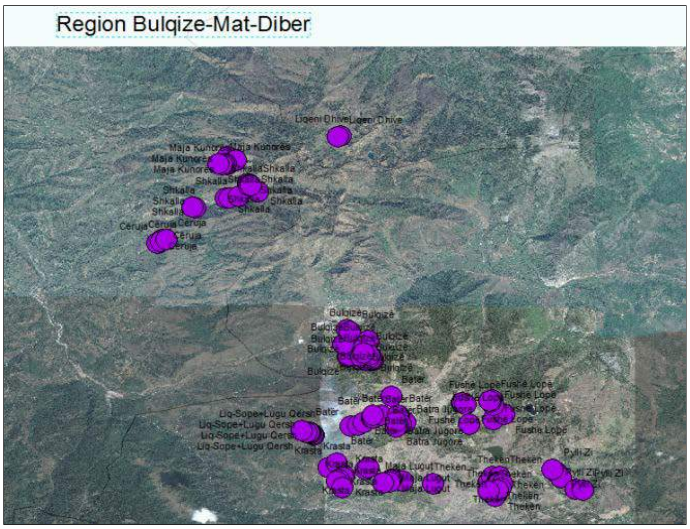

Figure 4. The distribution of chrome mining permits in Bulqizë-Mat-Dibër region.

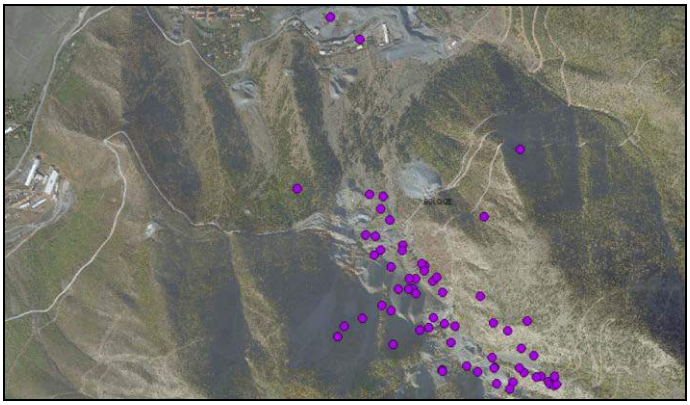

Figure 5. The distribution of chrome mining permits in Bulqiza region.

3 TECHNICAL ASPECTS OF THE REACTIVATION

Reactivation of abandoned exploitations first of all requires:

- The identification of existing opening, preparation and exploitation workings.
- Investigation of these excavations' conditions, related to the possibility of reactivation.
- Verifying the accomplishment, accuracy and clarity of geological, technical and surveying documentation.
- Recalculating the potential exploitation reserves.
- Designing a comprehensive project for the appropriate exploitation technology and safety.

Regarding Albania, focusing mainly on the chrome mines, the concession activity conduced so far is characterized by:

- The restoration of abandoned openings by "combing" the blocks (removal of potentially unstable blocks) of weak cohesion with rock mass and supporting with wooden frames, in areas evaluated as dangerous. The fill applied to realize the support cushions is also constructed with wooden materials.
- The design of exploitation excavations, outside the subsidence area. The size of influence of mining operations is calculated by adjusted models (Muka, 1989).
- Mineral extraction, both by old funnels (ore passes) unlock, as well as by exposing the miners to existing space, what has reduced the safety at work by increasing the number of fatalities and injuries (only during October 2011-August 2014, 11 miners were killed and 9 others were seriously wounded - Archival source, 2014).
- Deficiencies in proper fulfilment, according to standards, of the final exploitation documentation in order to eventually declare as abandoned the relevant exploitation zone.

4 CONCLUSIONS

a. The characteristic of abandoned exploitations in Albania, mainly for chrome, cooper and iron-nickel minerals is the necessity of their reactivation in order to exploit reserves classified as losses.
b. The lost reserves in these deposits are not created as a result of the inability of the existing technology used for exploitation, but as a result of policies to meet the needs of economic development in isolated conditions.
c. The reuse of abandoned excavations: opening, preparation and exploitation ones, provides the continuity of traditional methods of exploitation, the effectiveness of which islow, but justified by favourable market conjuncture and low cost of labour forces.
d. The perspective of further exploitation of these resources requires investments in scientific research with the main objective of increasing the safety of the mines.

The Practicable Combination of Open Pit with Underground Mining Methods- a Decade's Experience

E. Bakhtavar
Urmia University of Technology, Urmia, Iran

ABSTRACT Among all kinds of ore deposits, there is a special form of ore deposit which starts from or near ground surface and continues to a very high depth. Open pit or underground methods separately are not practicable for the extraction of this kind of deposits; therefore, a combined mining of open pit with one of underground methods is used. In this paper, the well-known (deposits) mines with the potential of combined open pit and underground mining have been first studied. They are categorized in two simultaneous and non-simultaneous modes from the viewpoint of the extraction time in both open pit and underground parts. The non-simultaneous mode of combined mining is more acceptable because the large scale underground caving methods with high productivity and low costs can be used. In simultaneous mode, horizontal and vertical slices underhand cut & fill with cemented backfilling is more feasible to be used with open pit mining.

Keywords: Simultaneous combined mining, non-simultaneous combined mining

1 INTRODUCTION

In general, ore deposits are divided into three major categories from the extraction viewpoint. The first category includes ore deposits with outcrop or near ground surface which are most suitable to be extracted only using the surface mining methods. The second one is deep deposits that starting from a high depth and laying under a thick overburden. These deposits are most practicable for mining by underground methods. Often, surface methods are not economically feasible for extracting these kinds of the ore deposits because of raising stripping volume. Third category of the ore deposits belongs to them which start from surface or near surface and continue to a very high depth. In this case, a combination of open pit with underground mining methods are used for the extraction of the ore deposits. Open pit is used at the beginning to a level which transition from open pit to underground mining should be done because of economic reasons. In this paper, the extraction of third kind of the ore deposits using both open pit and underground methods together has been considered. In this case, the most critical problems are finding the most practicable underground alternative to be used after open pit mining and optimization of transition from open pit to underground mining, especially in non-simultaneously combined mining of two methods. Finding the best combination of underground methods with open pit is majorly focused in this paper.

2 MINES WITH OPEN PIT AND UNDERGROUND POTENTIAL

In this section, the most well-known worldwide mines using combined mining of open pit and underground methods are taken into account together with Iranian combined mines.

Grasberg is one of the mines which was planned for extracting gold and copper ores by the use of combined open pit and black caving as the most practicable underground alternative. According to the planning of the mine, open pit mining must be finished in 2015. It is located in Indonesia (Srikant et al., 2007).

Chuquicamata Copper and molybdenum mine, which is located in Chile, is another

one with the combination potential of open pit and block caving. Final open pit depth was planned to be completed in 1100 m until 2013 (Flores, 2004).

In Ernest Henry gold and copper mine located in Australia, transition from open pit to open stope mining was planned at 560-m depth (Meyers, et al., 2008).

The other one which located in Congo is Dikulushi silver and copper mine. In this mine, open pit was ceased and sublevel caving as the most feasible underground method was started in 2006 (Robinson, 2007).

Palabora mine was planned for the use of combined open pit and block caving. Final pit depth in this case is 800 m which was completed in 2003 (Brummer, 2006).

Coala north pipe had high potential for extracting using a combination of open pit and modified sublevel caving among Ekati diamond ore deposits collection located in Canada. In Coala north mine, extraction using the underground method was started in 2002 (Jakubec et al., 2004). Furthermore, there are some other cases with the combination potential in Canada, such as Diavik diamond mine.

Argyle diamond mine located in Australia is another combination of open pit and block caving. Mining by open pit was finished at the end of 2007 due to economic considerations and the underground alternative was started. It is planned that extracting by underground mining will be continued until 2018 (Hersant, 2014).

Meng-Yin diamond mine in China includes two major deposits. One of them was planned for extraction using a combination of open pit and Cut and Fill methods (Changyu, 1984).

Kiruna iron ore mine is one of the well-known case located in Sweden. Open pit was ended and was changed to sublevel caving in 1960 because of increasing in open pit mining costs.

Angouran Lead & Zinc mine is one of the biggest mine which was initially planned for open pit mining. Although Angouran ore deposit could be extracted by open pit independently but a combination with underground option (modified cut and fill) was considered because of some unpredicted purposes. The reasons are (Aminzadeh, 2014; Khani, 2014):

- Zinc selling price has been increased.
- The ore deposit with high grade was located in lower levels which could not be extracted only using open pit even until next 20 years.

Another Iranian ore deposit which was planned for mining using a combination of open pit and underground mining is Chargonbad copper deposit (Aminzadeh, 2014). The main purpose for combined mining was to increase annual extraction capacity.

Gushfil Lead & Zinc ore deposit located in Iran was planned for extraction using combined mining of open pit and cut-fill (TETE Mine Team, 2006).

Chehelkureh copper ore deposit is another combined case using open pit and underground mining (Bakhtavar, 2009).

Gol-e-Gohar Area 3 iron ore deposit with a dip of about 20-degree is other deposit located in Iran which was planned for mining by combined open pit and a different kind of Room & Pillar (Bakhtavar et al., 2010).

Chah-Gaz iron ore deposit located in Iran is one of metaliferrous ones which was planned for mining using a combination of open pit and block caving (Bakhtavar, 2013).

Mining engineers can make an appropriate decision in relation to select one / more mining method(s) only with considering all effective parameters and the special conditions of an ore deposit. Totally, after studying the ore deposits and mines with combined case of open pit and underground mining, the following notes can be deduced:

- Opposite of worldwide trend and findings, all of the mentioned ore deposits located in Iran except Chah-Gaz deposit were planned for mining simultaneously using open pit and filling underground mining options.
- In the majority of large scale mines, a combination of open pit and underground mining was planned in

feasibility study (in design stage) before development stage. Block / panel caving, which is the only competitor with open pit, was selected as the best underground alternative because of high productivity and low mining costs.

- The problems of optimizing combined mining of open pit and underground options and accordingly optimization of transition from open pit to underground mining have been taken into account in the last decades and especially in relation to solving the problem of the mentioned-above combined mines.
- Some studied mines changed their base plans by adding an underground option to open pit mining at the end of or near the mine-life when it was exploited that the ore deposit below final open pit limit continues to a higher depth.

3 PRACTICABLE COMBINATIONS OF OPEN PIT AND UNDERROUND

Generally, a combination of open pit and underground mining can be used in simultaneous and non-simultaneous forms from the exploitation time viewpoint (Bakhtavar, 2008). Based on the global trend, the non-simultaneous form is more acceptable which provides a condition to use large scale underground caving methods with high productivity and low costs. In this form, by using the caving methods such as block / panel caving there are some instabilities resulted from caving and subsidence which are transmitted to open pit limit. This restricts a simultaneous form of open pit and underground, except during 2 to 3 years before the end of open pit mine life that combined mining is simultaneously. It is notable that a higher profit can be gained using non-simultaneous form of combined mining.

The simultaneous form of combined mining is unusual but it is feasible in special conditions and purposes. For instance, if ore deposit is small in dimensions and tonnage, only small scale underground methods are practicable together with open pit from technical and economical viewpoints. In this case, in order to provide a safe working place in both open pit and underground and also to minimize the impacts of interaction between open pit and underground, small scale underground methods should be used with in-filling or artificial support system.

3.1 Simultaneous Combined Mining

In the usual combined form of open pit and underground mining, which has been highlighted in this study, underground stope is placed beneath open pit limit. Therefore, if open pit and underground operations are used simultaneously for the extraction of an ore deposit, working in underground part causes some instabilities in the benches of pit. It causes stoppage in mining operation of open pit part. In order to prevent these problems in simultaneous form, the underground methods which completely control and support stope roof and walls must be used. The simultaneous form of open pit and underground mining can be used to get the following aims:

- To supply the required feed of processing plant when the extracted ore using open pit (capacity) may decrease.
- To supply the required feed of processing plant in case of small (thin) ore deposits and correspondingly its extraction using small scale open pit.
- An increasing in the selling price of ore
- Occurring an unexpected failure in open pit mining operation. For example, happening failure and collapse in one of pit walls which cause production stoppage in that pit wall. This causes decreasing in open pit production capacity.
- Finding the high grades of an ore deposit in lower levels

Underground methods with filling working stopes such as cut & fill are the most practicable underground options for the simultaneous form of open pit and underground mining on the basis of the mentioned notes. Therefore, shrinkage, sublevel stoping, and all kinds of the caving underground methods are not feasible to be

used simultaneously with open pit mining for ore extraction.

From the viewpoint of the extraction direction, overhand and underhand extraction modes are two kinds of cut & fill underground method. As shown in Figure 1, the overhand and underhand modes are different in design and mining operation (Williams et al., 2007). Among all forms of the practical cut & fill method, the underhand form with cemented filling is more acceptable for utilization in the simultaneous combined mining. Underhand cut & fill with cemented back-filling can be divided into two modes:

- Full width horizontal slices underhand cut & fill (FWHSUCF)
- Vertical slices underhand cut & fill (VSUCF)

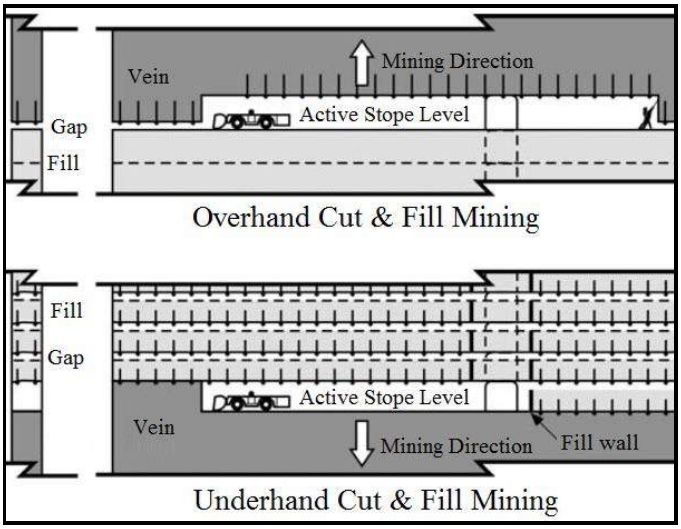

Figure 1. Overhand and underhand modes of cut & fill (Williams et al., 2007)

Often, hydraulic and pneumatic cemented-back fillings are used after the extraction of the full width ore deposits using underhand cut & fill with horizontal slices. As a rule, the thickness of each horizontal slice can be 3-4 m. In this mode of cut &fill (FWHSUCF), ore deposit is initially extracted in form of rooms with the width of 3-8 m. After extracting each room, it must be fully filled by the filling materials including a needed amount of cement. Then the remained long (barrier) pillars between each two filled rooms are extracted. After that they are filled using the materials with a less cement content in comparison to the first stage filling. The long pillars are approximately as the same width as the initial rooms.

In vertical slices underhand cut & fill (VSUCF), in order to achieve maximum mining capacity in a selective mode, the vertical slices should be perpendicular to along the direction of an ore deposit. The vertical slices of an ore deposit can be extracted successively or intermittently. In successive mode, the full width of an ore deposit should be extracted during the vertical slices. In intermittent mode, first, every other slice using the underhand cut & fill with cemented back-filling is extracted and subsequently pillars between each two extracted slices are remained. Finally, the pillars are recovered.

3.2 Non-Simultaneous Combined Mining

In contrast to the simultaneous one, non-simultaneous combination form of open pit and underground is preferred in practice because of the following reasons:

- Underground methods with high productivity and low mining costs, such as caving methods can be used.
- All kinds of underground mining methods can be used with open pit depends on an ore deposit geometrical dimensions and conditions.
- Backfilling underground methods, which impose high mining costs, do not essential for utilization.

It is notable that in non-simultaneous form, subsidence impact zone (profile) and consequently the environmental impacts are more extensive. Because large scale underground methods such as block caving are used.

Although a combination of open pit with all kinds of underground mining methods is acceptable in the non-simultaneous form but block / panel caving are more practicable.

Totally, there are three below different systems for large scale stope caving (Bakhtavar, 2009):

- Block caving: Ore deposit is divided to stopes in form of rectangular cubes. Usually, ore drawing from all draw-points is possible simultaneously.
- Panel caving: Ore deposit is divided to panels. Ore drawing from the draw-points is started from one side of the panel and gradually continues to other side.
- Mass caving: In this system, ore deposit is not divided to blocks or panels and the whole deposit is planned to be caved.

Selection of one of the caving systems mostly depends on geomechanical characteristics of an ore deposit. Block caving is most appropriate system for the extraction of the weak ore deposits which are crushed easily to small fragments. In this case, drawing rate is high. If an ore deposit is stronger and includes less discontinuities, panel caving system is more feasible. In case of a high strength massive ore deposit with low discontinuities mass caving system is preferred. In figure 2, mining direction as the main difference between block caving and panel caving is shown.

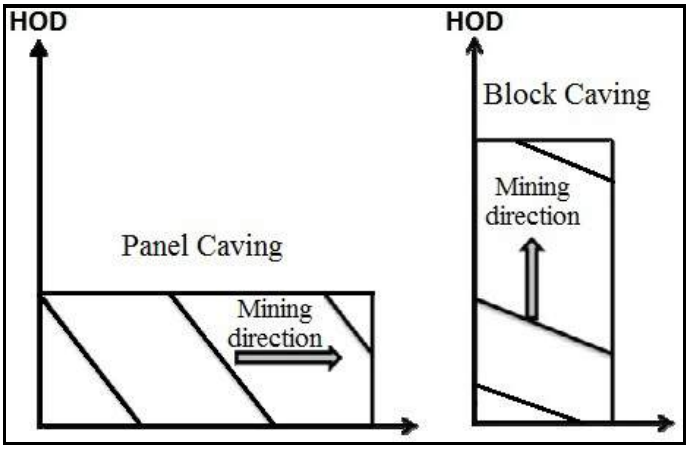

Figure 2. Mining direction in block caving and panel caving

4 CONCLUSION

When an ore deposit starts from or near ground surface and it continues to a high depth, a combination of open pit with one of underground methods is most practicable. In this case, there are two important problems to be considered correctly. First problem, which has been considered in this paper, is finding a practicable underground alternative in combining with open pit in both simultaneous and non-simultaneous extractions. Second one is optimizing transition from open pit to underground mining, especially in non-simultaneous combined of open pit and underground methods. Based on the global experience, the non-simultaneous form of combined mining is more acceptable which provides the utilization of large scale underground methods with high productivity and low costs such as block caving. In this case, there are many geotechnical challenges in interaction between open pit and caving stope. For example, instabilities from caving stopes are transmitted to open pit limit and therefore cause the slope instability of benches. This is a restriction for utilizing a simultaneous form of open pit and underground, except through 2 to 3 years of open pit mine life. Simultaneous form is strange although it is feasible in special conditions. If an ore deposit is small, only small scale underground methods are practicable from technical and economical viewpoints. Cemented backfill underground methods (such as vertical slices underhand cut & fill) are more feasible in the simultaneous mode of combined mining. In non-simultaneous mode, large scale methods with high productivity and low costs (such as block / panel caving) are more practicable. The problem of transition from open pit to underground mining, which has been regarded as a new challenge in mining engineering, is majorly related to the non-simultaneous combined mode of open pit and underground mining. The problems related to combined mining of open pit and underground methods are studied and discussed more, particularly during last decade. Now, a major portion of the mining researches belongs to the combined mining of open pit and underground mining because of its importance and desirability.

A Contemporary Approach in Geotechnical Slope Stability Analysis: Lithological Implicit Modelling

A.G. Yardimci, H. Basarir
Middle East Technical University, Ankara, Turkey

ABSTRACT Open pit slope stability is a major concern in any mine prefeasibility study. Most widely used numerical and limit equilibrium methods require two inputs: rock mass mechanical parameters and bedding geometry of lithological units. Traditionally, rough geological models prepared by time consuming explicit method of manual digitization or assumptions depending on lithological drillhole logs form the basis for geometry of stability analysis models. However, the real geometry can be dramatically different. A novel method named as implicit modelling is capable of creating solid volumes for lithological units within a few minutes, free of operator bias. Also, complex geological structures like bedding and folding can be represented with high accuracy. In this paper, theoretical background of implicit modelling is covered briefly and a sample application is presented on an open pit iron mine slope stability analysis. Advantages of the geological model prepared by the new method in geotechnical studies are clearly declared.

Keywords: Implicit modelling, slope stability, geological modelling

1 INTRODUCTION

Global stability of open pit mine slopes has a vital priority due to the safety of employees and wellness of mining equipment. In any open pit mine, there are some actions need to be taken prior to and during the mining activities, so that a safe working environment can be provided. Slope monitoring is a passive, during-mining measure that is capable of predicting slope failure time. On the other hand, geotechnical slope stability analysis using numerical and limit equilibrium methods is a major topic in mine planning phase for determining safe slope design parameters. It depends on a huge knowledge base of field and laboratory studies. Rock mass mechanical properties and bedding geometry of lithological units are the main inputs. Most of the times, it is impractical and unnecessary to examine the stability in the whole mining area. Compared to the 2D alternative, 3D numerical modelling has some disadvantages. Namely, large number of input parameters, hard to generate model geometry and long computation time are some of them. Under these circumstances, 2D analysis brighten by its speed and accuracy. The well-known methodology in 2D slope stability analysis is focusing on the most critical cross-section by a plane strain assumption. The crucial subject is to generate the model geometry. Difficulty comes from identifying the bedding orientation of multiple lithological layers. Commonly, experts tend to generate a global multiple layer geometry by depending on the lithological drillhole logs. In case of considerably thick and regularly bedding layers, average thickness and simplified bedding geometry for each lithological units provide the inputs for numerical model geometry. If the geology is complex, the most common approach is to use a single lithological unit, which is the weakest one. This approach is named as pseudo isotropic medium (PIM). Although these over safe approaches have been trusted and successfully used until now, implicit modelling with some recent advances have aroused as a comfortable way of generating geological models.

Compared to the time consuming conventional method of generating solid volumes, named as explicit modelling, implicit modelling comes up with its speed and accuracy. Although it is not a new

discovery, recent optimizations in the algorithm have solved the major problem of large consumption of computer resources. Industry professionals have been publishing successful geological models prepared by implicit modelling and compare their results with the conventional explicit models. Most of them are satisfied with its speed and the solid body shape. In a technical note of SRK Consulting (2012) it was mentioned that the novel implicit modelling allows interpretation of the data without the bias of the expert and this is advantageous in terms of exploring the raw drillhole data from a different perspective. Most of the popular mine planning software providers, like Maptek Vulcan, Minesight, Geovia Surpac, Micromine, have recently included implicit modelling modules.

This paper aims to present the advantages of implicit modelling in creating geological models as an input of slope stability analyses carried out by numerical and limit equilibrium methods.

2 SOLID BODY GENERATION METHODS

2.1 Explicit Modelling

In mathematics, relationship between x and y defines curves and relationships between x, y and z defines surfaces. Three types of functions exist, which are namely explicit, implicit and parametric. In explicit functions, y is directly obtained from x values and the generic format is describes as y = f(x). Considering the circle in Figure1, it is relatively easier to generate series of values lying on the circle. The main limitation is its incapability of supporting closed lines or surfaces. To mathematically describe, a variable z defined by x and y variables return a unique z value and it is impossible to obtain different z values from the same inputs by treating the x, y pairs in different ways. This fact limits the types of shapes that the surface function can estimate (Cowan, et al., 2003). In Figure 1, it can be seen that a closed circle needs to be defined by two explicit functions.

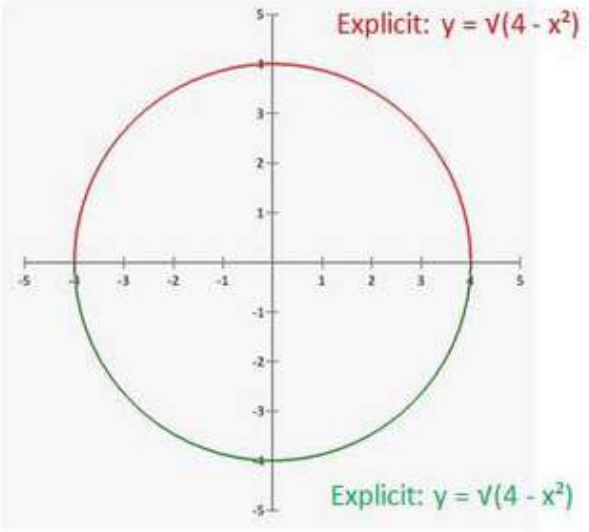

Figure 1. Mathematical representation of an explicit function *(Micromine Pty., 2014)*

Traditional explicit method of constructing geological model requires digitizing drillhole data in serial sections and joining the similar domain boundaries by polylines. In Figure *2*, illustration of this procedure using manual digitization can be seen. Black and grey sections represent two different lithologies (a) and explicitly defined border is observed in (b). The polylines generated for multiple cross-sections are joined by tie-lines to define the three dimensional relation between cross sections. Finally, each cross-section is connected to the other by triangulation and the solid model is created.

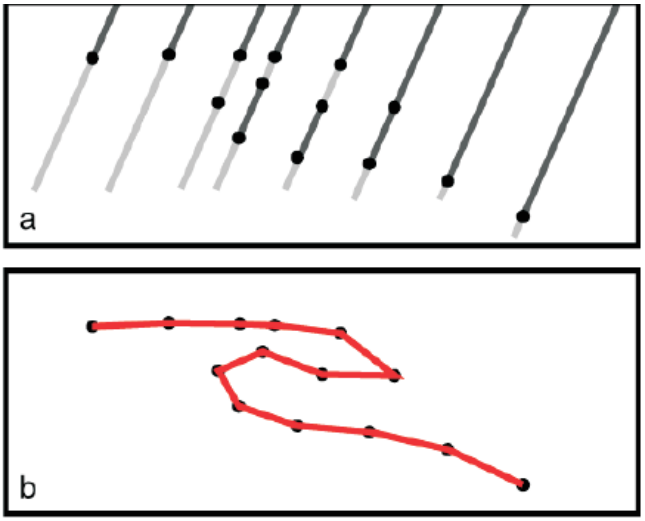

Figure 2. Cross-section view of a manually digitized domain using explicit modelling *(Cowan, et al., 2003)*

The above mentioned workflow is still the first choice of industry experts. However, it is a well-known fact that this time consuming method requires an experienced modeler and the model consists of operator bias. Cowan et al (2003) describes that each individual geologists' interpretation produces his/her unique model and the models are impossible to be replicated by others.

As it is obvious, solid model generation for multiple geological domains is a highly complex and time consuming task. Also, the generated model cannot be updated easily if new data is available. The mentioned static nature and high time dependency issues form the major drawbacks of explicit modelling

2.2 Implicit Modelling

Implicit modelling of space objects has a historical background. Field of Computer Graphics is more familiar with the subject; however, it is not well known by the Geological Society. Most of the studies on implicit modelling contain limited number of data points. This has been the limitation until now, for use in geological models in mines. A moderate mine has a drillhole database of thousands of data. To process this much data, huge amount of computer resources and time has been consumed by the algorithm, until now. Recent improvements in the algorithm and computer hardware technology made it usable in the mining industry.

Implicit functions have a general format of f(x,y)=0. Remembering the circle example (Figure 3), the function tests any random x, y couples if they lie on the circle (=0), inside the circle (<0) or out of the circle (>0). The main advantage of this method is its ability to model complex geological structures like overturned folds and enclosed surfaces such as spheres (Cowan, et al., 2003). It allows for the automation of creating solid models by using numerical data such as ore grades or even linguistic data by carrying out the conversion process explained above. Lithological implicit modelling, which is the main consideration in this paper, is just an example.

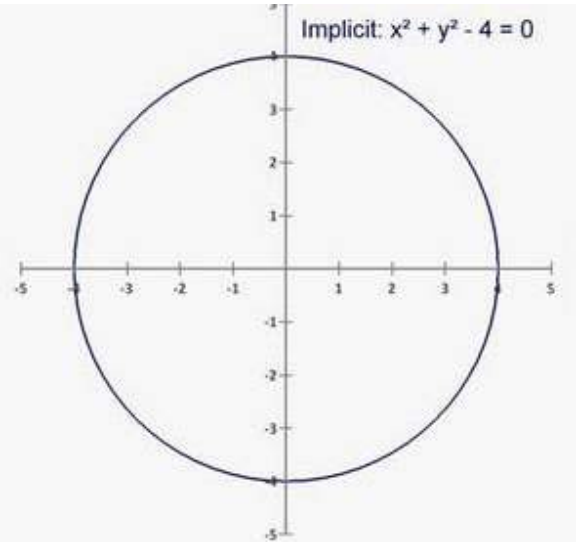

Figure 3. Mathematical representation of an implicit function *(Micromine Pty., 2014)*

In Figure 4, lithology symbolized by gray color is modeled implicitly. As can be seen in (c) lithology borders are marked by "0" because they lie on the border of the curve. Points at the upper part are marked by "+" values and the points inside the gray colored lithology are marked by "-" values. In this process, linguistic expressions are replaced by numerical values. The next step is to interpolate these values using the Radial Basis Function (RBF) in order to create a 3D (closed) surface representing the zero contour. This contour is also called as "isosurface".

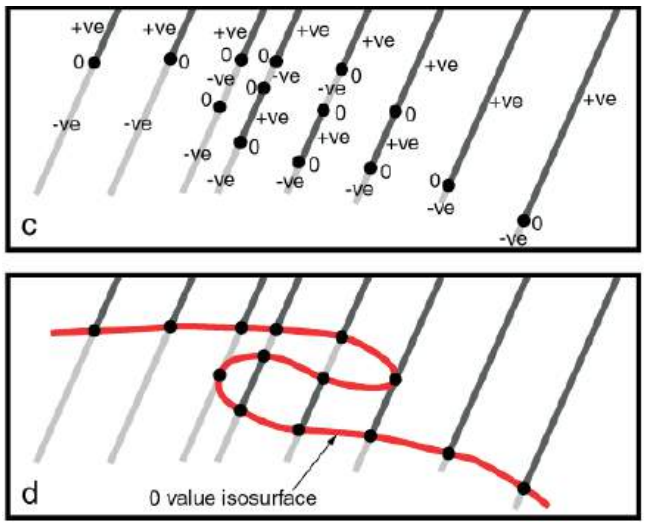

Figure 4. Cross-section view of joining a domain using implicit modelling *(Cowan, et al., 2003)*

2.2.1 Radial basis function (RBF)

In order to build up the soil volume, implicit modelling requires to have a 3D interpolation method. RBF is capable of interpolating grade and lithological data.

Cowan et. al. (2003) reported some of the drawbacks of RBF. One of them is the data storage problems in case of large data sets. Also calculation with large number of data points have been reported to be time consuming. For example, they mentioned about hours of calculation on a standard workstation of the year 2003 with 40 000 data points. These problems have been the main reason that implicit modelling has not been very popular among industry professionals. To solve this problem a fast form of RBF has been generated. The fast form avoids before mentioned problems because data matrix storage is not necessary. By this way, memory problems are avoided and the drillhole data of an entire mine can be processed within hours even on current PCs.

3 A CASE STUDY

3.1 Study Area & Rock Mass Characterizaiton

In this study, an iron mine located in Erzincan/ Bizmisen district of Turkey and owned by BILFER Mining Co. is focused on (Figure 5).

Donentas region drillhole database contains a total of 63 drillhole. 12 drillholes were selected and geotechnical logging study was carried out in terms of RMR_{89}, Q and GSI systems. 6 dominant lithological domains (including the ore) were determined. During geotechnical logging appropriate rock samples for laboratory testing were gathered and necessary rock mechanics test were done. Average rock mass and rock material properties can be seen in Table 1.

Figure 5. Erzincan/Bizmisen iron mine *(Google Earth, 2015)*

Table 1 Rock mass and rock material properties for Bizmisen dominant geological units *(Karpuz, Tutluoglu, Basarir, Yardimci, & Akdag, 2014)*

	Rock Mass Properties			Rock Material Properties				
Unit	**RMR_{89}**	**Q**	**GSI**	**γ (kN/m^3)**	**E (GPa)**	**ν**	**σ_t (MPa)**	**UCS (MPa)**
	Avg.	Avg.	Avg.					
Skarnfels	48	2.57	44	26.5	12.19	0.10	7.77	35.2
Limestone	40	1.20	35	26.2	24.54	0.16	7.10	48.8
Granodiorite	60	4.28	57	26.9	36.05	0.10	13.19	123.9
Mudstone	47	1.51	42	25.7	7.54	0.13	2.25	16.9
Serpantine	40	1.18	38	24.0	8.08	0.15	4.67	17.1

3.2 Lithological Implicit Modelling in Donentas Region

63 drillholes with a total depth of 13,051m had been logged in terms of lithological characteristics by BILFER and MTA. This study makes use of this existing database.

The database was imported into Micromine 2014 geological modelling and mine planning software. The recently established implicit modelling module of Micromine makes use of the before mentioned Radial Basis Function (RBF) to generate solid models. For the 6 dominant geological units, solid volumes were generated.

The software demands some inputs for the implicit engine. Drillhole database is the main requirement. Later, the software asks for "Include", "Exclude" and "Ignore" units. The lithology needs to be modelled should be under include box. The external units should stay in the "Exclude" box and the rock units to ignore can also be defined (Figure 7). The minimum length to be included into model should also be determined. If this value is too small, golf ball like blobs might be observed. Later, the amount of maximum points per partition is asked. Most of the times, all the points in a data set may be impractical to be included a single model. Thus, the data set is divided into overlapping regions. Each modelled separately with overlaps used to smooth out the transition from one partition to the next. It is suggested to start the analysis by 1/ 8 of the whole data and increase the number in case of observing golf ball like blobs.

If any trend exists in geological formations, anisotropic behavior can be reflected by using a search ellipsoid. The final and the most important input is the mesh size in grid units. As this value becomes smaller, the model will take more time to calculate but it will be more detailed.

In Figure 6 plan view of the Donentas can be seen on the left. On the right side, cross-section view of A-A' line is observed. The blank area between the complex geological units is the orebody. This figure is an evidence of the strong capability of implicit modelling for complex shaped volume generation. If modelled by conventional explicit way, complete modelling might take weeks and it would be very difficult for the operator. However, implicit model generated the 6 chaotic shapes just in seconds. Including the data preparation stage, whole of the process takes 15-20 minutes.

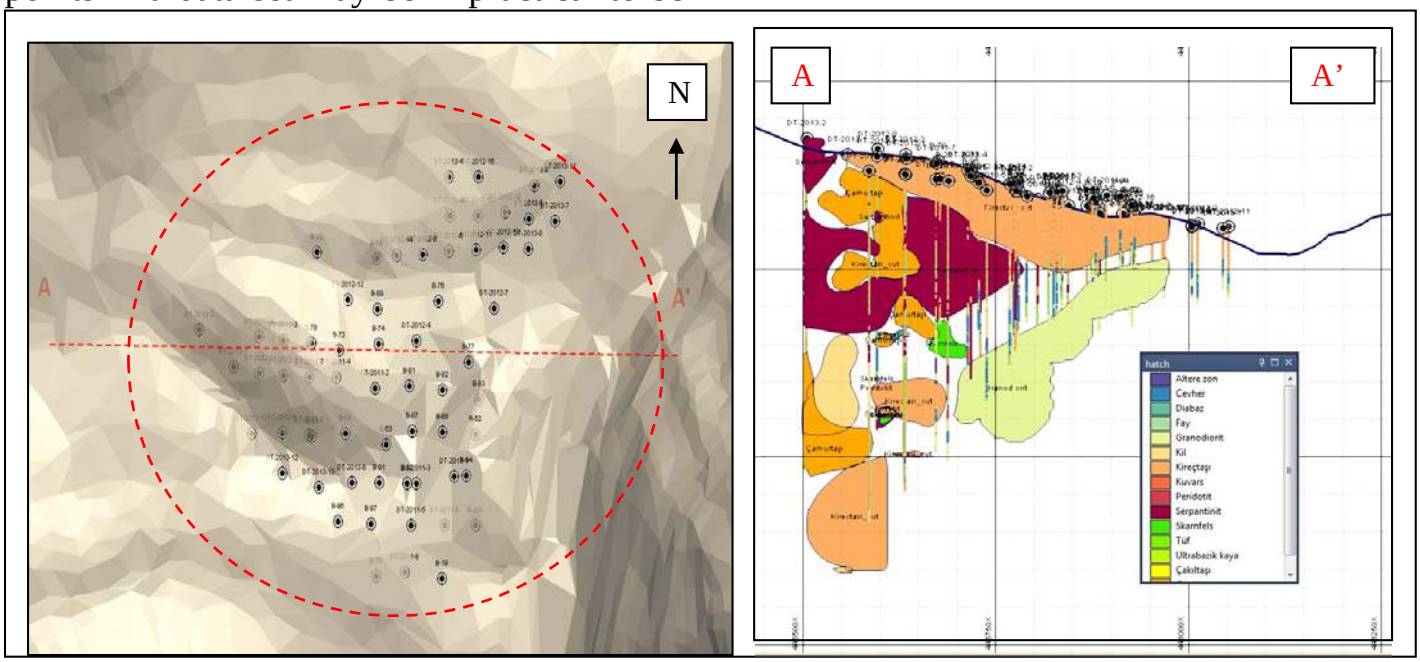

Figure 6. Plan view and section view of the lithological model of Donentas region *(Micromine Pty, 2014)*

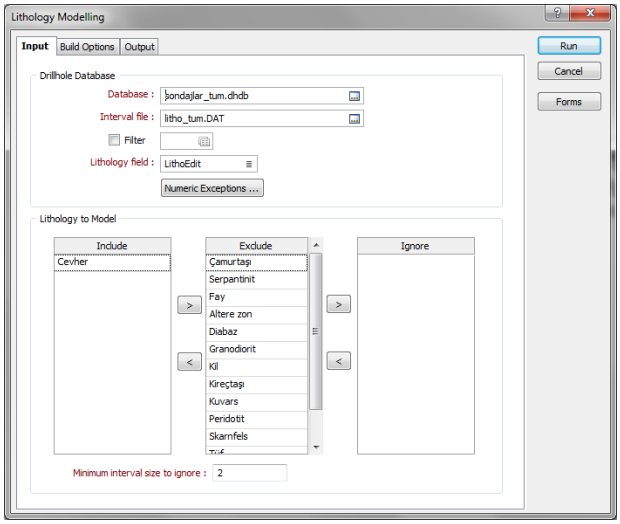

Figure 7. A screen view from implicit modelling module of Micromine 2014 *(Micromine Pty, 2014)*

3.3 Comparison of Numerical Models

In Donentas region 3D orebody model and DTM of the surface shows that topography and the orebody plunges in opposite directions. Consequence of this fact is a relatively deeper wall on the West side of the open pit.

In this study, global stability of a random production phase on the Western side of the pit will be under investigation. To describe the scenario, depth of the open pit is 180m and the overall slope angle is 41° on the West side. Numerical modelling will not be explained in detail because this paper mainly aims to show the effect of implicit geological model on numerical analysis. It is a kind of sensitivity analysis in the sense of model geometry.

Implicit lithological estimation could only be done for a limited zone in Donentas region. It is mainly the zone inside the borders of iron anomaly. The reason is that exploration drillholes only cover the iron rich zone and there is no data about the rockmass behind the open pit wall. Thus, the unknown area is defined by moderate rock properties to complete the model.

In Figure 8, cross-section of the analyzed condition can be seen. Figure 8 (a) and (b) declares the result of Shear Strength Reduction (SSR) analysis carried out by Rocscience Phase 2 software. Difference between the models lie in the geometry of dominant lithologies. In the first case the pseudo isotropic medium (PIM) approach is used. This approach relies on representing the complete host rock by the weakest rock unit. In Figure 8 (a), total displacement contours for a model with PIM approach can be seen.

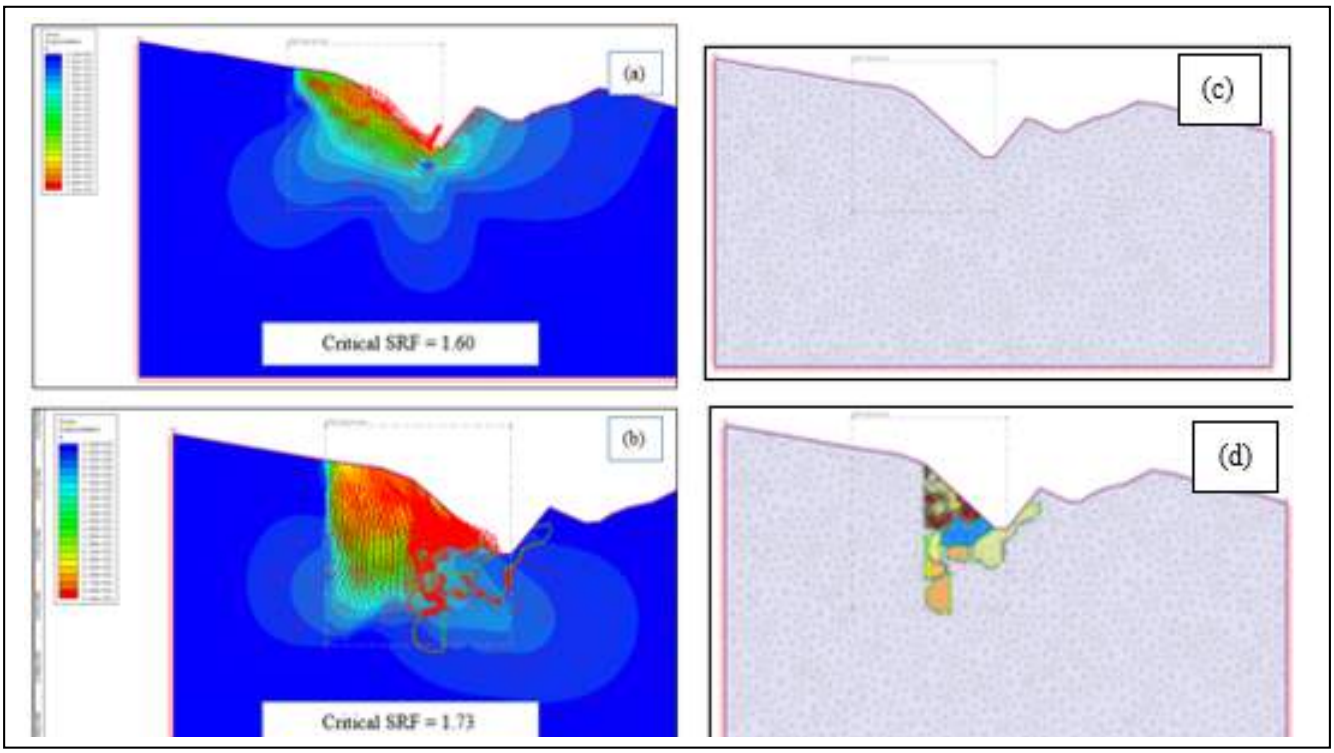

Figure 8. SSR results and total displacement contours from Rocscience Phase2 software for (a) rough model geometry, (b) lithological unit geometries determined by implicit modelling

Due to the complex geology, the assumption is plausible and in most cases provides meaningful results. The search area for SSR and the single unit domain geometry can be seen in (c). The critical SSR is found to be 1.60. In Figure 8 (d), the model geometry consisting of geological units modelled by implicit methods in detail and total displacement contours can be observed. Result of the SSR analysis can also be seen in (b) with a critical SSR of 1.73. It can be obviously seen that the first global model with PIM approach behaves more conservatively. This is mainly the consequence of assuming a weak rock unit in the whole rock mass. However, in the second model with lithologies generated by implicit model, there is a considerable increase in SSR factor. Detail geometries show a stratification in the favorable direction to the slope and this is the major reason for the increase in SSR.

4 CONCLUSION

As a proven, fast and comfortable technology, implicit modelling is a rising trend among the geological modelling society. Although geological modelling has known to be a time consuming job until now, (weeks or months especially for complex geologies), today, it can be handled within a matter of hours by the optimized algorithm of implicit modelling. This study specifically focused on its effects on the routine Geotechnical slope design. Results have shown that detailed geological modelling avoids overdesign in the studied case. SSR factor for the assumed slope geometry were 1.60 and 1.73 for PIM and implicit methods respectively. This novel modelling method also has the advantage of being free of operator bias. In complex structures, human knowledge may not be sufficient to observe some critical interrelations. The algorithm avoids human errors and theoretically provides volumes in infinite detail by using the Radial Basis Function (RBF). Implicit modelling has a high potential to be used as an auxiliary tool in geotechnical stability analysis by its speed and accuracy.

ACKNOWLEDGEMENT

The authors would like to thank the staff of BILFER Mining Inc. for their valuable supports. The company is also acknowledged for the permission to use and publish the data.

Analysis of Sulphur Contents in Coal by Means of Henry's Beneficiation Curve Approximation

T. Niedoba, A. Surowiak
AGH University of Science and Technology, Krakow, Poland

ABSTRACT In purpose of conducting analysis of sulfur contents in selected raw hard coal its separation was performed into particle size fractions by screening. Then, such prepared material was additionally separated into particle density fractions by means of dense media analysis. Because of the fact that Henry's beneficiation curve cannot be approximated by traditional random variables distribution functions. In the paper, the approximation of function of sulfur contents versus density was done by means of application of known statistical functions. Then, using statistical distribution functions the approximation of relation between cumulated yield and density was done. The main Henry's beneficiation curve was obtained by means of determining the reverse function of cumulated yield and joining sulfur contents versus density function and reversed cumulated yield function. To evaluate the quality of approximation the mean squared error (MSE) was used. By means of obtained function the mean sulfur contents was determined in the whole material as well in individual fractions. The obtained results were then verified empirically.

Keywords: Sulphur, Henry's beneficiation curve approximation, Mean squared error (MSE)

1 INTRODUCTION

To evaluate the beneficiation ability of material being processed the Henry's beneficiation curve can be used [Drzymala, 2001], which describes the relation between any qualitative coal parameter and certain fraction yield.

From the probabilistic point of view if the change of concentration of certain component W in product is investigated and only one feature X decides about the separation then the regressive function of first type $E(W|X=x)=\lambda(x)$ determines the Henry's beneficiation curve. If the analytic form of Henry's curve is known then the mean contents of investigated component in material is given by the formula (1) [Tumidajski, 1997].

$$\alpha=\int_0^1 \lambda(\gamma)d\gamma \quad (1)$$

where γ is percentage yield of fraction; λ - contents of component in this fraction; α - mean contents of the component in whole material.

In papers [Niedoba, 2013a; 2013b; 2013c] the beneficiation processes were discussed and the approximation of Henry's curve was presented which described ash's contents in relation to fraction's yield.

In this paper the approximation of Henry's curve is done by probabilistic approach describing sulfur contents in coal dependably on the yield.

2 ANALYSIS AND CALCULATIONS

To achieve the goals described in the introduction the raw coal, type 31 (according to Polish classification of coals, which means energetic coal) was collected from one of the Hard Coal Mines located in Upper Silesia, Poland and was divided into density fractions. The experimental results are presented in Table 1.

Because of the fact that Henry's beneficiation curve cannot be approximated by traditionally used distribution functions the complex approximation was performed in the paper.

Table 1. Separation of coal into density fractions

Density ρ [g/cm^3]	Mean density ρ_{0i} [g/cm^3]	Percentage share [%]	Cumulated share γ_i [%]	Sulfur contents λ [%]
1.20-1.30	1.25	51.11	51.11	0.64
1.30-1.40	1.35	34.79	85.90	0.69
1.40-1.50	1.45	6.43	92.33	1.20
1.50-1.60	1.55	2.59	94.22	1.27
1.60-1.70	1.65	1.76	96.68	1.51
1.70-1.80	1.75	1.55	98.23	1.565
1.80-1.90	1.85	1.77	100.00	1.65

In the beginning the approximation of function $\lambda = \lambda_0(\rho)$ was performed what meant the relation between sulfur contents λ and density ρ. It was done by means of functions being applied in regression analysis.

Then, the approximation of function $\gamma = F(\rho)$ was done what showed the relation between cumulated yield γ and density ρ. This function fulfills conditions for distribution function so is possible to be approximated by means of functions being applied in probability. Function $F(\rho)$ is growing so it has its inverse function $\rho = F^{-1}(\gamma)$. Taking complexion of functions $\lambda_0(\rho)$ and $F^{-1}(\gamma)$ the function approximating Henry's beneficiation curve is obtained in the form:

$$\lambda(\gamma) = \lambda\left(F^{-1}(\gamma)\right) \tag{2}$$

The approximation of function $\lambda = \lambda_0(\rho)$ was done by means of curvilinear regression. The best one was obtained by exponential function of the formula:

$$\lambda(\rho) = 0.3731\rho^{2.6113} \tag{3}$$

To evaluate the quality of approximation the curvilinear correlation coefficient R was used, given by the general formula [Kotz et al., 2000; Sobczyk, 2001]:

$$R = \sqrt{1 - \sum_{i=1}^{k} \frac{\left(\lambda_i - \lambda_i^*\right)^2}{\left(\lambda_i - \bar{\lambda}\right)^2}} \tag{4}$$

where λ_i are experimental sulfur contents in i^{th} fraction; λ_i^* are theoretical sulfur contents in i^{th} fraction (calculated from formula (3); $\bar{\lambda}$ - mean value of sulfur contents ($\bar{\lambda} = \sum_{i=1}^{k} \lambda_i$); k – quantity of fractions.

In the analyzed example, the value of coefficient R=0.9375 what means that the fitting was acceptable. To determine function $\gamma = F(\rho)$ the logistic distribution function was applied [Niedoba, 2013; Tumidajski, 1993; 1997; Tumidajski and Saramak, 2009], presented in general form of formula (5).

$$y = \frac{1}{1 + be^{-ax}} \tag{5}$$

As the result of approximation for γ, the values of a=-6.81 and b=2522.48.

To evaluate the preciseness of approximation the curvilinear correlation coefficient was used and the value of it was R=0.9283 what meant satisfying level of fitting.

By transforming equation (5), with calculated values of a and b, the reverse function $\rho = F^{-1}(\gamma)$ is obtained and its form in this case is:

$$\rho = 1.15 + \frac{1}{6.81} \ln \frac{\gamma}{1-\gamma} \tag{6}$$

Finally, composing functions given by equations (3) and (6) the approximation function of Henry's beneficiation curve can be obtained in the form:

$$\lambda_1(\gamma) = \begin{cases} 0 & for \quad \gamma \in [0, 0.0005] \\ 0.37\left(1.15 + 0.15 \ln \frac{\gamma}{1-\gamma}\right) & for \ \gamma \in [0.0005, 0.99] \\ 1.83 & for \quad \gamma \in [0.99, 1] \end{cases} \tag{7}$$

The curvilinear correlation coefficient R is equal 0.9344 what means that the selection of the function was appropriate.

The experimental and theoretical results for functions $\lambda_0(\rho)$ and $F(\rho)$ are presented in Table 2 and on Figs 1 and 2.

Table 2. Experimental and theoretical results for functions $\lambda_0(\rho)$ and $F_0(\rho)$

Density ρ [g/cm^3]	$F_0(\rho)$ exp [%]	$F_0(\rho)$ theor [%]	$\lambda_0(\rho)$ exp [%]	$\lambda_0(\rho)$ theor [%]
1.20-1.30	51.11	58.44	0.64	0.66
1.30-1.40	85.90	79.62	0.69	0.81
1.40-1.50	92.33	91.56	1.20	0.99
1.50-1.60	94.22	93.85	1.27	1.17
1.60-1.70	96.68	96.79	1.51	1.38
1.70-1.80	98.23	98.39	1.55	1.60

98.23	1.55	1.60
100.00	1.65	1.83

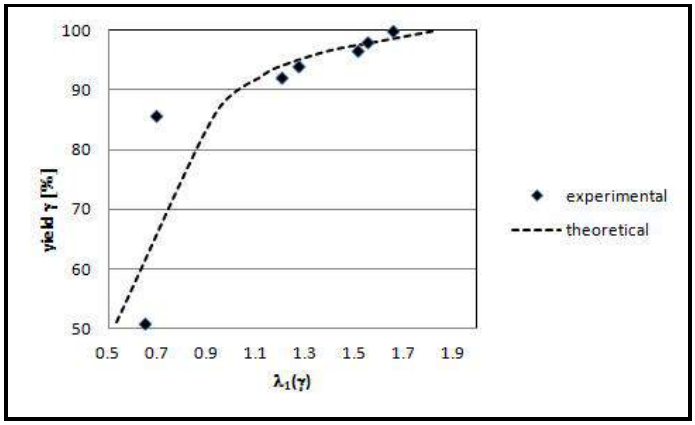

Figure 3. Experimental and theoretical results for function $\lambda_1(\gamma)$

Because the cumulated yield γ is growing function of sulfur percentage contents λ, the function $\lambda(\gamma)$ can be obtained by other method

First, the function $\gamma(\lambda)$ can be approximated by means of functions used as distribution functions in statistics and then, using the fact that function $\gamma(\lambda)$ as monotonic function is invertible function, the inverse function $\lambda(\gamma)=\gamma^{-1}(\lambda)$ can be obtained.

In this example the complexion of exponential function $y=ax^b$ with logistic function given by equation (5) was used.

The function obtained by this method is in form:

$$\gamma_1(\lambda)=\begin{cases} 8.19\lambda^{6.21} & for \lambda\in[0,0.69) \\ \dfrac{1}{1+1.47e^{-2.72\lambda}} & for\ \ \lambda\geq 0.69 \end{cases} \qquad (8)$$

Determining the inverse function to function $\gamma_1(\lambda)$ given by the equation (8) the analytical form of Henry's curve $\lambda_2(\gamma)$ is obtained.

$$\gamma_2(\lambda)=\begin{cases} 0.71\gamma^{0.16} & for\ \gamma\in[0,0.8156) \\ 0.14+0.37\ln\dfrac{\gamma}{1-\gamma} & for\ \gamma\in[0.8156,1) \\ 1.83 & for\ \ \ \gamma=1 \end{cases} \qquad (9)$$

The values of function $\lambda_2(\gamma)$ are shown in Table 4 and on Fig. 4.

Table 4. Values of function $\gamma_1(\lambda)$

γ [%]	$\lambda_0(\gamma)$ exp [%]	$\lambda_2(\gamma)$ theor [%]
51.11	0.64	0.64
85.90	0.69	0.80
93.56	1.20	1.06
94.22	1.27	1.17
96.68	1.51	1.39
98.23	1.55	1.61
100.00	1.65	1.83

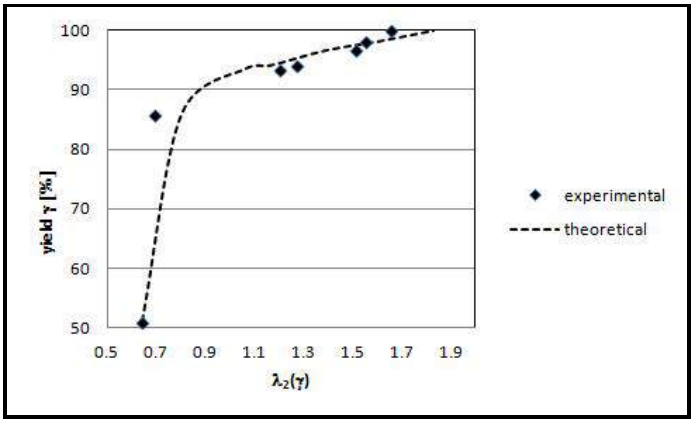

Figure 4. Experimental and theoretical results for function $\lambda_2(\gamma)$

The curvilinear correlation coefficient is equal, respectively, for function $\gamma_1(\lambda)$, R=0.99, for function $\lambda_2(\gamma)$, R=0.91.
Knowing the analytical Henry's curve form is possible to determine mean sulfur contents in the investigated material.

$$\bar{\lambda} = \int_0^1 \lambda_2(\gamma)d\gamma = \int_0^{0.8156} 0.71\gamma^{0.16}d\lambda + \lim_{\alpha\to 1^-}\int_{0.8156}^{\alpha}\left[0.14 + 0.37\ln\frac{\gamma}{1-\gamma}\right]d\gamma = \\ = \frac{0.71}{1.16}\gamma^{1.16}\Big|_0^{0.8156} + \lim_{\alpha\to 1^-}\Big[0.14\gamma + 0.37\big(\gamma\ln\gamma + (1-\gamma)\ln(1-\gamma) - 1\big)\Big]_{0.8165}^{\alpha} = 0.69 \quad (10)$$

The experimental mean value of sulfur contents in the whole material is equal to $\bar{\lambda} = \sum f_k\lambda_k = 0.75$, where f_k is percentage share of k^{th} fraction; λ_k – percentage contents of sulfur in k^{th} fraction.

Theoretical sulfur contents in individual fractions can be determined using the following formula:

$$\bar{\lambda}_k = \int_{\gamma_{k-1}}^{\gamma_k} \lambda_2(\gamma)d\gamma \quad (11)$$

where $\bar{\lambda}_k$ is mean sulfur contents in k^{th} fraction; γ_{k-1} – cumulated yield of k-1$^{\text{th}}$ fraction; γ_k – cumulated yield of k^{th} fraction.
The calculated mean contents of sulfur on the basis of formula (11) for individual fractions are shown in Table 5.

Table 5. Mean sulfur contents $\bar{\lambda}_k$

Density ρ [g/cm^3]	$\tilde{\lambda}_k = \sum_k f_k\lambda_k$ exp	$\bar{\lambda}_k$ theor
1.20-1.30	0.3271	0.3020
1.30-1.40	0.2401	0.2333
1.40-1.50	0.0772	0.0588
1.50-1.60	0.0329	0.0332
1.60-1.70	0.0266	0.3080
1.70-1.80	0.0240	0.0232
1.80-1.90	0.0292	0.0320

If the mean standard error (MSE) is applied to evaluate the fitting of theoretical sulfur contents in fractions, given by the formula (12) [Kotz et al., 2000; Sobczyk, 2001; Tumidajski, 1997; Tumidajski and Saramak, 2009].

$$MSE = \sqrt{\frac{\sum_i \left(\tilde{\lambda}_i - \bar{\lambda}_i\right)^2}{k-2}} \quad (12)$$

where $\tilde{\lambda}_i$ is mean sulfur contents in i^{th} fraction; $\bar{\lambda}_i$ - mean theoretical sulfur contents in i^{th} fraction; k – number of fractions.

3 CONCLUSIONS

Comparing the results of mean sulfur contents in the whole material (difference is equal to 0.16%) and investigating the difference between sulfur contents in individual fractions in ratio to the whole material obtained on the basis of the experimental results and results obtained by approximation (MSE=1.44%) it can be accepted that the obtained Henry's beneficiation curve describes well the course of the process.

In the paper, two methods of approximating Henry's curve were presented. Both curves are well approximated (curvilinear correlation coefficients were equal R=0.93 and R=0.91, respectively).

It can be noticed that the curve obtained by the first method is more complicated what makes difficult to apply it practically (it requires numerical integral).

The curve obtained by the second method is much simpler in form (it can be solved analytically) but to use this method for other components of researched material the assumption that cumulated yield is monotonous function of investigated component contents must be required.

Development of New Correlations to Predict Acid Fracture Conductivity Based on Rock Strength

M.R. Akbari, M.J. Ameri , S. Kharazmi, and H.A. Zafarian
Amirkabir University of Technology, Tehran, Iran

ABSTRACT One of the fundamental ways to stimulate and increase the production rate of a well completed in a carbonate reservoir is acid fracturing. Acid fracture conductivity is an important parameter for designing a fracture job. The amount of rock dissolved, fracture surface etching patterns, rock strength, and closure stress impact the resulting acid fracture conductivity. A model of acid fracturing conductivity must accurately anticipate fracture conductivity versus closure stress. The fracture conductivity is substantially influenced by rock type. A serious challenge of recent studies has been to predict behavior of different formations under various closure stresses. This study develops intelligent model to precisely predict fracture conductivity by incorporating experimental data from various formations, whereby resulting in a good match between model predictions and experimental data. The effects of rock type and treatment parameters are investigated on fracture conductivity under various closure stresses. The results show rock type plays a significant role when anticipating fracture conductivity, as various formations have behaved differently under various closure stresses.

Keywords: Acid fracture conductivity, genetic algorithm

1 INTRODUCTION

Acid fracturing is one of the preferred methods to stimulate wells in carbonate reservoirs. It consists of injecting an acid solution at high enough pressure to break down the formation and to propagate a two-wing crack away from the wellbore. The acid reacts with the carbonate formation and this causes the etching of the fracture surface (Rodrigues, 2011). In a heterogeneous formation, acid fracturing has proved to be a successful method to enhance hydrocarbon recovery. Moreover, in a tight-gas reservoir, acid fracturing becomes the most economical method to produce the gas reservoir (California Council, 2014).

Success of acid fracturing depends greatly on the created conductivity which must be retained under closure stress. Acid fracture conductivity is a measure of the capacity for fluid flow through an acidized fracture. The resulting conductivity is influenced by the amount of rock dissolved, the pattern in which the rock is dissolved, the strength of pillars that prop the fracture open, and the amount of closure stress on the fracture.

Designing acid fracturing treatments primarily aim to optimize live acid penetration distance and conductivity. Acid type and strength, acid injection volume, and injection rate are the key elements in such a design. There are many studies for live acid penetration distance. In contrast, few studies have been completed for acid fracture conductivity, and more studies are necessary to improve accuracy of conductivity predictions (Nierode and Kruk, 1973, van Domselaar et al., 1973; Coulter et al., 1974; Roberts and Guin, 1975; Anderson and Fredrickson, 1987, Beg, 1996, Ruffet & Fery, 1997, and Gong et. al., 1999). Moreover, few previous studies have considered the role of rock strength in the conductivity retained with elevated closure strength (Mou et al., 2009).

While success of the acid fracturing process depends highly on the resulting fracture conductivity, the resulting conductivity is very difficult to predict as it

inherently depends on a stochastic process and is affected by a wide range of parameters (Mou, 2009).

There have been many experimental and theoretical studies to improve understanding of acid fracture performance. There has been also extensive work on fluid flow in rough walled natural fractures. However, very few studies have concentrated on fracture conductivity, especially on developing a correlation for prediction of conductivity (Pournik, 2008).

Initially Nierode and Kruk (1973) developed an empirical correlation for fracture conductivity which is widely used in industry. The correlation is based on experimental study conducted on different formation samples acidized with HCl acid. The conductivity estimation depends on amount of rock dissolved, rock strength and closure stress.

Anderson et al. (1989) stated that formation characteristics, such as hardness, will strongly affect etched conductivities that result from fracture acidizing. For example, etched surfaces of chalk formations can be easily closed due to its natural softness (Anderson et al. 1973). Nasr-El-Din et al. (2006) suggest that the correlations developed by Nierode and Kruk (1973) were lumped together rather than separated by lithology. They recalculated the correlation by graphing and evaluating the data again both as a lumped set and as individual sets by lithology. The modified correlations kept the same form as the original ones, but made the constants different and were more precise (Gomaa & Nasr-El-Din, 2009)

The objective of this work is to develop a precise model to estimate conductivity for acid fracturing treatment based on a new approach in evaluation algorithms. Predicting conductivity is difficult because it is a function of the rock's strength, heterogeneities present in the rock, the transportation and dissolution of acid, the closure stress and other variables. The study uses a treatment parameter called dissolved rock equivalent conductivity (DREC) that stems from the total amount of rock dissolved by injected acid at zero stress. Then lets the conductivity decline as the fracture width reduces when closure stress is applied. DREC derived according to the cubic law indicates the acid dissolving power and the total volume of injected acid proportional to the geometry of the fracture created. Due to the complication of predicting acid fracture conductivity and also the capability of genetic algorithm (GA) in optimization and modelling, in this paper, a robust intelligent model based on genetic algorithm is developed to predict acid fracture conductivity accurately. The input data are considered according to rock strength to provide a better understanding of the rock type effect. Ultimately, the resulting conductivity given by GA models is compared to prior models.

2 GENETIC ALGORITHM AS AN OPTIMIZATION TOOL

Genetic algorithms are a type of optimization algorithm, meaning they are used to find the optimal solution(s) to a given computational problem that maximizes or minimizes a particular function. Genetic Algorithms are direct, parallel, stochastic method for global search and optimization which imitates the evolution of the living beings, Charles Darwin. This adaptive method may be used to solve search and optimization problems. Genetic Algorithm which is based on the genetic process of biological organisms, is used to solve both constrained and unconstrained optimization problems and could be applied to a variety of problems that are not well suited for standard optimization algorithms (especially the problems with nonlinear objective function) (Kosters et al., 1999).

Sometimes genetic algorithms are applied as a process of optimization coefficients in the engineering and mathematics. The problems are first formulated as mathematical models expressed in term of functions and then to find a solution, discover the coefficient that optimize the model or the function component that provide optimal system performance (Yeniay, 2005).

3 METHODOLOGY

In this research genetic algorithm is used to optimize coefficients of Nierode and Kruk and Nasr-El-Din's correlations. Three optimized correlation based on all input data, the data in which rock embedment strength is lower 20000 psi and the data in which rock embedment strength is higher than 20000 psi are developed. In the next step three new correlations are generated according to three data category. Absolute relative error (ARE) and regression coefficient (R) were considered as criteria to evaluate ability of proposed correlations. The quality of the fracture conductivity prediction is quantified in terms of the average absolute relative error and correlation coefficient (R^2 or R) by comparison with experimental data. Equations 1 and 2 are applied to calculate the performance criteria.

$$R = \frac{\sum_{i=0}^{n}(m_i-\bar{m})(p_i-\bar{p})}{\sqrt{\sum_{i=0}^{n}(m_i-\bar{m})^2(p_i-\bar{p})^2}} \quad (1)$$

$$ARE = \frac{WKf_P^{predicted}-WKf_P^{measured}}{WKf_P^{predicted}} \times 100 \quad (2)$$

3.1 Data Analysis

In this study, Nierode and Kruk (1973) experimental data sets are applied as input data. 116 experimental data set including dissolve rock equivalent conductivity, rock embedment strength and closer stress for specific fracture conductivity are considered as input data.. The data sets are divided into three groups; the first includes all 116 data sets to develop correlations, however all data have many different in specification of rock strength and lithology. The second group consists of 36 data sets in which rock embedment strength is lower 20000 psi. The third group includes 70 data set in which rock embedment strength is upper 20000 psi. Table 1 shows properties and ranges of all input variables in detail.

Table 1. Ranges of input data used in this study

Parameter	Min	Max	STD	Mean
DREC (md-ft)	3.E+04	1.30E+08	107826007	6.E+07
Closure Stress (Psi)	0	7000	2379.809	2939
Rock Strength (Psi)	5600	88100	1802.509	35170
Fracture Conductivity (md-ft)	1.2	7400000	1264474.65	2.E+05

3.2 Development of Acid Fracture Conductivity Correlations

Genetic algorithm begins by creating a random initial population (N chromosome). The algorithm then creates a sequence of new population. At each step, the algorithm uses the individuals in the current generation to create the next population .The algorithm creates crossover children by combining pairs of parents in the current population. At each coordinate of the child vector, the default crossover function randomly selects an entry, or gene, at the same coordinate from one of the two parents and assigns it to the child. For problems with linear constraints, the default crossover function creates the child as a random weighted average of the parents. Then GA creates mutation children by randomly changing the genes of individual parents. For unconstrained problems the algorithm adds a random vector from Gaussian distribution to the parent. For bounded or linearly constrained problems, the child remains feasible. Then the first step, the function selects parents deterministically according to the integer part of the scaled value for each individual. In the second step, the selection functions select additional parents using the fractional parts of the scaled value, as in stochastic uniform selection. If the result not suitable the code use generated population for further run of the algorithm so if the end condition is satisfied , stop and return the best solution in current population (Omid E. David, 2013).

In this study, Genetic Algorithm (GA) is used as a dominant tool. A general flow chart of GA is presented in figure 1. The parameters used to perform Genetic Algorithm are listed in Table 2. The values of these parameters are shown in table 3.

Table 2. The parameters used to set Genetic Algorithm parameters

Chromosome	A set of genes; a chromosome contains the solution in form of genes
Gene	A part of chromosome; a gene contains a part of solution. It determines the solution
Individual	Same as chromosome
Population	Number of individuals present with same length of chromosome
Fitness	The value assigned to an individual based on how far of close a individual is from the solution; greater the fitness value better the solution it contains
Fitness function	A function that assigns fitness value to the individual
Breeding	Taking two fit individuals and then intermingling there chromosome to create new two individuals
Mutation	Changing a random gene in an individual
Selection	Selecting individuals for creating the next generation

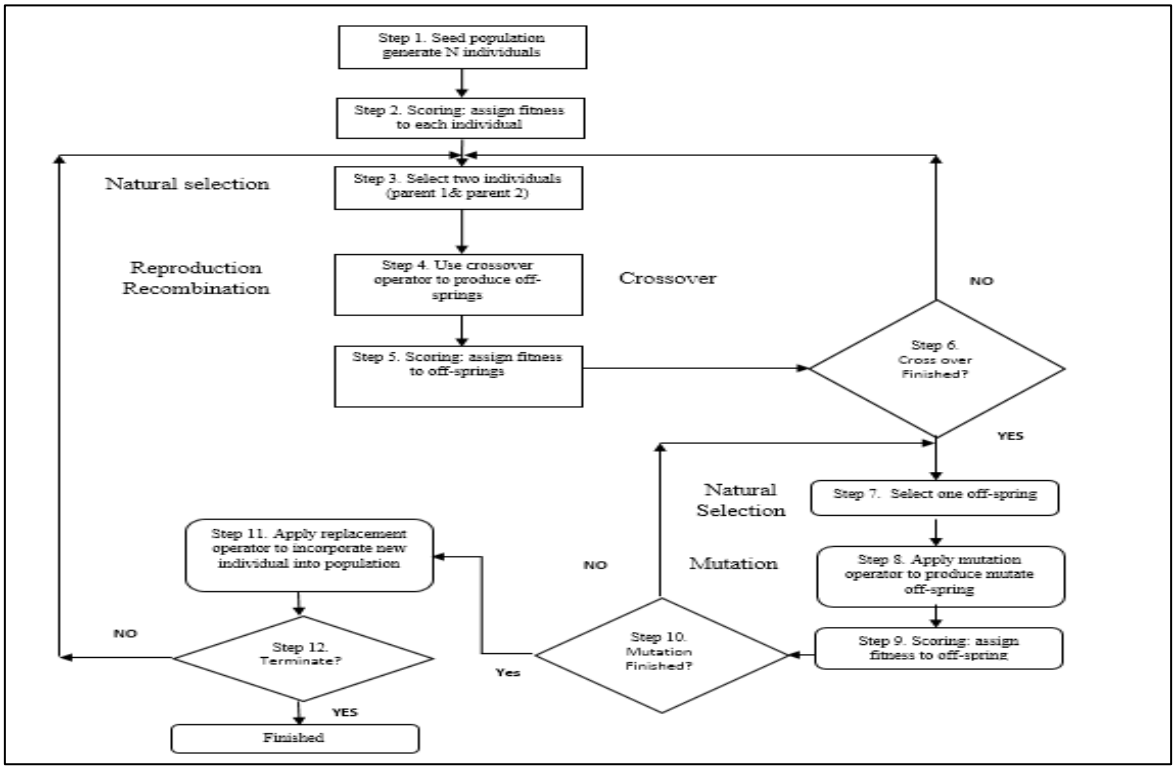

Figure 1. GA program procedure chart.

Table 3. Set GA parameters for optimized and new correlations

Input Data	**Correlation**	**N Pop**	**Pc**	**Pm**	**mu**
All Data	New Correlation	10000	0.90	0.10	0.30
	Optimized Correlation	3000	0.80	0.30	0.30
RES<20000	New Correlation	4000	0.80	0.50	0.70
	Optimized Correlation	4000	0.80	0.40	0.50
RES>20000	New Correlation	3000	0.80	0.30	0.30
	Optimized Correlation	4000	0.80	0.30	0.30

The comparison of accuracy of Nierode & Kruk, Nasr-El-Din, optimized and new correlations is shown in figure 2. As the results illustrate, the new correlation is more precise compared to other correlations at various rock strength.

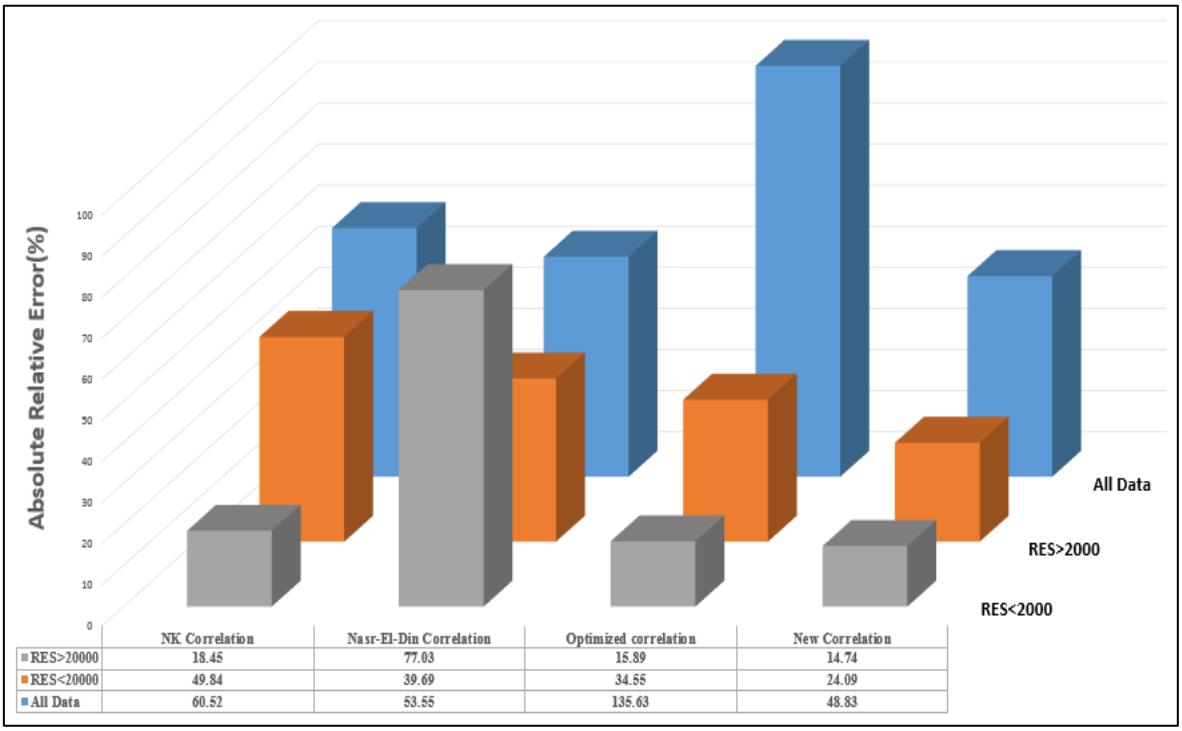

Figure 2: Average relative error of the predictive correlation

4 RESULTS AND DISCUSSION

The results show rock strength is a significant parameter to determine acid fracture conductivity. Predicted values of fracture conductivity by proposed correlations that are developed according to rock strength have good match with experimental results. Table 4 shows coefficients of optimized correlation for all input. As the results of this category was not good, new functions were used to present new correlations. Optimization algorithm were applied to find the best coefficients. Proposed correlation and their coefficients are tabulate in table 5. The correlation has 13 coefficients. Accuracy of predictive correlations to predict fracture conductivity based on all input data were compared in table 6. Although the precision of optimized correlation is very low, but the accuracy of new correlation is better than prior correlations (Nierode & Kruk and Nasr el din's correlations). Figure 3 illustrates the predicted values of conductivity by different correlations versus measured values. As shown, Nasr el din's correlation overestimates the values of conductivity. While optimized and new correlations underestimate theses values. The predicted values by Nierode & Kruk's correlation have the most deviation from experimental data

Table 4. Coefficients of optimized correlation for all input

Correlation	Coefficients
$WfK = \alpha \exp(-a_3 \beta \sigma_c)$ $\alpha = a_1 (DREC)^{a_2}$ $\beta = [a_3 - (a_4 \ln RES)] \times a_5$	a(1) 0.431 a(2) 0.742 a(3) 0.086 a(4) 0.300 a(5) 0.024 a(6) 0.547

The effect of rock strength were considered to provide a better understanding by using data of second and third categories. Table 7 shows coefficients of optimized correlation for rocks in which RES is less than 20000 Psi. The average relative error of the correlation is 34.55%. For this category new functions were used to improve accuracy of predictive correlation too.

Table 5. Proposed correlation and their coefficients to predict fracture conductivity based on all input data

Correlation	Coefficients			
$W_f K = a_1 \exp(a_2(\alpha) + (\beta)^{a13}$ $\alpha = a_3 (DREC)^{a4}$ $\beta = \gamma + \lambda$ $\gamma = a_5 + (a_6 RES) + a_7$	a(1)	0.27	a(8)	45

Nasr El Din	53.55	3.536	0.81
Optimized Correlation	135.63	3.889	0.62
New Correlation	48.83	4.10	0.72

Table 8 indicates proposed correlation and their coefficients. The correlation has 15 coefficients. The results show the new correlation is more precise compared to other correlations (Table 9). Comparison between the measured and predicted values of conductivity by predictive correlations has been depicted by figure 4

.

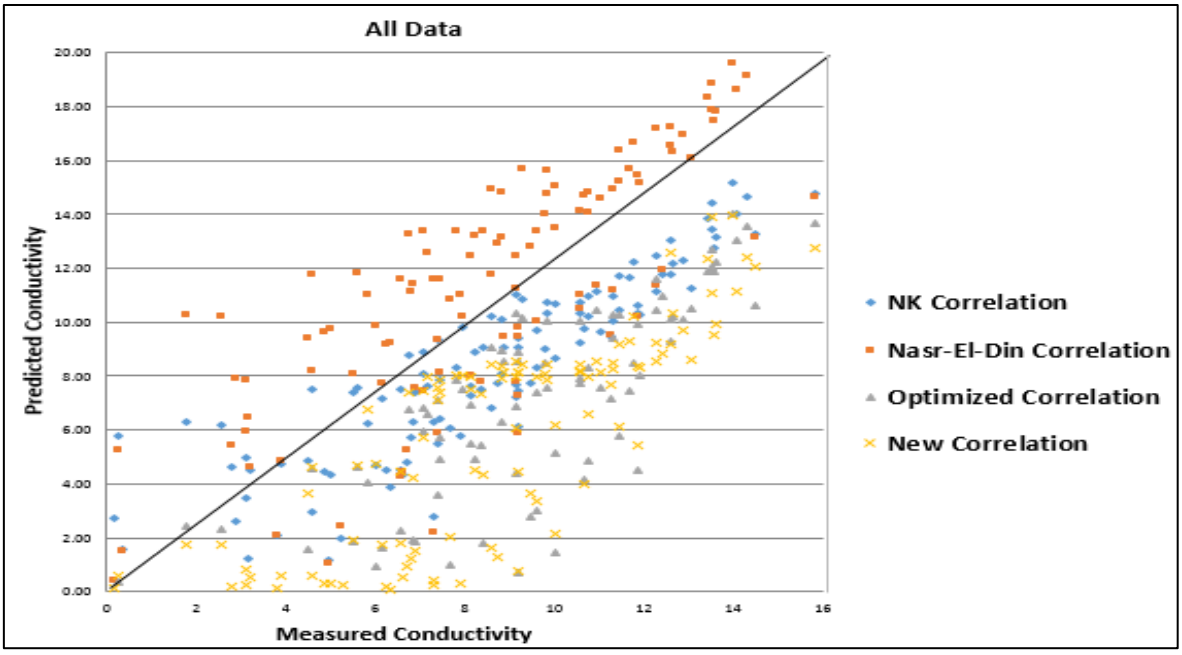

Figure 3. Comparison between the measured and predicted values of conductivity by predictive correlations for all input data

Table 10 shows coefficients of optimized correlation for rocks in which RES is higher than 20000 Psi. The average relative error of the correlation is 15.89%. Table 11 indicates proposed correlation and their coefficients. The correlation has 14 coefficients. Accuracy of predictive correlations to predict fracture conductivity for the category were compared in table 12. The Relative average error of new correlation is 14.74% that show there is a good match with experimental data. In these category, the values predicted by Nasr el din's correlation has a high error in comparison with other correlations.

Nierode & Kruk correlation but with the same parameters. Here the parameters never change. Table 9 illustrates the new correlation relative average error had shown the best result in compare with the main correlation and optimizing correlation of Nierode & Kruk with 24.09 percentages. Table 9 shows the relative average error, standard deviation and regression coefficient of different correlation that use for rock embedment lower 20000.

5 CONCLUSION

1. GA is a powerful tool to precisely and rapidly predict acid fracture conductivity at different closure stresses as compared to prior well-known models. The fracture conductivity predicted by GA correlation closely matched experimental data.
2. Rock strength plays a significant role when anticipating fracture conductivity, as various formations have behaved differently under various closure stresses. Because it is not possible to present a universal precise model to predict acid fracture conductivity for all rock types, predictive models must be developed based on rock strength.
3. Although the optimized correlations show a good match with experiment data, new correlations are more precise than them. However, new correlations are more complicated. It reveal that the functionality of fracture conductivity is not necessarily exponentially.

Nomenclature

$DREC$	Dissolved rock equivalent conductivity
σ_c	Closure stress
m_i	measured data:
$\bar{m}$	mean of the measured data
n	Number of data
p_i	Predicted data
$\bar{p}$	mean of the predicted data
RES	Rock embedment strength
WK_f	Fracture conductivity

Forecasting Crude Oil Price with an Artificial Neural Network model based on a Regular Pattern for Selecting of the Training and Testing Sets using Dynamic Command-Line Functions

M. H. Basiri, F. Javadnejad, and A. Saeedi
Department of Mining Engineering, Tarbiat Modares University, Tehran, Iran

ABSTRACT This paper presents a model based on a comprehensive regular pattern for selecting training and testing sets to forecast the crude oil price. The West Texas intermediate crude oil prices from 1994 to 2011 were selected for this study. The 80% of these data applied training and 20% for testing the model. Then a neural network model was designed using dynamic command-line functions to predict the monthly prices of crude oil. By examining a substantial number of tests, the influence of numbers of input neurons, the number of neurons in hidden layers, the transfer functions of layers, types of learning algorithms and a variety of fundamental economic variables (including changes in OPEC crude oil production and oil demand in industrialized countries, changes in world gold prices, changes in Dow Jones stock market index, and changes in the United States consumer price index) have been investigated. The results suggest a superior model includes two-layer back propagation network (N 8-8-1) with 2.21 in the root mean square error (RMSE), 85.71% in the directional symmetry of the model in determining the increasing or decreasing the prices and 91% in the coefficient of determination.

Keywords: West Texas Intermediate Crude Oil Price, Forecasting, Artificial Neural Network, Regular Pattern and Dynamic Command-Line Functions

1 INTRODUCTION

An uncertainty characteristic is an undesirable and inevitable property for investors in various markets including stock market and oil market. So naturally, all the investors endeavor to reduce uncertainty; hence market forecasting is one of the beneficial tools to slake the uncertainty.

Although the occurrence of the oil crises confronts the degree of reliability of these predictions with skepticism, a trustworthy prediction of world oil price can ease the process of buying and selling of oil in the world markets. It can determine the best time for performing transactions and investments.

As addressed in literature survey, there are myriad tools in forecasting discussions such as regression models, time series, and artificial intelligence approaches.

In this research we have focused on artificial neural network method based on regular pattern for selecting training and testing sets for designing a comprehensive forecasting model for West Texas Intermediates oil prices. Using dynamic command-line functions and examining a substantial number of tests, the most optimum model has been approached. In addition, we have investigated the influence of a variety of fundamental economic variables (including changes in OPEC crude oil production and oil demand in industrialized countries, changes in world gold prices, changes in Dow Jones stock market index, and changes in the United States consumer price index) on the model.

2 RELATED WORKS

Kaboudan has forecasted monthly price of crude oil by discussing the Artificial Neural Networks and compared the results with the random walk method. The data used in this study from June 1993 to December 1998 are the closure of market prices of crude oil exported to the United States. In the presented Neural Network model, it is trained using feed forward networks and only static error back propagation training algorithm. The network has one hidden layer

and the sigmoid function is used. MSE is considered as an error criterion to compare models. This researcher believe that over the time crude oil prices follow the cycle patterns which tend to greatly increase then reversed their direction and may rise again (Kaboudan, 2001). Moshiri and Foroutan to predict WTI crude oil price index suggested an artificial neural network model and compared with the results predicted by linear models and nonlinear ARMA GARCH. Results demonstrated that the neural network model has better predictive power than the ARMA model and GARCH (Moshiri et al, 2004).

Michael Ye et al have predicted short-term South Texas crude oil prices and have been reviewed the impact of market including inventory, production, imports and demand changes on monthly crude oil prices (Michael Ye et al., 2005). Zamani reviewed the performance of the international oil market in order to identify the variables required for modeling. The most important factors are the oil storage of OECD region and the affecting exchange rate of dollar. Data from the statistical viewpoint is reviewed and long-term relationships between WTI prices and other variables are estimated. Then auto regressive, error correction and auto regressive distribution models were used to predict and identify a model with minimum error (Zamani, 2005). Gori et al for examining the relationship between prices and oil consumption have studied three scenarios for oil prices. The result shows that the oil price time series is correlated with the oil consumption during 1980 to 1989. Oil prices increasing in 2003, reduced the consumption in the same year. (Gori at al., 2007).

Farjamnia et al, using two methods, ARIMA and artificial neural networks, predicted the daily world price of crude oil with 5 lags. the results show that ARIMA model is of superior to artificial neural network to predict the prices (Farjamnia et al., 2007). Bahradmehr using wavelet smoothing and artificial neural network predicted daily crude oil prices of New York and the Gulf of Mexico for 2000 to 2004. In this study, the smoothing property of wavelet transform is used to reduce noise levels and then oil prices are predicted by using the neural network and smoothed data. The results indicate that the noise reduction and data smoothing improve the performance of prediction (Bahradmehr, 2008).

Lin Yu et al have presented an empirical model decomposition (EMD) based on neural network for training trends in oil prices and predicting their future. Daily data for the modeling of oil prices from 1986 to 2007 is used. Initially, the data using transfer functions are pre-processed into limited values and then these data are trained using a feed forward three layers neural network model. This model on the West Texas and Brent oil market under using various transfer functions is used and then results of various scenarios using the neural network and ARIMA approaches have been compared based on direction symmetry criteria. The best results is obtained using empirical model decomposition in a feed forward neural network and linear transfer function with 86% accuracy in directional symmetry (Lin Yu et al., 2008).

Kullkarni and Haider in a study has forecasted the WTI crude oil price for the next three days, and concluded that a dynamic model with 13 delays to predict short-term expected crude oil spot price is suitable. Also the price prediction accuracy has been estimated 78%, 66% and 53% respectively for one, two and three days (Kullkarni at al., 2009). Azadeh used Nero-fuzzy hybrid approach to predict the price of oil annually. The amount of oil production, America's refinery capacity, oil consumption of Non-OECD the countries and excess capacity has been selected as affected indicators. Data of 1985 to 2002 for training and 2003 to 2007 to testing the model is used (Azadeh, 2011).

3 ARTIFICIAL NEURAL NETWORK

Artificial neural networks as one of the main component of computational intelligence have important properties. Learning, generalization and function approximation

ability and parallel structure are the most important properties of artificial neural networks. These properties caused their importance and application in science and engineering problems.

An artificial nerve is a model that its component directly similar to that of a real nerve. These processing elements are composed of two parts: the first part sum the weighted inputs and the second part is a linear or nonlinear smoothing called transfer function.

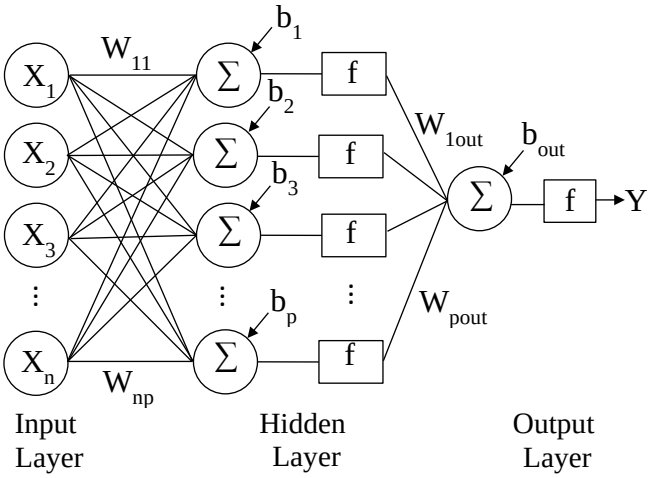

Figure 1: Mathematical model of a feed forward two layers artificial neural network.

Figure 1 shows mathematical model of a feed forward Multi-layer artificial neural network. In this model, n is the number of input layer's neurons, p is the number of hidden layer's neurons, X_1 to X_n are the input variables, W_{11} to W_{np} are neuron synaptic weights, b_1 to b_p are neuron biases, f is the neuron transfer function and Y is the output. Each input signal influenced by weights called synaptic weights. These weights can be positive or negative. W_{np} demonstrates the connection intense from nth unit to pth unit. By putting together of neural units, artificial neural networks is achieved. Obviously, by various combinations and how weights connected different types of neural networks are designed. Feed forward Multilayers networks usually called Multi-Layer Perceptron networks or MLP are considered as the most widely used type of neural networks.First in 1986 presented by Rumelhart and Mc. Holland, the algorithm of back propagation of errors is the most common learning algorithm. This algorithm is based on the error correction learning rule generalization of the least mean squares. In this method after calculating the network output, the result is compared with the desired output and the difference of them calculated. In back, the obtained error is propagated within the network and the network weights are modified so that the real answer is closer to the desired response.

Criteria	Functions
Adjusted R-Square	$\bar{R}^2 = \frac{(n-1)\sum(\hat{Y}_t - \bar{Y})^2}{(n-m)\sum(Y_t - \bar{Y})^2}$
Root Mean Square Error	$RMSE = \sqrt{\frac{\sum(Y_t - \hat{Y}_t)^2}{n}}$
Mean Absolute Error	$MAE = \frac{\sum\lvert Y_t - \hat{Y}_t\rvert}{n}$
Directional Symmetry	$DS = \frac{\sum_{i=1}^{n} di}{n} \times 100$, $di = \begin{cases} 1 & \text{if } (y_{i+1} - y_i)(\hat{y}_{i+1} - y_i) > 0 \\ 0 & \text{otherwise} \end{cases}$
Akaike Information Criterion	$AIC = \log\left(\frac{SSE}{n}\right) + \frac{2m^d}{n}$

4 EVALUATION OF NEURAL NETWORK MODEL

Different performance criteria can be considered for evaluation of a neural network model. Criteria used, depending on which issues of neural networks are in used. When using neural network to predict, the measure of prediction accuracy can be considered as the best measure for network performance. Some of these criteria are shown in Table 1. Where "Yt" is the target value, "Ŷt" is model output value, "n" is number of observations, "m" is the number of model parameters and "d" is a coefficient between 0.50 to 2.

Table 1: Some model performance evaluation criteria

5 DATA

The time series studied are data on the West Texas Intermediate crude oil prices from 1994 to October 2011. The data are on a monthly frequency and dollars per barrel. From total of 208 data categories, 80% of

which were selected for training data (of course 10% is assigned to the validation category) and 20% for testing the neural network model.

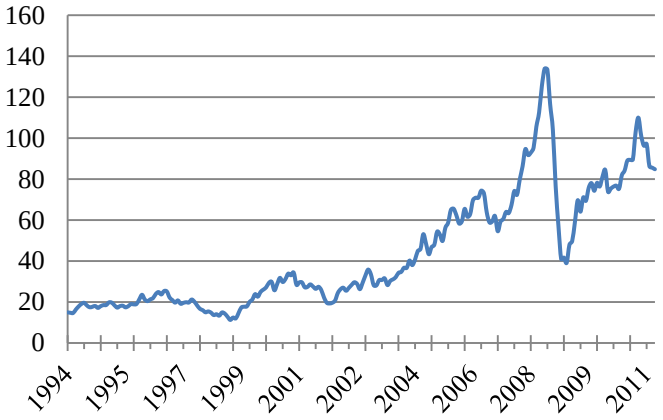

Figure 2: The time series of West Texas Intermediate crude oil prices from 1994 to 2011 -The vertical axis unite is dollars per barrel.

6 DESIGNING AN ANN MODEL BASED ON REGULAR PATTERN FOR SELECTING TRAINING AND TESTING SETS

In many researches on the field of predicting future time series, mostly the initial part of data is considered as the training set and terminal of which as the testing set. But choosing such sets make losing a large part of the data that is relevant to the terminal part of the course. This part of the data more than anything else is important and efficient to predict the future of a market because of closeness of which to the present time. In addition overlooking this part of data in such a turbulent time series of oil prices leads model to error in the test section. A model can represent a comprehensive model of a time-series data when it encompasses all parts of the model during training and testing process. In this research, testing and training sets are selected based on a regular pattern of 52 (208÷4) subsets with length 4 (proportion the training set to testing set). This regular set dividing pattern is provided the possibility of designing a superior artificial neural network model through comprehensive dynamic command-line functions.

Neural network model designing process and determining its parameters are implemented by series of trial and error process. So that a prototype model is made and then trying to change the parameters to get a better of which. During designing the model, performance criteria reflected the accuracy of the model is determined. Then by comparing these criteria together, the best model whit the best performance is chosen. For designing neural network model, delayed values of oil prices (P_{t-1}, P_{t-2}, …, P_{t-n}) and the fundamental economic variables (X_{t-1}, X_{t-2}, …, X_{t-n}, Z_{t-1}, Z_{t-2}, …, Z_{t-n}, …) are appointed as the network inputs and current prices are appointed as the outputs. Actually what the model learns is a function as follows:

$P= f (P_{t-1}, .., P_{t-n}, X_{t-1}, …, X_{t-n}, Z_{t-1}, …, Z_{t-n}, …)$

Through using the dynamic command-line functions, parameters of the model are adjustable and can be linked together. so the impact of adjusting these parameters can be investigated on the model evaluation criteria (These parameters are including the number of input neurons, the number of hidden layers and neurons of which, transfer functions, training algorithms, number of training cycles, learning rate and proportion of validation data.

In this section the process of designing the model is explained step by step. Dynamic command-line functions in MATLAB software is given at appendix.

6.1 Step 1: Definition of Input Data

Given to the research literature of oil market, the current prices are not dependent on delayed prices more than few months. The column of current Oil prices (the last column) along whit 9 columns of delayed values of which is imported into a 208×10 double workspace (named data). However after determining the optimal delayed lags, extra columns are replaced by 5 columns of past month changes of fundamental and economical parameters. Thus there are 208 data categories (observations). In command-line functions, Lag represents number of

delayed price values. This number, among 1 to 9 months, after many trials and adjustments of which, is set 3. Finally to show the input variables the columns of the extra delayed values is omitted and substituted by five columns of changes in fundamental and economic variables. As shown in table 2 we have 8 input versus 1 output.

In the command-line functions "Trainingpercentage" shows the percentage of data used as the training set. "Hiddenln" defines number of neurons of hidden layers. H1 is number of training sets, M1 is number of testing sets and L is the length of the regular pattern. Commands in lines 8 to 15 refer to designing a regular pattern to select the training and testing sets.

6.2 Step 2: Designing the Artificial Neural Network Model

After arranging the data into a regular pattern of training and testing sets, to designing an artificial neural network model we need to determine the input and target vectors in form of both training and testing sets. First "P" matrix involved the columns of input values (in table 2 the columns 1 to 8) and "T" matrix involved the column of target values (in table 2 the column 9) are arranged as training sets.

Next using similar fashion "a" matrix involved the input columns and "s" matrix involved the target column are arranged as testing sets. Other commands in this section are to define the parameters of the model (the parameters such as learning algorithm, Transfer functions, percentage of validation data set and other net training parameters.

6.3 Simulation and evaluation of model's performance

After designing the structure of network, it is time to simulate and evaluate the model. For this purpose, the network is simulated by training sets and evaluated by testing sets. Calculating almost all performance criteria, Evaluation of the model is carried out for both training and testing sets.

7 IMPROVING MODEL'S PERFORMANCE

To achieve the superior model, the structure of the model should be modified. The dynamic command-line functions provide the possibility to easily change different parts of the network structure. In the next section conducting trials and errors, network structure and parameters have been modified to improve performance.

7.1 Determination of Number of Delayed Lags

In oil turbulent market, price changes are so diverse that a significant correlation more than few months between the delayed values is not expected. In this study, using the performance criteria (especially RMSE) and trials and errors, the optimum month number for delayed values is determined three.

7.2 Determination of the Optimal Hidden Layers and Neurons

Rarely, using more than three hidden layers for prediction issues has the model shown performance improvement. In other words, more increasing number of layers, more overestimates network. To determine the optimal number of hidden layers and how many neurons in which, models in various scenarios for the numbers one to three hidden layer has been simulated. Performance criteria reflect the best scenario when the model has one hidden layer and eight neurons in that.

7.3 Determination of Optimum Transfer Functions

To determine the optimum transfer functions, using different transfer functions scenarios have been investigated. And which ones have the best performance are selected as the optimum transfer functions. the model demonstrates a better performance through using linear transfer functions in each layer. In Table 5 for instant T-P symbol used as the transfer function, illustrates hyperbolic tangent sigmoid transfer function in hidden

layer and liner transfer function in output layer.

Table 2: The influence of Delayed values on the performance of the model.

7.4 Study of Influence of the Learning Algorithms

Levenberg Marquardt (LM) learning algorithm is the common learning algorithm used in the all above models. This algorithm in scientific applications has high speed and performance. In forecasting issues besides presenting a better performance, LM is converged faster than other learning algorithms.

According to the results of Table 7, however, other learning algorithms are also used to train the model, LM shows the best performance.

Table 6: Symbols of learning algorithms.

Symbols	Descriptions
lm	Levenberg-Marquardt back propagation
bfg	BFGS quasi-Newton back propagation
br	Bayesian regularization
cgb	Powell-Beale conjugate gradient back propagation
cgf	letcher-Powell conjugate gradient back propagation
cgp	Polak-Ribiére conjugate gradient back propagation
gda	Gradient descent with adaptive learning rule back propagation
gdx	gradient descent with momentum and adaptive learning rule back propagation
oss	One step secant back propagation
rp	Resilient back propagation
scg	Scaled conjugate gradient back propagation

7.5 The study of influence of economical and fundamental variables in the model

Factors affecting oil prices are out of financial markets and most related to current political issues in the oil producing countries and demand from major consumers such as China, Europe and the United States.

In this research on top of oil supply and demand, the influences of some key economic parameters on oil prices are examined. These parameters comprise of the oil production from OPEC, oil demand in industrialized countries (Organization for Economic Cooperation and Development member countries), the global price of gold, Dow Jons stock market index, consumer price index in the United States.

The changes in these parameters over one month ago have been added to the model. The results of adding these variables to the neural network model are shown in Table 8. The implementation of each parameter improves the network performance to forecast the prices. So that adding all of these parameters reduces the RMSE criterion to 2.21 and increase directional symmetry to 85.71 percent.

Table 8: Used input and target data for Training and Testing the artificial neural network model for forecasting crude oil price

Factors	Train`		Test			
	$\overline{R}^2_{Train}$	AIC	$\overline{R}^2_{Test}$	RMSE	MAE	DS
OPEC	0.97	3.05	0.94	2.66	2.02	80.95
OECD	0.97	3.05	0.91	2.68	2.10	83.33

8 PREDICTION RESULTS

Through a trials and errors process and doing plenty experiments, ultimately an optimal neural network model is presented to predict future short-term oil prices. This comprehensive model is a two-layer feed forward neural network ($N^{8\text{-}8\text{-}1}$). The structure of such a network is composed of 8 neurons in the first layer as the network's inputs (3 numbers of delayed values and 5 numbers of fundamental variables), 8 neurons in Hidden layer and 1 neuron in the last layer as a network's output. Transfer functions used in each layer are pure linear and training algorithm is Levenberg-Marquardt algorithm. This optimum model in the test section shows following results: Root mean square error (RMSE) equal to 2.21, directional symmetry in determining the increase or decrease of the prices is 85.71 percent and the adjusted-R^2 is 91 percent. In Figure 3 the predicted values are compared with actual prices.

9 CONCLUSION

In this study, the usual method of selecting the initial part of time series as training set and the terminal part as testing set in designing a model for forecasting of crude oil price has been criticized. Such set selecting in the training and testing of the models cannot provide a comprehensive model of a turbulent time series like oil market. If such models are used to predict future market, a large part data of terminal periods are excluded, while changes in these parts of data have an effective and significant role in determining the future market. Using a regular pattern for selecting training and testing sets ensures that the comprehensive proposed model includes data from all sectors of time series during the training and testing process.

In a turbulent crude oil market, the price changes are so diverse that are not expected more than few month correlations between the current prices and far delayed prices; so that in this model 3 lags are determined as the optimum and effective lags. Increasing the number of hidden layers and the neurons of which cause overestimate problems and increasing the errors of model. Using linear transfer functions, especially in the output layer, enhances the performance of the model. Among training algorithms used in the models, Levenberg-Marquardt has appropriate speed and, and converges faster than other algorithms and presents a better performance compared with other algorithms.

Adding monthly changes with one delayed in parameters included the OPEC's oil production, oil demand by industrialized countries (Organization for Economic Cooperation and Development member countries), the global price of gold, Dow Jons stock market index and consumer price index in the United States improves network performance to predict prices. So that when these parameters are implemented in the model the error criterion reduces to 2.21 and directional symmetry reaches to 85.71 percent.

Impact the Parameter Effect of Vibration on Collision Efficiency in Flotation

K. Dedelyanova
Scientific and technical union of mining, geology and metallurgy, Sofia, Bulgaria

J. Dimitrov
University of Mining and Geology, Sofia, Bulgaria

ABSTRACT The paper presents research of mechanism for the creation of air bubbles in vibratory column flotation machine. Discussed the factors influencing increasing the duration of the bubble in the area of contact with the mineral particles.

Formulas are derived for the parameter effect of vibrations, applicable to the design of flotation machine. The collision efficiency of the bubbles in vibratory column flotation machine is determined.

Keywords: Collision efficiency, vibratory column flotation machine

1 INTRODUCTION

The increase of air bubbles flotation activity is connected with the increasing of the time of their conditioning, i.e. the interval between the formation moment and the bubble mineralization. In consequence of the column considerable height the sojourn duration of the air bubbles in it is not longer than 20 sec, i.e. a mineralization process at optimal flotation activity of the bubbles is realized (Rubinschayn, 1989).

In column apparatus under low turbulence probability of attachment and retention of large particles to the bubble is greater because under certain conditions, the use of column flotation machine can be useful for flotation of coarse material (Foot, 1986).

Dedelyanova & Metodiev (Dedelyanova & Metodiev, 2002) are presented a laboratory model of vibratory column flotation machine constructed in the Laboratory of "Vibro-acoustic Intensification of the Technological Processes" at the department of "Mineral Technologies" of the University of Mining and Geology, "St. Ivan Rilsky". It is realized on a modular principle, which provides a possibility for determination of optimal height the feeding device, infinitely – variable regulation of the pulp level and precise determination of the necessary quantity of extra water for the froth layer irrigation. The vibratory column flotation machine basic elements are sensor, vibrator, air disperser, module for creation of single gas bubbles, feeding device, machine chamber (Figure 1).

Figure 1. Photo of laboratory column flotation machine

2 EXPERIMENTAL RESEARCHES

In (Dedelyanova, 2004) is presented the study on the influence of frequency and amplitude of vibrations on the rate of sedimentation of mineral grains with different density. It is known that with the increase of the intensity of

fluctuation the rate of sedimentation decreases. However, the issue what is the influence of this effect on the diameter and the relative weight of the particles still remains open. For this purpose, a series of experiments has been carried out, during which single mineral grains with a diameter of 0.09 to 0.155 mm and density of the different grains of 2.65, 5.1 and 7.6 g/cm^3 have been used. The frequency of fluctuation changes from 20 to 70 Hz and the amplitude – from 1.5 to 3.0 mm. The average results from the tests are presented in Figure 2.

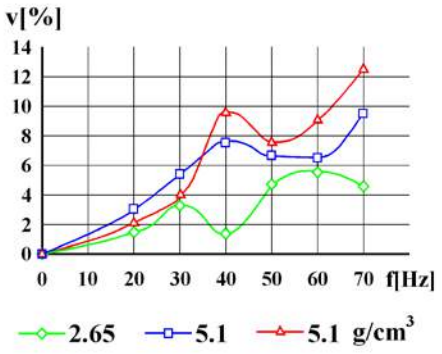

Figure 2. Reduce the speed of sedimentation depending on the vibration frequency and density of particles

In (Dedelyanova, 2004) are presented the results from the tests with vibratory column flotation machine with copper raw material (cake, taken from a control thickener). The experiments were carried out in laboratory conditions – columns flotation machine with height of 2000mm and diameter of 50 mm under vibration impact with values of Af^2 1500, 1800, 2250, 2450, 3200, 3675 and respective vibration frequency from 25 Hz to 40 Hz and amplitudes of 2.0 mm, 2.5 mm, 3.0 mm. The air dispersion is done via vibratory dispersing agent constructed for vertical vibrations. Parallel to the creation of bubbles the vertical fluctuations create vibro-acoustic field which is distributed along the height of the chamber in the flotation machine.

With values of the vibration impact Af^2 3200 ($f = 40Hz$, $A = 2.0mm$) the copper content in the concentrate reaches up to 32.23%, with copper content in the exit sample 22.76%. The copper content in the concentrate with the vibration impact increases with 3%, up to 12%. When tracking the results it was found that at value of the vibration impact of $Af^2 = 3675$ ($f = 35Hz$, $A = 3.0mm$) and content of the solid substance in the pulp 3.8%, whose value is the highest for the series of flotation experiments, the extraction is the highest – 90.68%. This coincides with the highest value of the copper content in the concentrate – 31.44%. Via this dispersion of the gas phase, the copper content in the concentrate increases with 3-3.5%, with initial content of the copper ranging from 23.31% to 27.89%.

3 IMPACT THE EFFECT OF VIBRATION ON BASIC PARAMETERS

3.1 Changing the Size of Bubble

The law of harmonious movement of the liquid is $z = A\sin(\omega t)$, where z is the vertical displacement; A - the amplitude of the harmonic movement; $\omega = 2\pi f$ and f is the frequency of vibration; t - is during the process. The speed of the fluid is determined by the relationship $v_l = A\omega\cos(\omega t)$. As a result of vibrations an affiliated part of the liquid near the bubble is subjected to harmonic effects and it causes change of the pressure p. Assume that the process of fluctuation in the volume

$$V = \frac{\pi d^3}{6} \qquad (1)$$

of the bubble is isotherm $pV = const$. In a state without of vibration on a certain level h from the surface of the liquid, the pressure in the bubble is $p_1 = p_0 + \rho_l hg$, where p_0 - atmospheric pressure; p - pressure in the bubble; ρ_l - density of liquid and g - acceleration of gravity. To this is added pressure p_2 fluctuating pressure caused by the harmonious impact on the associated mass of liquid

$$p_2 = k\rho_l \frac{\partial v_l}{\partial t} = k\rho_l A\omega^2 \sin\omega t. \qquad (2)$$

where $k << 1$ is a coefficient representing the participation of associated mass at vibrating bubble

Due to the relatively small amount of p_1 and symmetry its sign labeled with ε, does not matter. Total, the pressure in the bubble on level h is

$$p = p_0 + \rho_l hg + \rho_l kA\omega^2 \sin\omega t = \\ = p_1 + qAf^2 \sin\omega t, \quad (3)$$

where $q = 4\pi^2 k\rho_l$. By comparing the states of the bubble on level h and near surface and we obtain from the law for isothermic process

$$p_0 \frac{\pi d_b^{\,3}}{6} = p \frac{\pi d_0^{\,3}}{6}, \quad (4)$$

where d_b the diameter of the bubble; d_0 - the diameter of the bubble on the surface. Therefore

$$d_b = d_0 \sqrt[3]{\frac{p_0}{p_1 + qAf^2 \sin\omega t}} \quad (5)$$

From equation (3) can be inferred about the impact of effect of vibrations Af^2 on variation changing on the size of bubble in the process of emergence.

3.2 Determination of the Contact Angle

According to Bogdanov (Bogdanov, 1990) forces acting on the bubble and attached to him particle, accounted on the vertical axis are two types - forces acting on the particle and forces caused from the attachment of particle to the bubble. The first type forces are gravity of particle and ejection Archimedean force, as follows: gravity $P = -\pi d_p^{\,3} \rho_p g / 6$, where d_p is aligned particle diameter, ρ_p is the density of the particle and g is the gravity acceleration; ejection Archimedean force $F_A = \pi d_p^{\,3} \rho_l g / 6$, where ρ_l is the density of the fluid displaced by the particle. The second type of forces are the Laplace force F_L and capillary force F_K: Laplace pressure force that is acting on the upper wall of the particle is $F_L = -\pi d_p^{\,2} \Delta p / 4$ where $\Delta p = p_g - p_l$ is the Laplace pressure, p_g and p_l are respectively pressure in the gas and pressure in the liquid on the level of contact; capillary force $F_K = \pi d_p \sigma \sin\theta$, where σ is the surface tension recorded per unit length of contour of tangent wall of the particle and θ is the angle between the tangent wall of the particle and the surface of the bubble. As result receives equilibrium equation of bubble and attached to him particle

$$P + F_A + F_L + F_K = \frac{\pi d_p^3 \rho_p a_l}{6}, \quad (6)$$

where $a_l = A\omega^2 \sin\omega t = 4\pi^2 Af^2 \sin\omega t$ is the acceleration of the liquid, due to the harmonious movement. To determine the angle θ the equilibrium equation is expressed in the form

$$\sin\theta = \frac{d_p^2 g(\rho_p - \rho_l)}{6\sigma} + \frac{d_p \Delta p}{4\sigma} + \frac{2\pi^2 d_p^2 \rho_p Af^2 \sin\omega t}{3\sigma}. \quad (7)$$

3.3 Changing the Form Constant of Bubble

The ratio of the hydrostatic pressure on the contact side of the particle to the Laplace pressure are defined as form constant to the bubble near the particle

$$\beta = \frac{\rho_l g d_b}{\Delta p} = \frac{\rho_l g d_b^2}{4\sigma} = \frac{\rho_l g d_0^2 \left(\frac{p_0}{p_0 + 4\pi^2 qAf^2 \sin\omega t} \right)^{\frac{2}{3}}}{4\sigma}. \quad (8)$$

From the expression (8) follows that the size of the constant harmonic variation β is function of effect of vibration Af^2.

4 IMPACT THE EFFECT OF VIBRATION ON COLLISION EFFICIENCY

For obtaining an integrated evaluation of the flotation machine efficiency introduces the concepts of collision efficiency

$$E = \frac{M_0}{M}, \quad (9)$$

where M_0 is the mass of particles that meet with bubbles and M mass of all particles which are located in the level of contact at a point in time t. In (Ralston, 1999) is regarded the parameter k (called flotation rate constant) as proportional to the defined there parameter collision efficiency E. In

(Rubinschayn, 1989) the parameter E is called coefficient of grip.

4.1 Some Known Models

In (Rubinschayn, 1989) are presented multiple formulas determining the number of collisions N and collision efficiency E, divided in two groups – a relatively small group - formulas derived by accepting the model of turbulent motion of bubbles and particles; - formulas derived by analyzing the deterministic description of the bubbles and particles movement, processes of interaction and relevant forces governing these processes.

According to Derjaguin (Derjaguin et all 1960) around the bubble can define three zones:

- Zone 1 – most outside part – of hydro-static interaction;
- Zone 2 (of attachment) – area of effect of surfaces;
- Zone 3 – of stability efficiency of the bubble – particle aggregate

In order to make an analysis of the process of collision we assume that the bubble is spherical and around it we go over a rotational body with vertical axis passing through the center of the sphere. We denote with d_b the diameter of the bubble, d_p - diameter of the particles and a - diameter of

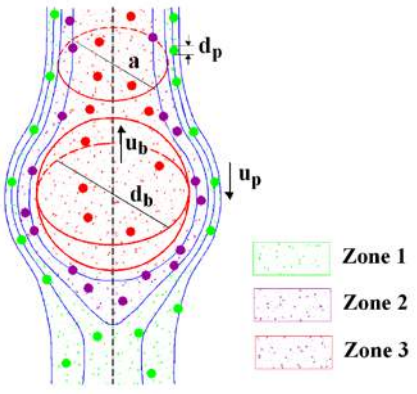

Figure 3. Scheme of collision of the particles with the bubble

the section of the cylindrical area including zones 1 and 2 prior to the level of collision (Figure 3).

In accordance with the areas of interaction in the aggregate bubble - particle (zone 1 and zone 2) the effectiveness of a collision can be represented by $E = E_{il} + E_{vl}$ where E_{il} is efficiency of laminar (gravitation) flow (ideal liquid) and E_{vl} - efficiency of viscous flow (viscous liquid). Taking into account the formulas presented in (Rubinschayn 1989). and (Bogdanov, 1990). with some approximations can accept the formulas

$$E_{il} = \frac{G}{1+G}\left(1+3\frac{d_p}{d_b}\right) \text{ and } E_{vl} = \frac{3}{2}\left(\frac{d_p}{d_b}\right)^2 f, \quad (10)$$

where $G = \frac{u_p}{u_b}$, $f \in [0.1,1]$.

Of the ways of expressing the effectiveness of conflict we can conclude that from the vibrational motion of bubbles and particles affect the effectiveness of a collision. The impact is both through variable diameters of the bubbles and by the rate of ascent of the bubbles. Given that the collision efficiency is a dimensionless quotient of ratio of the mass of the particle meeting the bubble and whole mass of flotation material, it is clear that we can not directly use formulas presented in the literature in the case of column vibration flotation machine.

4.2 Effectiveness of a Collision at Vibration Impact

To determine the increasing of effectiveness of collision in the presence of vibration will use another approach. Consider the model given by Bogdanov (Bogdanov, 1990) and will supplement it with vibrational defor-mations of the bubble. We will use and results of experimental studies of Dedelyanova (Dedelyanova, 2004).

For an analysis of the collision process we accept a bubble for sphere and and we consider a rotating body around a vertical axis, that passing through the center of the sphere. We denote by d_b is aligned bubble diameter, d_p is aligned particle diameter, and a - diameter of the cylindrical areas include zones 1 and 2 before the level of collision.

The cross section of the cylindrical region in diameter a is $S_0 = \pi a^2/4$ and at the level of collision $S_b = \pi\left(d_b + d_p\right)^2/4$. Produced for the effectiveness of conflict

$$E = \frac{S_0}{S_b} = \left(\frac{a}{d_b + d_p}\right)^2 . \quad (11)$$

According presented in Figure 3, the parameter E is ratio from the section of the straight part of the area, including areas 1 and 2 to section at the center of the bubble. Because the bubble vibrates with sound frequency f, then the mean diameter d_b is the same as without vibration. While performing a harmonic cycle of bubble volume remains the transition from sphere in rotating ellipsoid. When the bubble diameter is $d_b = 4\ mm$ and amplitude $A = 0.7\ mm$ extremes on the vertical axis of the ellipsoid are $z_{\min} = 3.3\ mm$, $z_{\max} = 4.7\ mm$ with horizontal axes, respectively $x_{\max} = y_{\max} = 4.4\ mm$ and $x_{\min} = y_{\min} = 3.69\ mm$. Due to the high velocity of the bubble oscillation at a given frequency f parameter a on Figure 5 reaches the diameter of the bubble d_b. This is confirmed by Figure 3 at value of effect of vibrations $Af^2 = 3750\ mm \cdot Hz^2$.

5 CONCLUSIONS

Experimental researches involved the conclusion that vibrating media provided additional force of resistance, applied ad to the mineral particle, which provoked decrease of the speed of falling down. This force is a function not only of the intensity of the vibrations of a complex variable vibration, but also is a function of frequency of vibration.

From the analytical study of the collision efficiency are confirmed experimentally proven facts. Enables to increase the residence time of the bubble in the zone of contact with the mineral particles. The vibrations of the hydrated layer allow for cost-effective implementation of the elementary act of flotation by providing larger relative velocities at a meeting of the bubble with the solid phase.

ABSTRACT In recent years, precious metals production through hydrometallurgical process has been attended; however the Low grade of metals is one of the main problems. Thus, solvent extraction method was purposed for concentration and purification of aqueous solution. In this study, Tri butyl phosphate (TBP) was used to $PdCl_3$ low concentrations of TBP could extract Pd chloride ions. The Solution containing 180 mg/l Pd was extracted by 0.05-0.25 M TBP in different HCl concentration. Increasing HCl concentration decreases Pd extraction percentage. It seems that different chloride complexes formations cause the extraction percentage to change in various HCl concentrations. The extracted macromolecule is determined $PdCl_3^-$.TBP.xH_2O. HNO_3 and NaCl has negative effect on Pd extraction.

Keywords: Solvent extraction, Palladium, TBP, Chloride media

1 INTRODUCTION

In recent years, consumption of palladium has grown; in addition, this has extensive use in jewellery, dentistry, electrical contacts, corrosion resistant apparatus, and biomedical devices. Thus there has been a renewed interest in studying new approaches for the recovery of this metal from raw and secondary resources.

As we know, PGM (Platinum Group Metals) resources are restricted. For metal recovery, palladium sources (primary or secondary) were leached in aqueous solution. But Pd concentration, basically, is low and the impurities (such as Fe, Cu, Ni, PGM and etc.) are dissolved. Concentration and purification of pregnant solution have been done in various methods. Solid/liquid (carbon active and ion exchange resin) and liquid/liquid methods were proposed for Pd ionic species transferring. Among them, solvent extraction of Pd has been applied in many cases to extract palladium from aqueous hydrochloric acid solutions (Rane and Gopal, 2006, Rovira et al., 1999, Bendekar and Dhadke, 1998).

Oximes (Shen and Xue, 2007), phosphoric acids (Bendekar and Dhadke, 1998), phosphonic acid (Bendekar and dhadke, 1998) and thiophosphinic acid (Kakio and Goto, 1994) are the popular Pd extractants from chloride media.

In the present work, extraction mechanism of palladium from chloride solutions by TBP is evaluated as well as the effect of pertinent parameters, namely as HCl, NaCl and TBP concentrations, on the extraction process that are identified. “Slope analysis” method is employed to clarify extraction mechanism of palladium with TBP diluted in kerosene.

2 MATERIAL AND METHODS

Commercial tri-n-butyl phosphate (TBP Fluka) as extractant and kerosene (Isfahan Refinery Co) as diluents were utilized. Hydrochloric acid (35%-37%vol) was

obtained from Dr. Mojallali chemical laboratories in Iran. Also, palladium ions were prepared by the standard metal chloride (PdCl, MERCK). Initially, kerosene was purified being washed by 3M HC1 solution then diluted with TBP. Palladium chloride was diluted by HCl and distilled water in different ratios. Batch experiments were carried out in a flask containing equal volumes (20 ml) of aqueous and organic solutions. The mixture was agitated at constant temperature (20 C) by a mechanical shaker at 400 rpm. Agitation was carried out for 30 min to assure equilibrium conditions then agitated samples were poured in a separating funnel for 15 min to allow complete separation of the two phases. The metal content of the aqueous phase was determined by atomic absorption spectroscopy (varian, A240) and chemical composition of the organic phase was determined by mass balance calculations.

3 RESULTS AND DISCUSSION

3.1 Effect of HCl Concentration

Figure 1 illustrates the influence of HC1concentration on palladium extraction by TBP diluted in kerosene. As shown, extractant concentration increased Pd extraction percentage but an increase in hydrochloric acid concentration leads to lower extraction percentage.

Keshavarz Alamdari and Darvishi and Haghshenas and Yousefi and Sadrnezhaad, (2011), shows that the mechanism of metallic complexes extraction by TBP involves an ion association process in which the protonation of TBP molecules by H (H_3O^+), brings the extraction ability for TBP to extract anionic species. But in this case, increasing acid concentration (or pH decreasing) leads to negative effect on Pd extraction. It seems that presence of acidic ions (H^+ or Cl^-) in solution reduces Pd extraction.

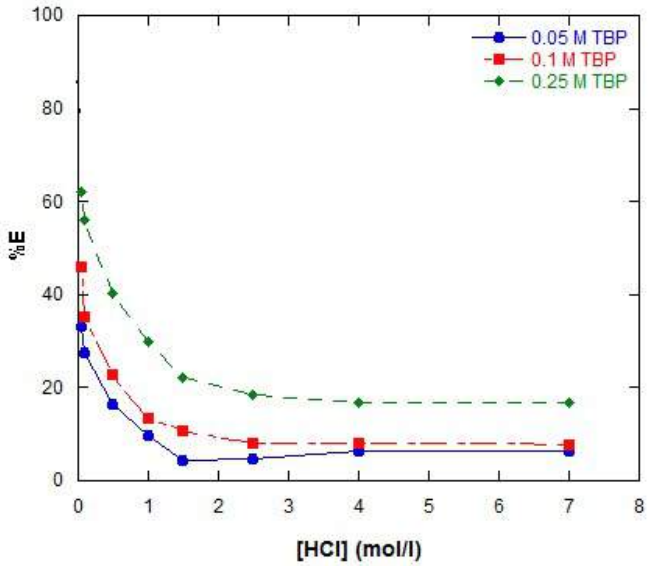

Figure 1. The influence of HCl and TBP concentrations on palladium extraction percentage.

3.2 Effect of Chloride Salts on Pd Extraction

For a closer look at the anionic chloride complexes formation, the chloride salt (NaCl) was added to solution at constant acid concentration. Increasing charged components in aqueous media may change chloride complex species and metal extraction percentage.

Fig 2 shows the results obtained from experiments carried out with organic solutions of 0.25 M TBP in kerosene and aqueous solutions which contained 0.1 M HCl and various concentrations of NaCl. It can be seen that the palladium efficiency decreases with an increasing NaCl concentration. By integrating the results of Figs 1 and 2 can be concluded that chloride ions have significant on palladium complexes formation.

3.3 Stability of Palladium Chloride Complexes in Aqueous Media

Reliable thermodynamic data on Pd-Cl system make it possible to predict palladium complexes stability. In aqueous solutions containing the Cl^- ion, Pd chloride forms complexes of the composition $[PdCl_n]^{2-n}$ (Polotnyanko and Khodakovskii, 2014).

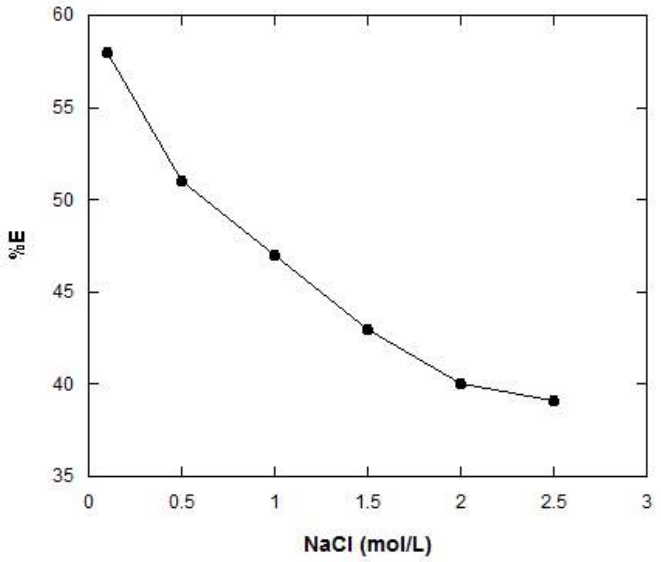

Figure 2. influence of NaCl concentration on extraction percentage by 0.25 M TBP in kerosene.

This work, mechanism of palladium chloride salt dissolution was assumed eq. 1 to eq.3:

$$PdCl_{2(s)} \rightarrow PdCl_{2(aq)} \qquad K_{sp} \cong 3 \times 10^{-12} \quad (1)$$

$$PdCl_{2(s)} + Cl^{-} \rightarrow PdCl_{3(aq)}^{-} \qquad K_{sp} \cong 0.6 \quad (2)$$

$$PdCl_{3(aq)}^{-} + Cl^{-} \rightarrow PdCl_{3(aq)}^{2-} \qquad K_{sp} \cong 36.2 \quad (3$$

As can be seen, $PdCl_2$ can't dissolve in distilled water, significantly. But palladium chloride solubility increased when low amount of hydrochloride acid was added to the system. In this case $PdCl_3^-$ is the main chloride complex. By adding further amount of acid, palladium chloride complexes are altered, again. Hence, $PdCl_3^-$ and $PdCl_4^{2-}$ are known as the main palladium chloride complexes.

UV-visible spectrophotometry can be used for palladium complexes detection. Biryukov and Shlenskaya conducted spectrophotometric studies of chloro palladate (II) at 25°C and *I* = 0.26–1.01 *m* in the UV regions. They reported UV absorption peaks occurring on 210 and 240 nm. In a later report (Elding, 1972), they were defined as $PdCl_3^-$ wave length. Boily and coworkers have carried out a comprehensive study on palladium chloride formation at different condition. They reported $PdCl_3^-$was formed in low HCl/Pd (II) ratio, but palladium complexes changes with HCl concentration increase, as UV peaks were formed at 220 280 nm. These wave lengths were known as $PdCl_4^{2-}$ Characteristic peaks.

3.4 Effect of Extractant Concentration on Pd Extraction

To make a better understanding of palladium extraction, extraction efficiency in different TBP concentration and constant HCl has been shown in Fig 3. At lower HCl concentration, TPB concentration increase leads to increasing causes to higher extraction percentage. But TBP does not effect on extraction percentage at higher HCl concentration.

$PdCl_3^-$, that forms low acid concentration, was extracted by TBP. But $PdCl_4^-$ couldn't be extracted by TBP, significantly. Hence, different extraction mechanisms should be assumed for palladium complexes.

3.5 Palladium Extraction Mechanism

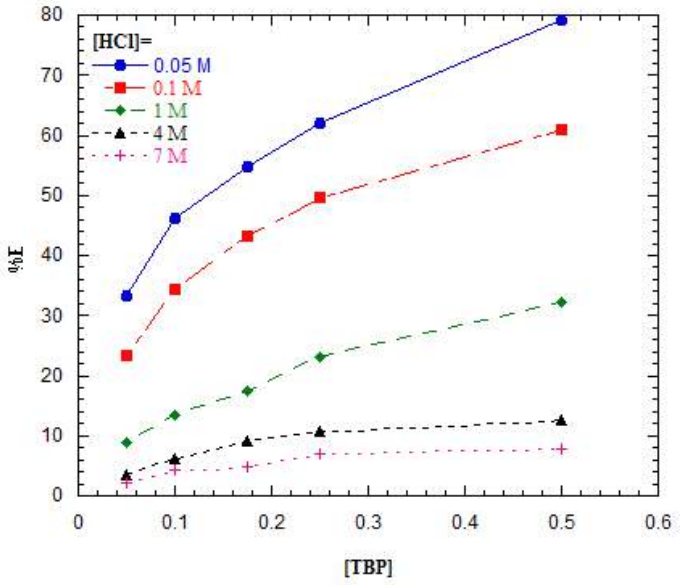

Figure 3. Effect of TBP concentration on Pd extraction percentage at constant HCl concentration and [Pd]=180 mg/l.

The extraction reaction of Pd via TBP can be represented by Eq.4:

$$[PdCl]_n^{n-2} + H^+ + H_2O + nTBP = PdCl_n^{2-n}.H.H_2OnTBP \quad (4)$$

and the corresponding equilibrium constant is:

$$K = \frac{\gamma_{HPdCl_n^{2-n}.TBP.H_2O}[HPdCl_n^m .nTBP.H_2O]_{org}}{\gamma_{H^+}[H^+]\gamma_{PdCl_n^{2-n}}[PdCl_n^m]\gamma_{TBP}^n[TBP]^n a_{H_2O}} \quad (5)$$

where brackets stand represent concentrations, and γ stands for activities coefficient. Since TBP concentration is varied in a specific range, γ_{TBP} may be considered constant. Beside, our observations indicate that pH variation in given HCl concentration is negligible, and γ_{H^+} is also constant. Furthermore, $PdCl_n^{2-n}$ is in dilute (trace) concentration, the concentrations of two palladium solutes in aqueous and organic phases are very low in which $\gamma_{PdCl_n^{2-n}}$ and $\gamma_{HPdCl_n^{2-n}.nTBP}$ can be constant (Henry behaviour). So, product of all the constant coefficients was represented as Q.

Regarding the definition of distribution coefficient ($D= [Au]_{org} / [Au]_{aq}$) as well asEq. 5, can be written as:

$$K=Q.D.[TBP]^n \quad (6)$$

Taking logarithm of Equation 6 leads to:

$$\log K=\log Q +\log D + n\log[TBP] \quad (7)$$

At constant temperature, K and Q don't change, so just logD and log TBP are variable this equation. The plot of log D *vs.* [TBP] yields a straight-line with slope ***n.*** Such plots are depicted in Fig 4; the slopes are estimated in the range 0.86 to 1. As be shown in Figure 3, an increase in HCl concentration decreases Pd extraction percentage. Hence, $PdCl_4^{2-}$ is not extracted by TBP. In the other hand, $PdCl_3^-$and TBP significantly react with each other. So, the extraction mechanism of was rewritten as eq. 7:

$$[PdCl]_3^- + H^+ + H_2O + TBP = PdCl_3^-.H.H_2O.TBP \quad (7)$$

3.6 Effect of Nitric Acid Concentration on Pd Extraction

Since the use of nitric acid in the chloride leaching of palladium bearing sources is a conventional issue, the effect of NaCl on the extraction efficiency of palladium was evaluated. As observed in Fig 5, HNO_3 have a negative effect on the extraction percentage of palladium. It seems that an increase of H^+ and NO_3^- ions solution leads to the extraction by TBP and the sit position on TBP molecules has decreased. Hence, the extraction percentage has been reduced.

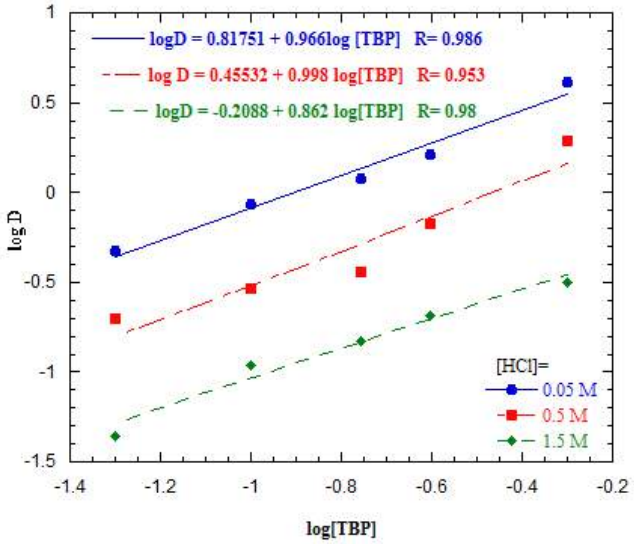

Figure 4. Variation logD of palladium vs. log[TBP] (Pd=180 mg/l).

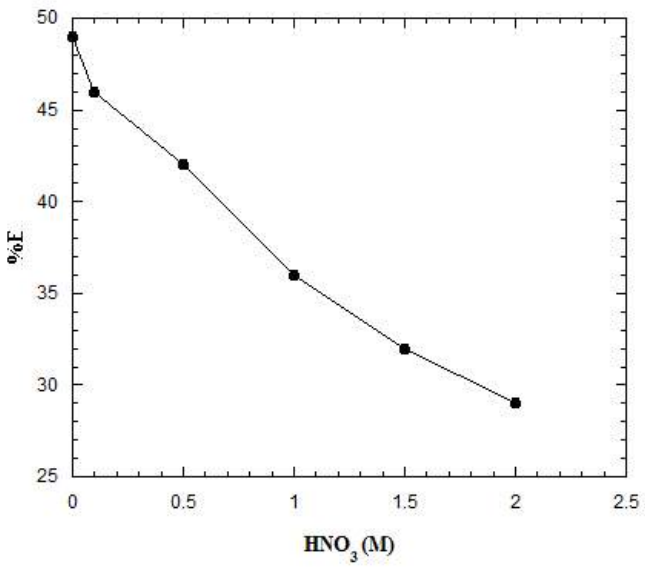

Figure 5. Effect of HNO_3concentration on Pd extraction percentage at 0.1 M HCl and [Pd]=180 mg/l.

4. CONCLUSION

1. Based on the obtained results, it was shown that the commercially available tributyl Phosphate (TBP) is an appropriate extractant for the recovery of palladium from low acidic solution.
2. Hydrochloride acid and chloride salts have negative effect on palladium extraction.

3. Presence of nitric acid decreases the Pd extraction percentage due to simultaneous extraction.
4. In the aqueous media stable complexes of palladium are $PdCl_3^-$ and $PdCl_4^{2-}$, that TBP could extract $PdCl_3^-$.
5. The organo-metallic complex of Au and TBP is proposed as $HPdC1_3L.H_2O$ where represents the extractant molecule.

ABSTRACT The kinetics of hematite decomposition during pellet induration was studied. Decomposition reaction of hematite results in a decrease in compression strength of pellets. Thermogravimetric analysis (TGA) was used to obtain conversion values. Initially, an integral estimation method was applied and then further analysis was carried out according to ASTM standard code for model-free studies. Evidence implied the uncertainty and ambiguity of non-isothermal data. While, using isoconversional kinetic model resulted in more reliable data. Mean values for activation energy and pre-exponential factor were found to be 515 kJ and 10^{18}, respectively. So it may be assumed that chemical reaction is the controlling step in the reaction progress and thus, high temperatures in the firing zone have to be avoided.

Keywords: Hematite decomposition, Non-isothermal kinetics, Model-free kinetics, Pellet induration

1 INTRODUCTION

1.1 Pelletizing

Production of pellet as a desirable feedstock for ironmaking furnaces has exceeded 400 Mt per year in 2012, accounting for almost 23% of the iron ore processed globally (UNCTAD, 2012).

The production of iron ore pellets involves two major steps, forming the “green” pellets in rotary disks or drums, followed by heat hardening them subsequently at elevated temperatures around 1200 to 1400 °C to increase the pellet strength (Barati, 2008). The oxidation of magnetite is one of the primary physico-chemical processes associated with the heat treatment of magnetite pellets. The hematite formed on roasting pellets is a very active chemical component. Sintering of the hematite grains increases the pellet strength. The end of oxidation is associated with uniform pellet structure (Meyer, 1980).

Knowing the oxidation kinetics of iron ore pellets at high temperatures is useful in assessing the completion of indurating at any time and in optimizing the thermal conditions within the zones of the induration machine (Ru-quan et al., 2013, Yurev and Spirin, 2011).

At 1250°C, hematite begins to dissolve in the slag melt. After the firing, the iron oxides should always be present as hematite in the indurated pellets. In high temperature firing, the hematite dissociates and secondary magnetite with a high Fe_2O_3 content is formed in the maghemite stage. The equilibrium reaction

$$2Fe_3O_4 + 1/2O_2 = 3\ Fe_2O_3 \quad (1)$$

shifts to the right up to a temperature of about 1400 °C. The equilibrium again shifts to the left causing once more the formation of Fe_3O_4 and thus, an impairment of the pellet quality. This hematite dissociation starts at lower temperatures if the pellets contain basic additives (Meyer, 1980, Xiao-hui et al., 2010).

1.2 Kinetic Studies

The thermal decomposition of inorganic solids refers to reactions of the type:

$$A(s) = B(s) + C(g) \quad (2)$$

The kinetics of the thermaldecomposition of solids is heterogeneous and as such it differs fromclassical homogenous kinetics in twoaspects.One is a non-uniform distribution ofreactive sites in the reactant A(s). The other ispossible interactions between A(s) and C(g) as well as between B(s)and C(g) that can control the kinetics of the decomposition of A(s)and formation of B(s) and C(g)(Vyazovkin et al., 2014).

Considering the diversity of thereaction situations, a number of physico-geometrical reaction models, f(a), have been derived for reactions under isothermalconditions. However, it is reported that first-order rate law is completely suitable to describe this type of reactions (House, 2007). During the non-isothermal period of an isothermalexperiment, the sample undergoes some transformations that are likely to affect theresults of the following kinetic analysis. This problem especially restricts the use of high temperatures in isothermal experiments(Vyazovkin and Wight, 1998).

For non-isothermal data, one can use the Coats and Redfern equation. This method is reported to be one of the most frequently used to process non-isothermal data(House, 2007). When it comes to choosing a unique kinetic triplet, statistical methods are used in themajority of cases. These methods are based on the idea that an adequate kinetictriplet should be the best statistical description of experimental data. In other words, the adequacy of kinetic description is judged by the goodness of model fitting. However, even if the statistical analysis is performed correctly, it has one serious flawthat the capability of a mathematical model to produce meaningful information cannot be characterized by the goodness of fit(Vyazovkin and Wight, 1998).

The model-free approach to kinetic analysis rests upon the isoconversionalprinciple, according to which the reaction rate at a constant extent of conversion is only a function of temperature. This principle is the basis of so-called isoconversional methods (Vyazovkin et al., 2011, Vyazovkin and Lesnikovich, 1988). ASTM E1641 standard code provides a method to determine kinetic parameters based on isoconversional analysis. This test method covers determination of Arrhenius activation energy and pre-exponentialfactor by thermogravimetry, based on the assumption that thedecomposition obeys first-order kinetics(ASTM, 2004).

2 EXPERIMENTAL PROCEDURE

High-grade hematite powder obtained from Merck KGaA was examined by X-ray diffraction, which proved that sample met the required purity levels (Figure 1).

Since mass loss caused by the decomposition reaction is small (Gaviria et al., 2007), it is necessary to assure that samples bear no volatiles. Therefore, samples were held at 110 °Cfor three hours. Mass loss during the decomposition in air was measured using a NETZSCH 409 PC/PG simultaneous thermogravimetric analysis device under three different heating rates. Initial weight of samples, m_0, was in range of 9 to 11 mg. Conversion fraction of hematite was calculated using Equation 3 with

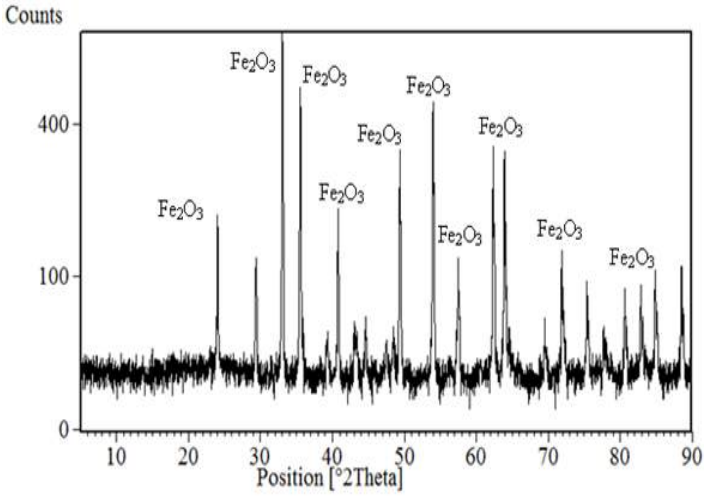

Figure1. XRD pattern of the hematite powder provided by Merck KGaA.

m_t as sample weight at time *t*, and m_∞ as the final weight (Piotrowski et al., 2007):

$$\alpha(t) = \frac{m_0 - m_t}{m_0 - m_\infty} \quad (3)$$

3 RESULTS AND DISCUSSION

The obtained results from thermogravimetry are shown in Figure 2. As it may be observed, decomposition in all tests completed before reaching 1425 °C. Using the aforementioned formula conversion fraction was calculated and illustrated in Fig. 3. Increase in heating rate that causes larger differences between sample and container temperature led to a delay in reaction progress, which is why conversion curves shifted to right.

3.1 Activation Energy

In Coats and Redfern method, higher values of n gave to larger activation energies. As it may be observed in Fig. 4, activation energy in air varies from 4000 to 8000 kJ. The obtained results imply a huge uncertainty and ambiguity to a point that is impossible to be neglected. The mean value is too high and clearly unreliable. However, isoconversional analysis resulted in much more uniform data and the mean value of activation energy was 515 kJ (Fig. 5). It seems more reasonable to take isoconversional results into account and conclude that controlling step is chemical reaction. Thereby, reaction progress is highly affected by temperature.

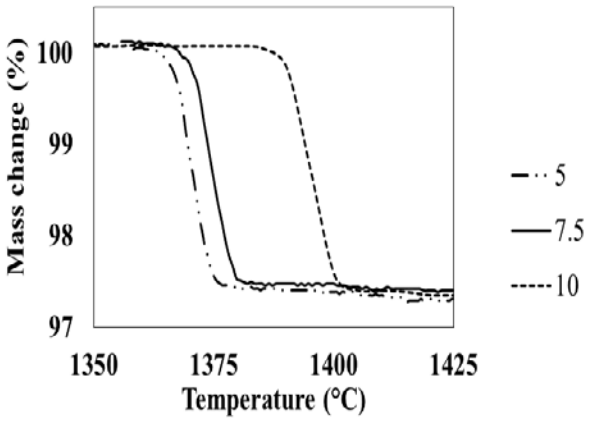

Figure 2. Loss of mass in hematite during different heating rates.

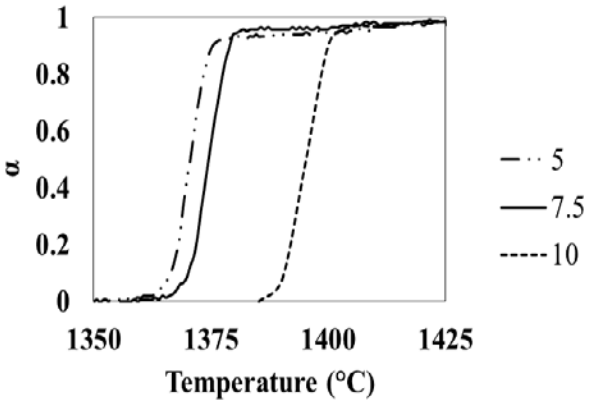

Figure 3. Conversion values recalculated by means of Equation 3.

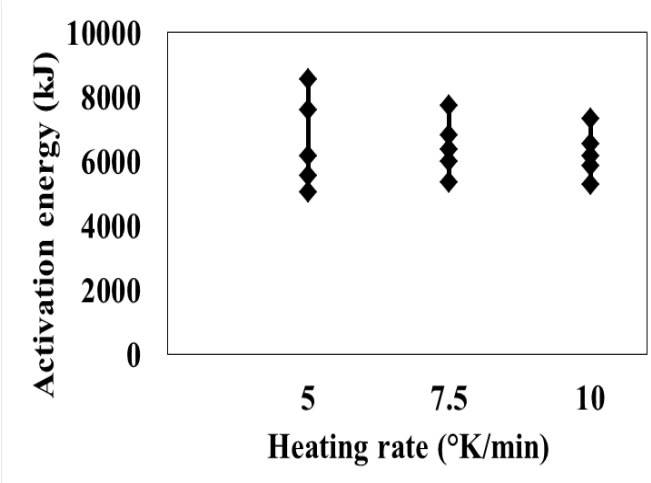

Figure 4. Obtained activation energy values using Coats and Redfern method.

3.2 Pre-Exponential Factor

Figure 6 shows that pre-exponential factor data obtained by Coats and Redfern method are ambiguous and may not be used to develop any exact explanation. Yet again, isoconversional analysis led to a uniform and acceptable results; so that, the mean value for pre-exponential factor may be considered as 10^{18} (Figure 7).

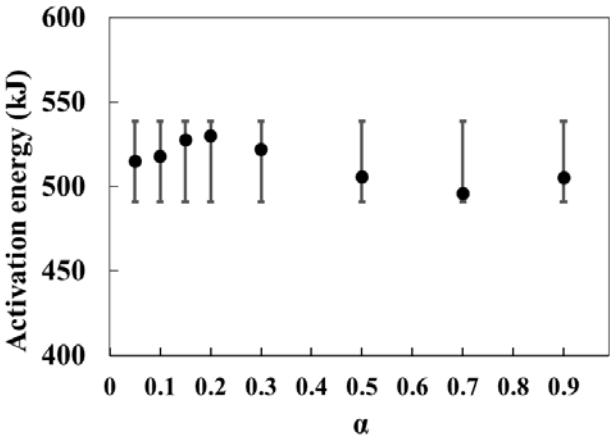

Figure 5. Obtained activation energy values using ASTM E1641.

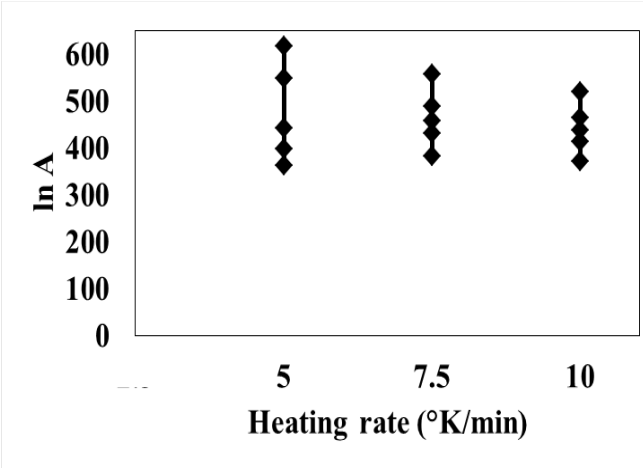

Figure 6. Obtained pre-exponential factor values using Coats and Redfern method.

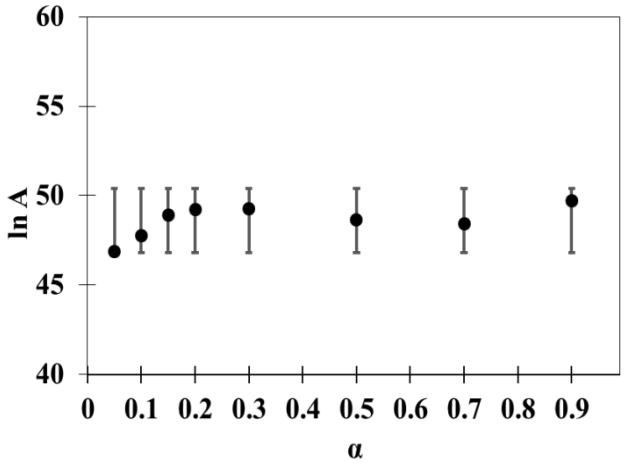

Figure 7. Obtained pre-exponential factor values using ASTM E1641.

4 CONCLUSION

In the present work, hematite decomposition in air was investigated using thermogravimetric analysis. Two different methods were applied to calculate kinetic parameters of the reaction. It was revealed that reaction temperature increased with increase in heating rates. Isoconversional method resulted in more uniform data in comparison to the Coats and Redfern method, which is a recommendedmethod for processing non-isothermal data. According to the isoconversional results, mean values for activation energy and pre-exponential factor was found to be 565 kJ and 10, respectively. Rather high value of activation energy implies on that the chemical reaction being the controlling step and thus, high temperatures must be avoided in order to prevent secondary magnetite formation.

ABSTRACT Mean residence time (MRT) in a flotation cell is one of the most important parameters especially in terms of designing aspect and also as a key factor on recovery. The objective of determining MRT was to evaluate the effectiveness of this factor on industrial flotation cells as well as its role on 8% and 4% reduction on rougher and final flotation cells recoveries at Sarcheshmeh concentrator, respectively. Therefore, this paper was aimed to determine it by taking advantage of salt tracer. Results showed that, MRT in rougher cells at feed rate of 225 t/h and 280 t/h were 11.79 and 10.00 minutes, respectively. Also, the results indicated that the mixing condition of slurry inside the rougher cells follows N-Mixer model. RTD curves along with size-by-size copper recovery analysis of particles in different cells pointed out that, decreased residence time around 15% was the major cause of the lower recovery.

Keywords: Flotation cell, Mean residence time (MRT), N-Mixer model, copper recovery

1 INTRODUCTION

To simulate the kinetic behavior of a continuous flotation process and design a flotation cell, it is required that the mixing conditions of material be properly described (Massinaeia, 2007). Analysis of residence time distribution (RTD) offers a way to describe the mixing conditions (Lelinski, 2002). A model describing the degree of mixing of the particles in the pulp phase is essential for designing a flotation cell and this can be achieved by carrying out residence time distribution (RTD) studies using solid or liquid tracers.

Typically, RTD measurement in industrial cells involves in discharging a specific tracer inside the feed main stream and continuously monitoring the response at the outlet stream in terms of concentration or conductivity of fluid. If the tracer is injected as a pulse, then the fraction of tracer that remains in the system at any time can be described by the distribution function mathematically. The resulting patterns can be considered in connection with two ideal types: plug flow and perfect mixing (Levenspiel, 1972). Plug flow is equivalent to a batch processing system, whereas, the perfect mixing model can be considered a special case of the population balance model. But real equipment always deviates from these ideals (Kelly, 1982).

Woodburn and Loveday showed that a considerable simplification was obtained by assuming that the floatability distribution may be fitted by a Gamma function, which also represents a good approximation to describe the flotation rate constant in continuous operations (Woodburn, 1965). Measurement of RTD by the radioactive tracer technique is adaptable to different kind of equipment (Blet, 1999). A measurement was performed with the purpose of determining MRT in industrial

rougher column flotation cell by means of a liquid radioactive tracer (Massinaeia, 2007).

In this research, as flotation rougher feed rate in Sarcheshmeh copper concentration plant is increased from 225 to 280 tph in average, rougher recovery decreases in amount of 8% in comparison of criteria design. Therefore, this study is aimed to quantify the RTD in two levels, low (225 t/h) and high (280 t/h)), so that specify the role of MRT of rougher cells on 8% and 2% reducing of copper recovery of rougher cells and final copper recovery, respectively.

1.1 Sarcheshmeh Flotation Circuit

Sarcheshmeh deposit is one of the largest copper ore body in the world that it contains 1 billion tons of ore averaging 0.90% copper and 0.03% molybdenum. It is located in the southeast of Iran processing 47000 t/d of ore since 1982. The mine produces 100000 tons of copper and 2200 tons of molybdenite concentrate per year. After three stages of crushing, the ore with 80% passing size of 12.7 mm was fed to eight parallel ball mills in closed circuit with hydrocyclones to produce a product 70% finer than 75 microns. Rougher flotation cells are comprised of eight rows, divided into two sections. Each section consists of four rows of flotation cells. Each row, in turn, consists of fourteen 8.5 m^3, stepped 4-5-5 cells. Totally, a rougher bank is divided into three units of 4, 5, and 5 cells. The combined rougher flotation circuits are designed to receive ground ore at a rate of 43360 dry metric tons per day (Wunder 1979).

A schematic diagram of flotation circuit of Sarcheshmeh copper concentrator is presented in Figure 1. Rougher tailing comprises the main component of the plant final tailings. On the other side, concentrate with an average grade of 31% copper (mainly Chalcocite and Chalcopyrite minerals) obtains after cleaning and re-cleaning stages.

2 MATERIAL AND METHODS

2.1 Performance Evaluation of Rougher Cells

In flotation circuits where rougher tailing is the main tailing stream, overall recovery of the plant is mainly dependent on the rougher tailing grade. In order to prevent losses of copper values through this stream, it is essential to keep the grade of the tailings as low as possible.

Four times sampling performed from 7 different streams. A sampling period of 3 hours was chosen in which every 30 minutes, one sampling increment was taken. Before and during sampling, the circuit was checked for the steady state operation. The samples were taken from flotation circuit were dried, weighed and sieved. All samples were wet screened with a 400 mesh screen. The sub sieve analysis was carried out using the cyclosizer developed by CSIRO. Particle size distribution of each sample was determined. Then, each size fraction was assayed for copper element. Flow rates of each stream were calculated and balanced by using copper assays of the head samples. The data was mass balanced using mass balancing software (Movazen 2.1) (Yarahmadi, 1998).

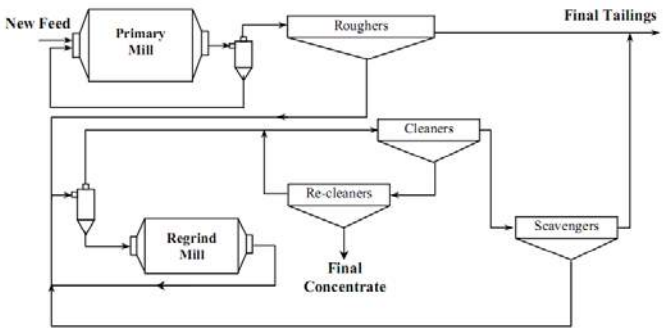

Figure 1. Sarcheshmeh copper concentration plant circuit.

2.2 Residence Time Distribution Measurement

After careful evaluation of possible tracers, sodium chloride was selected for RTD measurements in the present study. It should be noted that, each rougher cell has volume

of 8.5 m^3, which it is run in open circuit. Two sampling in practical manner were conducted on the rougher flotation cells to determine the mean residence time of slurry. In each experiment it was applied around 100 kg of sodium chloride which was dumped into the inlet stream of hydrocyclone overflow in one row of rougher circuit (row#5) almost instantaneously (within 5s) and the response was monitored in the rougher tailing at regular time intervals. Timed samples were collected manually into 500 ml plastic bottles over the duration of 60 minutes for conductivity analysis. It should be mentioned that the mill was allowed to stabilize at a feed flow rate and specific solid concentrate for about 2 hours before and during sampling time. A summary of the experimental program time is presented in Table 1. Also operating variables of rougher flotation cells during 2 series RTD measurements are listed in Table 2.

Table1. Experimental time layout for industrial sampling of rougher tailing stream.

Time (min)	10	20	30	40	50	60
Sampling interval time	0.25	0.50	1	1	2	2
Number of samples	40	20	10	10	5	5

Table 2. Operating variables of rougher floatation cells during RTD measurement.

Operational	Value	Units
Dry feed tonnages	225, 280	Metric ton/hour
Particle Size	65	%< 200 mesh
% Solids	30, 32	Wt %
pH	11.28	

After filtering, 90 samples in each MRT measurement, conductivity-meter model-712 was used for measuring conductivity of each sample. To be sure that conductivity alteration is only by the cause of added salt, various samples were collected from rougher feed and analyzed by conductivity-meter (Table. 3).

The resultant conductivity measurements of all samples were applied as inputs of RTDWEN software to model slurry mixing behaviors and determine the mean residence times according to related feed flow rates. The measured residence times were obtained from the RTD data using Eq. 1.

$$\tau = \int_0^\infty tE(t)dt \quad (1)$$

Where *E(t)* is distribution function and *t* is time (second).

The model parameters were optimized by minimizing the error between experimental tracer response data and model predictions using different software such as MATLAB, Excel and RTDWEN (Javadi, 1997). Based on the optimum values of the model parameters, eventually the mean residence time of slurry evaluated.

Table 3. Conductivity results of samples from rougher feed in different times of sampling.

Time (min)	Conductivity (ms)
0	2.92
3	2.91
5	2.86
10	2.75
20	2.80
30	2.83
40	2.92
50	2.88
60	2.78

3 RESULT AND DISCUSSION

3.1 The Importance of Mrt in Sarcheshmeh Rougher Flotation Cells

The comparison of the measured mean residence time with its expected value, as well as analysis of the shape of the RTD curve, give the most useful and valid information about the mixing properties in the cell. In a continuous flotation process and in this case the copper recovery can be described by the general Eq. 2 (Yianatos, 2006):

$$R = R_\infty \int_0^\infty \int_0^\infty (1 - e^{-kt}) F(k)E(t)dkdt \quad (2)$$

Where R_∞ represents the maximum flotation recovery at infinitive time. The

term *(1-exp (-kt))* represents copper recovery of a first order process with invariant kinetic constant *k*, as a time function. *F(k)* is the kinetic constant distribution function for mineral species with different flotation rates, and *E(t)* is the residence time distribution function for continuous processes with different mixing characteristics.

According to Eq. 2, the copper recovery depends on flotation rate of floatable minerals as well as the mixing regime in collection zone, and the actual mean residence time which is related to the effective pulp volume in flotation cell.

Based on Agar theory the rougher split should be made at the flotation time where separation efficiency is maximized (Agar 1980). At maximum separation efficiency, the grade of concentrate produced is equal to the flotation feed (Eq. 3).

$$\frac{dSE}{dt} = \frac{100m}{f(m-f)}\left[(c-f)\frac{dC}{dt} + C\frac{dc}{dt}\right] \quad (3)$$

Where *f* and *c* are grades of valuable mineral in feed and concentrate streams, respectively and *m* is the maximum grade in terms of chemical composition of that mineral. However, the big difference can be seen in our case. Whereas, four stages of sampling assay analysis show that the average copper grade of the concentrate of final unit (cells 11-14) is 3.24, while copper grade in rougher feed is 0.71. As a result of this, the reduced MRT in rougher cells can be played a significant role on copper recovery in the most of fractional sizes.

Recovery of all size fractions versus particle size depicted in Figure 2. It reveals that reducing degree of liberation and MRT for +74 microns particles caused to dramatically copper recovery diminishing in third unit of rougher flotation cells bank (cells 10-14).

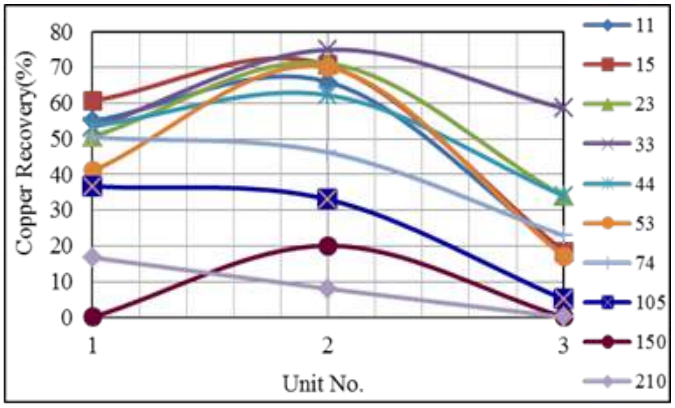

Figure 2. The size-by-size recovery at various units of the rougher bank.

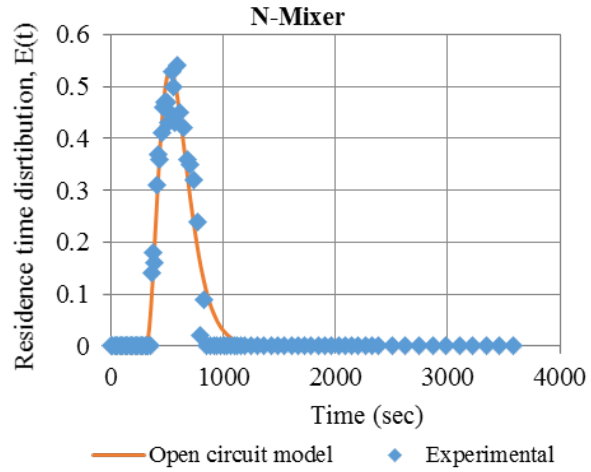
3.2 Modeling of Mixing Condition in 280 Tph

The measured mean residence time is calculated from the RTD data using the following formula (Eq. 4):

$$\tau = \frac{\int_0^\infty tC_{(t)}\Delta t_i dt}{\int_0^\infty C_{(t)}\Delta t_i dt} \quad (4)$$

Where τ is the experimental mean residence time and $C_{(t)}$ and *t* are tracer intensity at time t and the measured time, respectively. In fact, to correct for background noise, the natural intensity of flotation slurry (before injection) is subtracted from the intensity measured after the injection of the tracer. Slurry RTD curves for tailing are presented in Figure 3 for N-mixer and Weller models. Data analysis and modeling are conducted using RTDWEN software (Javadi, 1997). The obtained results show that N-mixer model is the best fitted model to RTD data of tailing stream than large and small tank-in-series (Weller model). It should be noted that, Weller model consists of one plug-flow mixing cell, one large perfect mixer and two small perfect mixers. While, N-mixer model comprises of N-perfect mixers in series.



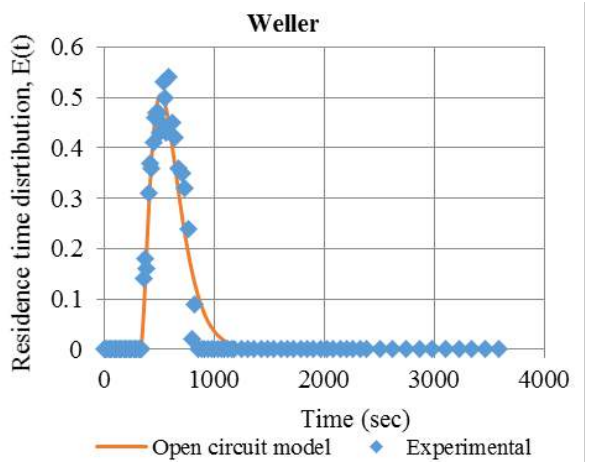


Figure 3. Residence-time distribution function for the slurry in a continuous rougher bank (14 cells) at 280 t/h by Weller model and N-Mixer model.

The comparison of measured with expected residence time, as well as analysis of the shape of RTD curves, give the most useful and valid information about the mixing properties in the cell. The quality of the fit is judged by choosing the model parameters to minimize the sum of squared errors (SSE) which is driven by the differences between the experimental and models values. Mathematically, this is expressed, as minimizing the function Z:

$$Z = \sum_{i=1}^{n} [F_m(\theta_i) - F_e(\theta_i)]^2 \qquad (5)$$

Where $F_m(\theta)$ and $F_e(\theta)$ are the model and experimental RTD results, respectively.

It can be seen that some of the tracer leaves instantaneously. Indeed, it was found that the RTD function at 280t/h can be properly represented by a model of N-perfect mixers in series with pure delay, according to the normalized distribution function. Equation 6 allows the fitting of non-integer values of N.

$$E(t) = RTD = \frac{t^{N-1}\exp(\frac{-t}{(\frac{\tau}{N})})}{(\frac{\tau}{N})^N \Gamma(N)} = (\frac{1}{\tau^N})\frac{t^{N-1}\exp(\frac{-t}{N})}{(N-1)!} \qquad (6)$$

In the case of rougher banks the best fit is obtained for an N value approximately equals to 4.

3.3 Modeling of Mixing Condition in 225 tph

The most important outcome from RTD experiments is the measured mean residence time. Figure 4 shows the RTD function in rougher bank (14 cells) at 225 t/h, where the mean residence time was 10 and 10.14 minutes by N-Mixer and Weller models, respectively. Figures 3 and 4 indicate that, there are dead volumes and short-circuiting in rougher cells. A good model should respect the parsimony principle (low number of parameters), showing a good fitting with experimental data. A number of tanks-in-series closer to 6 gave the best fitting to describe the liquid RTD in all flotation banks. Taking into consideration that the necessity of the flow through rotor, the slurry pumping rate together with the highest achievable mean residence time in a flotation cells are the best possible indication of cell performance. Figure 4 shows the residence time distribution of slurry at 225 tph.

Table 4 shows a summary of the mean residence time and other calculated parameters which are estimated from RTD measurements in the rougher flotation banks. According to SSE criteria, in two cases (225 tph and 280 tph), N-Mixer model describes the mixing condition much better than Weller model. Then, the most accurate model for rougher flotation cells in Sarcheshmeh concentrator is N-perfect mixers in series.

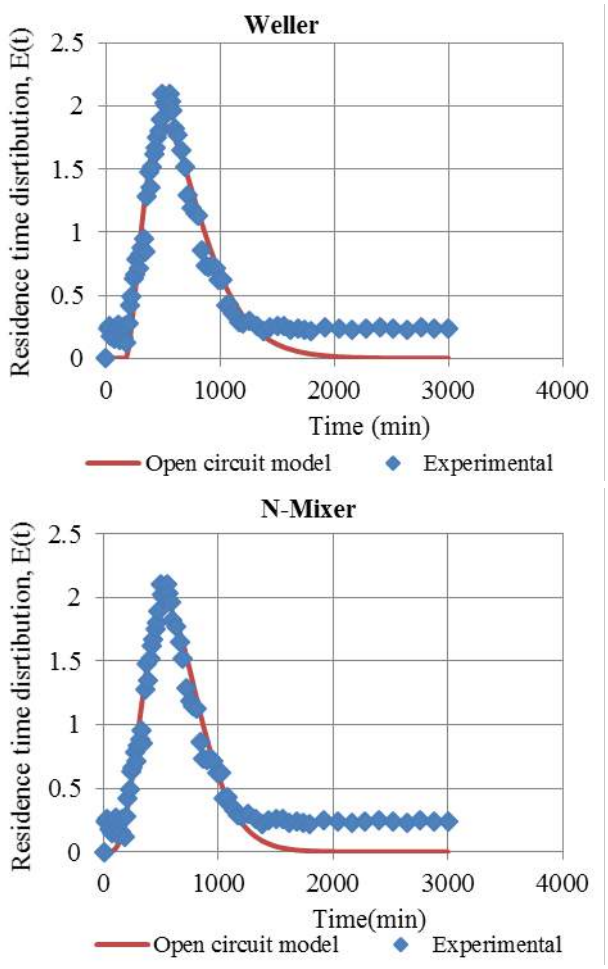

Figure 4. Residence-time distributions function for the slurry in a continuous rougher bank (14 cells) at 225t/h by Weller model and N-Mixer model.

Table 4. Statistical components in comparison of N perfect mixers model and Weller model.

Model	Term	280 tph	225 tph
N-Mixer	τ_{pf}	4.96	0.02
	τ_{av}	10	11.79
	N	4	6
	SSE	0.096	1.892
	σ_r	0.16	0.167
Weller	τ_{pf}	5.47	2.81
	τ_s	1.56	2.40
	τ_1	10.1	4.06
	τ_{av}	10.14	11.67
	SSE	0.109	2.537
	σ_r	0.071	0.206

The mean residence time of pulp in 280 t/h is 15% lower than its amount in 225t/h. The difference can be explained due to solids segregation by gravity, particularly for coarse particle sizes (>100-200 microns). Moreover, it reflects mass transfer phenomenon and the relationship between the vessel volume (V) and volumetric federate (Q). The variance (σ_r) reflects the degree of mixing which occurs within the vessel. Thereupon, for N-mixer model at 280 tph, it can be seen that relative variance is closer to perfect mixing condition compared with Weller model.

Mean residence time and relative variance are estimated from RTD data, which are calculated with three software in order to reduce error (Tab. 5).

Table 5. Software outputs in relation of MRT measurements.

Applied software	**τ_{av} (min) in 280 tph**	**τ_{av} (min) in 225 tph**
Excel	10.41	11.35
MATLAB 7.10.0	10.18	11.23
RTDWEN	10.00	11.79

4 CONCLUSION

In summary, measurement of residence time distribution in rougher flotation cells at Sarcheshmeh concentrator was performed by sodium chloride as a tracer. The results showed that the mean copper grade of third unit in rougher cells is much larger than feed. The mixing condition in industrial rougher cells using residence time data was modeled. Data analysis showed that N perfect mixer in series was the best model to present the flow pattern of liquid transferred to tailing. In addition, it is found that increase in the aeration rate resulted in a decrease in mean residence time of liquid and increase in mixing degree, which is reflected in relative variance and dispersion number. MRT in rougher cells at feed rate of 225 and 280 tph were 11.79 and 10 minutes, respectively.

ACKNOWLEDGMENT

The author would like to thanks National Iranian Copper Industries Company (N.I.C.I.Co.) for supporting this research. Special appreciation is also extended to the operating, maintenance, metallurgy and R&D personnel for their continued help.

Optimal Mine Extraction Sequencing Using Meta-heuristics

Y. A. Sari and M. Kumral
McGill University, Department of Mining and Materials Engineering,Montreal, Canada

ABSTRACT Mine production scheduling is an interconnected decision problem of block sequencing, ore-waste destination classification and production rates. We propose to solve this problem for poly-metallic (by using equivalent grades), multiple destination plans by combining ranked positional weight algorithm and Simulated Annealing approach. The success of the proposed approach is demonstrated in a case study.

Keywords: Meta-heuristics, Mine production scheduling, Ranked positional weight algorithm, Simulated Annealing approach.

1 INTRODUCTION

Mine production scheduling consists of three sub-problems that are block sequencing, ore-waste destination classification and production rates. These decisions result in a mine plan, in which mine life is usually divided into years and each unit is called a period.

Block sequencing problem is to assign a time of extraction to each block. In other words, decisions are made in such a way that each block is assigned to a period of extraction otherwise not included in the mine plan.

Ore-waste destination classification problem, also can be called ore-waste discrimination problem in cases with only one waste destination and one process destination, is the problem of distinguishing the destinations of each block to one of the waste material destinations or process destinations.

Lastly, production rates sub-problem makes the decision of the amount of material that is sent to each destination at each period. When the production rates are known, destination capacities are adjusted accordingly thus the costs are calculated as they are influenced by economies of scale.

To solve the mine production scheduling problem, multiple approaches have been taken. These approaches can be mainly classified under three clusters; iterative approaches, ultimate pit limit based algorithms and exact methods.

Iterative approaches are heuristic methods that give an insight about the plan. Examples for these approaches include moving cone method (Carlson et al.), Korobov algorithm (David et al.), and ranked positional weight method (Gershon). Although these approaches are fast and practical, they do not yield optimal results. They are suited very well as a reference, starting point but fail to produce the most profitable plan.

Ultimate pit limit based algorithms include graph theory and maximum flow approaches. The commercial software used in mining industry is usually based on these approaches because of fast processing time and easy formulation. Notably, graph theory based Lerchs-Grossmann is the most frequently used approach in commercial software. Although these methods yield the optimal pit limit, they do not have capacity constraints thus required to be parameterized. Dagdelen and Johnson (1986) attempted to solve this problem by incorporating the Lagrangean multiplier. The selection of Lagrengean multiplier is a significant problem and the viability of sequence generated depends on this selection. This requirement of parametrization lifts the optimality of these methods.

Exact optimization methods, on the other hand, guarantee an optimal solution. However, given the number of parameters and constraints in the open pit production scheduling problem, even for the medium sized data, the problem cannot be solved via exact methods because exact optimization

methods require exponential endeavour (Rothlauf; 2011). Linear, integer, mixed integer linear Programming were proposed to solve block sequencing problem. These approaches have become popular techniques because of swiftly expanding computer and software technologies (Johnson, 1968, Gershon, 1983, Knowles, 1999, Manabe et al, 2004, Caccetta & Hill, 2003).

Roman (1973) and Dowd and Elvan (1987) used dynamic programming for various elements of mine production scheduling. Dynamic programming is a strong method for sequential decision making problem. In this approach, the block sequencing problem is divided into simpler sub-problems (are called stages). Each stage is optimized. Bellmann (1956) developed the method. Bellman's Principle of Optimality prescribes, at a certain time, the value of a decision problem depends on the pay-off initial choices and the value of the remaining decision problem. Koeninsberg (1982) used dynamic programming for three-dimensional case. Later, Wright and Weiss (1989) modified Koeninsberg algorithm.

Metaheuristics such as simulated annealing (Kumral, 2012), genetic algorithms (Denby and Schofield, 1997) and ant colonies have been also proposed to solve the problem.

In this paper, we are taking simulated annealing approach one step forward to solve poly-metallic, multiple process destinations and multiple rock types mine production scheduling problem using the equivalent grade factors.

2 METHOD

Cut-off grades for multiple destinations are calculated according to Equation 1. In multi-metallic cases, first, the cut-off grades are calculated according to the primary metal.

$$cut-off_{d} = \frac{\text{processing cost}_{d} - \text{processing cost}_{d-1}}{(\text{recovery}_{d} - \text{recovery}_{d-1}) * \text{price}} \quad (1)$$

where d is the number of destinations.

Calculation of the multi-metallic cut-off grades is done by taking the approach of Osanloo and Ataei (2003). Following this approach (1) Metal 1 is divided into a pre-set number of intervals by taking zero grade as minimum and maximum grade of Metal 1 as maximum. (2) For each metal, average grades within these intervals is calculated. (3) Separately, equivalent grade factors (F_{eq}) are calculated for each metal to metal 1 according to Equation 2. (4) A total equivalent grade of Metal 1 is obtained by adding all average grades multiplied by their F_{eq}. (5) Cut-off grades of each destination are calculated for Metal 1, following Equation 1. From the equivalent Metal 1 reference formed in Step 4, the interval the cut-off corresponds to is found and interpolation is used to determine the equivalent cut-off grade in the initial interval that is formed in Step 1. This is repeated for each destination cut-off. (6) From then on, only equivalent cut-off grades are used and other metal grades are disregarded.

$$F_{eq} = \frac{price_{i} \times recovery_{i}}{price_{1} \times recovery_{1}} \quad (2)$$

Using this factor an equivalent cut-off grade is calculated. Equivalent cut-off grade is applied to all blocks to destine blocks processing routes, which generate maximum profit. After this, a quick sub-optimal result was generated to use as an initial input to simulated annealing. Moving cones, Korobov or positional weight is ideal approaches to generated reasonable solutions in quick time.

In this model, the decision variable is not only extraction period but also block destination. In other words, ore – waste discrimination is managed by the optimization process.

$$Max \quad f(x) = \sum_{i=1}^{T} \sum_{j=1}^{N} \sum_{d=1}^{D} V_{ijd} * x_{ijd}$$

- Access constraint

$$\sum_{d=1}^{D} x_{ild} \geq \sum_{d=1}^{D} x_{ijd} \quad i = 1,...,T; \quad j = 1,...,N \text{ and } k \in L_{j}$$

- Destination capacity constraint

$$\sum_{j=1}^{N} f_j x_{ijd} - Upp_d \le 0$$

$$i = 1,...,T \quad and \quad d = 2,...,D$$

$$\sum_{j=1}^{N} f_j x_{ijd} - Low_d \ge 0$$

$$i = 1,...,T \quad and \quad d = 2,...,D$$

- Process control constraint

$$\sum_{j=1}^{N} c_j \ f_j x_{ijd} \le H_{du} \sum_{j=1}^{N} f_j x_{ijd} \quad i = 1,...,T$$

$$and \quad d = 2,...,D$$

$$\sum_{j=1}^{N} c_j \ f_j x_{ijd} \ge H_{dl} \sum_{j=1}^{N} f_j x_{ijd} \quad i = 1,...,T$$

$$and \quad d = 2,...,D$$

- Block conservation constraint

$$\sum_{i=1}^{T} \sum_{d=1}^{D} x_{ijd} \le 1 \quad j = 1,...,N$$

- Binary constraint

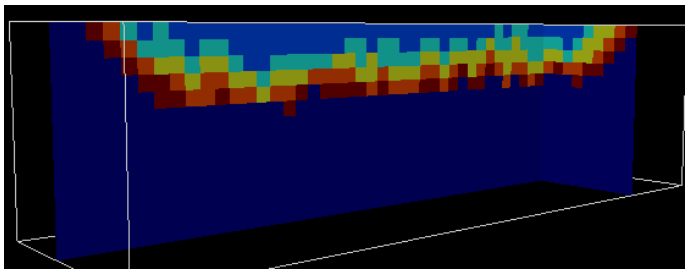
$$x_{ijd} \in \{0,1\} \quad i = 1,...,T, \ j = 1,...,N$$

$$and \quad d = 1,...,D$$

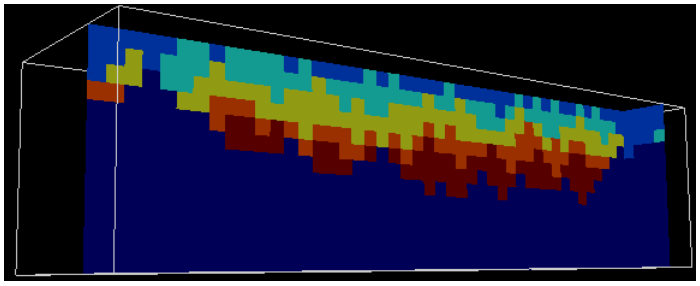
where D is the number of destinations that should be at least two (waste dump and one processing destination), V_{ijd} is net present value of block (NPV) j in period i in destination d, f_j is tonnage of block j and x_{ijd} is binary variable (if block j is sent to destination d in period i, the variable is 1; otherwise, it is zero).

3 CASE STUDY

A case study was carried out to evaluate performance of the proposed approach. Orebody was simulated through Sequential Gaussian co-simulation for gold and silver drill-hole data. Average values of simulations were used the input the proposed approach. In this case study, there were 5 time periods. Figure 1 provides two cross-sections of the plan generated. As can be seen from the figure, iterative approach produced a relatively small pit. However, the annealing expanded pit such that net present value of project was increased. In this case study, there are two mineral processing options: low and high grade processing. Ore prices were \$38/gr and \$0.75/gr for gold and silver, respectively.



(a)



(b)

Figure 1. A cross-section of plan generated by (a) sub-optimal approach and (b) simulated annealing

Slope angles are 50^0 at all directions. Mineral processing costs are \$25/ton and \$35/ton, respectively. Mining costs are \$5 and \$10/ton for low and high grade processing, respectively. Gold recoveries are 70% and 90%, and silver recoveries 50% and 75%, respectively. Mining capacity is 350 ton/period, mineral processing capacities are 300 ton/period and 250 ton/period, respectively. The number of iteration at every temperature level was 4,000. If there are no improvement in net present value at three consecutive temperature levels, program stops and record best solution up to now as optimal result. This was stopping criterion used in the annealing approach. In terms of running time, iterative approach generated an output 30 seconds. This is very fast output that suits annealing logic. This was submitted the annealing that produces an output in 85 minutes. Given that there are a large number of decision variables and constraints, this is a quite reasonable time.

The project NPV was calculated as $1,356,309,983 for five years. For a poly-metallic mineral deposit, this is a quite profitable result.

4 CONCLUSIONS AND FUTURE WORK

In this paper a new block sequencing approach was proposed. The approach is a combination of an iterative technique and simulated annealing. Iterative approach produced a feasible result quickly and submitted to annealing module. Main problem associated with the annealing is on optimality. Even though the annealing finds optimal solution with sufficient number operations, it is difficult to find what sufficient number is. At the moment, using different random seeds, we observe the evolution of the approach in terms of the convergence to determine the number of iterations required. The case study conducted produced very promising results. In the future, the focus will be searching on optimal annealing parameters such as temperature decrement, new configuration mechanisms, optimal number of iteration at every temperature level and stopping criteria.

Physical And Numerical Modeling Behavior Of Two Piles Under Horizontal Loading Cyclic

M. Akchiche, A. Rouag, K. Djedjig
University of Sciences and Technology Houari Boumediene, FGC, Algeria

ABSTRACT Piling is commonly used as foundation system in all countries. Design standards remain quite different, for school and cultural reasons, but also due to the different types of soils encountered in each country.

As part of the project of the great Mosque, numerical modeling using the CESAR-LCPC software was performed. It provided an opportunity to compare calculation results with test horizontal cyclic loading model on real stake made on construction site results. This paper presents a comparison between the three approaches in terms of accumulation of displacements

Keywords: Piling, physical modelling, numerical modelling

1 INTRODUCTION

When designing piles in cohesive soil and grained soil, one of the major concerns is the degradation of the lateral capacity under cyclic loading.

An early study on this topic was carried out by Matlock (1970), who reported two field tests on laterally loaded piles and proposed p-y curves for the pile-clay interaction under both static and cyclic loadings. The recommendations were adopted in the code of the American Petroleum Institute API (2002) and are widely applied. Other contributions in this field include the studies conducted by Hamilton & Murff (1995), Vucetic & al. (1988), Lesny, K. & Hinz, P. (2007), Peng, & al (2006), Hajialilue-Bonab & al. (2011) Ismael (2010) and Su (2012). The results of these studies indicate that the cyclic degradation of clays and the degradation of pile-clay interaction under lateral cyclic loading are progressive and that the degree of the degradation depends on factors such as the type of clay, overconsolidation ratio, number of loading cycles, loading frequency, and the cyclic displacement level or cyclic loading level.

On the other side, research testing of full-sized piles in sand under both static and cyclic loading conditions are given by "Reese & Impe" (2001) Reese & al. (1974) and O'Neill & Murchison (1983), Leblanc & al (2010)

However, Analysis of settlement is based on solutions that involve the stress-strain behavior of linear ground. However, soils behave nonlinearly. Therefore, we will evaluate in this section the results of two isolated settlement of piles, carried out in two different soil types with non-linear soil models in the absence of interface elements. Templates are created and analyzed using programs based on finite element method CESAR-LCPC. The results of the finite element model are compared with experimental results and analytical studies.

2 PROJECT BACKGROUND

An experimental study was carried out on the site of the great yard of the mosque in Algiers. The minaret has a total height of 264.05 m and a base of 26.86m aside and based on a system of deep foundations (Figure 1).

The horizontal static loading tests were conducted on two piles with diameters of 1 m and a test length of 20 m. These profiles across different geotechnical to PH1 it crosses the clays, marls and sands while PH2 powder crosses the sands (Figure 2). These piles were subjected to a series of horizontal axial cyclic loading. The cyclic tests were carried out to study the controlled accumulation of movement and load transfer along the pile during and after cycle strength.

3 PILE INSTALLATION AND INSTRUMENTATION

3.1 Description of the Instrumentation of the Pile

For horizontal loading tests pile driver, it was used as a reaction system a reaction piles torque. The reacti on piles (PR1-1, PR1-2 for PH-1 and PR2-1, PR2-2 for PH-2) are 45.5 m deep (figure.3 and 4). For piles of PH-1 and PH-2 trial, 20 m, the pile diameter is 1.0 m. For measuring deformations of piles testing PH1 and PH2 during the load test, it was installed on the reinforcement cages of each pile 20 strain gauges to vibrating strings arranged in sections 5 to 90 °. The test load will be applied to 50 cm above the working platform (figure 3).

The execution of the test includes several loading cycle, each with first attained the limit load calculation. During the first loading cycle, each increment will be maintained 20 minutes, in the discharge level and in all subsequent cycles loads shall be maintained for 10 minutes.

For measurements of lateral displacements are arranged two reference beams (IPE270) longitudinally with respect to the test, and the bars support eight centesimal comparators, fo ur on the pile of test and four on the reaction. Two of its comparators will report horizontal displacements of the metal plates connected to the baseboard, the other two will be positioned vertically on the front and back of the plinth to raise its head in rotation of the pile.

At the end of achieving horizontal loading tests, it was prepared:

• Pushed Equipment consists of:

- 3 hydraulic cylinders (figure. 5)
- 1 hydraulic unit

• The reaction structure (figure.4) à consisting of:
- 2 piles reactions
- 1 main beam load distribution
• For the measurement of the load during the test, it was installed between the hydraulic cylinders and the nut of the head of the pile, three load cells. The cells were attached to a panel of centralization so that they can be rapidly measured during the conduct of the trial.

3.2 Load Program

For the realization of the test loading, a loading program loops and unloading was carried out and apply on several levels.

In the charging program, it has been provided first 9 loading and unloading cycles (Table 1). The load amplitude should increase by increments of 750kN to 1.500kN

For partial discharges, a minimum value of about 5% of the maximum load should not be exceeded to avoid loss of adhesion of the system elements. The charges must be brought by at least 4 equal steps. These results are shown in figures 6a, 6b, 7a and 7b.

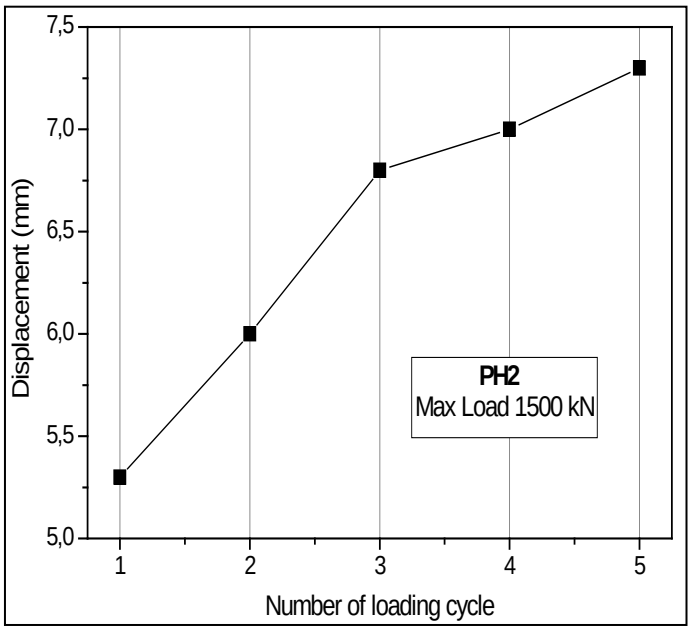

Figure 7.b. Evolution of displacement / load cycles for PH2 (load of 1500 kN).

4 ANALYTICAL CALCULATION OF PILES UNDER LATERAL LOADS

The interactions between soil and laterally loaded piles are typically accounted for by the use of p–y curves, originally introduced by Reese & Matlock (1956) and McClelland & Focht (1958). The p–y curves adopt the Winkler approach by uncoupling the response of various layers in the soil, and can therefore easily include effects of non-linearity, soil layering and other soil properties. A p–y curve defines the relationship p(y) between the soil resistance p arising from the non-uniform stress field surrounding the pile mobilized in response to the lateral pile displacement y, at any point along the pile.

We have conducted an analysis of transverse displacements of two piles testing in a lateral force in mind, this analysis was done using the method known as p–y curves method. We will compare the results with the results obtained during the lateral displacement pile load tests. p–y curves are constructed at different depths, and introduced into nonlinear FOXTA calculation software. These results are shown in the figure 8a and 8b.

5 MODELING OF PILES UNDER HORIZONTAL LOAD

The modeling of laterally loaded piles is done by the CESAR-LCPC 2D code. The different characteristics of soil layers are shown in Figure 3. The behavior of the ground is modeled by the failure criterion Mohr Coulomb by cons for the stake was modeled by a criterion of isotropic linear elastic fracture. These results deformed PH1 and PH 2 of piles are shown in the graphs figure 8a and 8b.

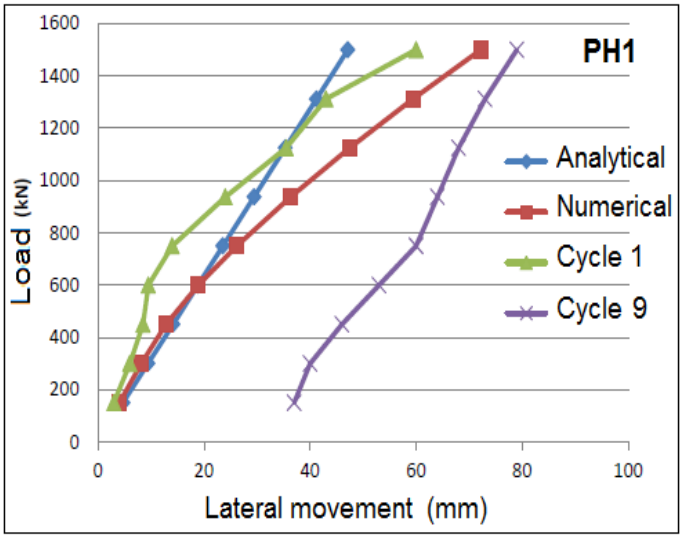

Figure 8.a. comparaison des déplacements latéraux de PH-1 en fonction des différentes méthodes de calcul

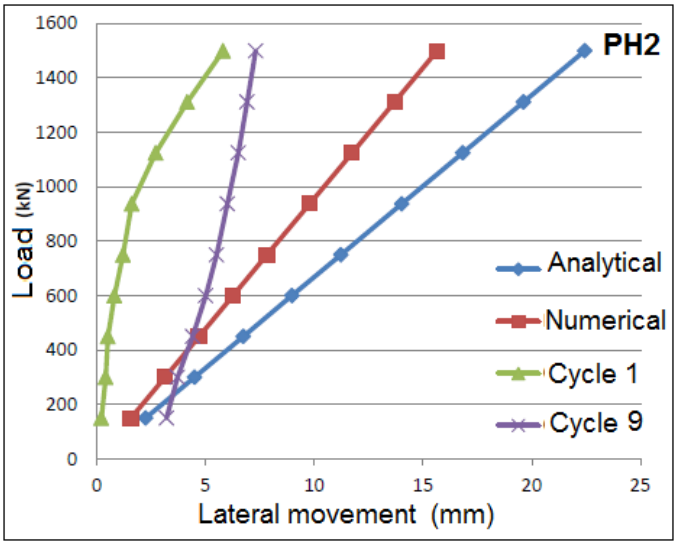

Figure 8.b. comparaison des déplacements latéraux de PH-2 en fonction des différentes méthodes de calcul

6 ANALYSIS OF THE RESULTS

In the figure 6a and 6b, Settlement of the pile "PH2" base in the final loading cycle reached the value nearly 6,3 mm for sand, corresponding to 6,3 ‰ of the pile diameter (1000 mm), But for PH1, the settlement of pile base in the final loading cycle reached the value nearly 6 mm for sand, corresponding to 6,0 ‰ of the pile diameter (1000 mm). It is observed that settlement for PH1 or PH2 are almost identical for the two soil types for the same load.

Figure 7a and 7b shows the evolution of horizontal movements based on discharge loading cycles for a load of 1500 kN for both soil types. There is a different pattern of horizontal displacements for the same load. For pile PH1 the measured value and 79 mm for the pile against PH2 is 7.3 mm. This evolution is the deformation has the effect of consolidation of clays.

Figure 8a and 8b shows the results of changes in horizontal movements of numerical modeling for both piles "PH1 and PH2". We are seeing displacements in the pile PH1 for greater load is five times greater in value to the modeling of the pile PH2 founded in sands. Horizontal movement, estimated by different methods shows a significant gap between PH-1 and PH-2. The differences in the results are due to very different soils conditions and are thus justified from a geotechnical standpoint. In Figure 8a, movements recorded during the last loading cycle are higher than the displacements of previous cycles. This variation is due to the nature of cross soils. for figure 8b, the displacements measured for the big load "pH2" does vary in a substantial way, the pile PH2 crosses sands.

Lateral displacement of the curves of piles, obtained by the numerical code CESAR-LCPC are confronted to that of the experiment, the two curves present the same appearance, the gap on displacement increases with the load level. For a maximum load of 1.5 MN displacements of the pile head was 72.20 mm for PH-1 and PH-2 to 15.65mm. By comparing the experimental values, they can be considered successful. Especially, we have not recorded lower values than the experimental values.

7 CONCLUSIONS

The calculation of lateral displacement of the two test piles realized in different soils under cyclic horizontal loads, by different methods. Allowed us to obtain results that were the subject of our analysis.

The effect of the loading on the drained response of laterally loaded piles in sand is limited. But for piles excavated in clay, we observed large horizontal displacement.

It would be of significant value to create the international database with complete static and dynamic test results of piles and the information regarding the measurements of soil resistances over the pile shaft and under the base referred to careful description of the subsoil and the in situ tests itself.

Practical Considerations for Real-time Recovery Calculation Using an On-Stream Analyzer

J. Timperi, J. Loimi
Outotec, Espoo, Finland

ABSTRACT This paper discusses about different aspects that need to be considered when on-stream analyzer measurements are utilized to calculate metal recoveries of minerals processing plants in real-time. Different data reconciliation methods are described and their practical feasibility for the application is evaluated. Also a versatile recovery calculation module for a commercial on-stream analyzer system is presented.

Keywords: Metal recovery, on-stream analyzer system, recovery calculation

1 INTRODUCTION

Metal recoveries of minerals processing plants are typically calculated according to composite shift sample assays by a metallurgical on-site laboratory. These measurements give the best indication about the plant's metallurgical performance.

However, sometimes it may be useful to get a real-time indication about the plant's current recovery. For actual control purposes of the plant it is typical to use direct metal assay percentages given by the on-stream analyzer (OSA). Naturally these assays have correlation with the plants metal recovery and thus metallurgical performance. For example, when rougher tailings assay starts to climb up, it can instantly be concluded that plant's recovery is dropping.

Indication of tailings assay alone doesn't give explicit information about the plant's recovery since head grade and final concentrate grade need to be considered also. However, if the on-stream analyzer provided also the metal recovery figure in addition to individual assays, it will give plant operators more tangible indication about the current performance of the plant.

Other purposes for the use of real-time recovery figure are plant performance assessments. Rantala et al. (2014) describe a method of utilizing on-stream analyzer as a tool to evaluate changes in plant's metallurgical performance. While absolute accuracy of assays from the metallurgical laboratory is the highest, the on-stream analyzer has proven useful instrument to detect relative changes in process performance due to high sample rate of measurements and good relative accuracy.

2 RECOVERY CALCULATION

As described by Wills and Napier-Munn (2006), flotation circuit recovery can be calculated according to the "two-product" formula as follows:

$$R = 100 \times \frac{c(f-t)}{f(c-t)}\% \quad (1)$$

Where f is metal content in flotation feed, c is metal content in final concentrate and t is metal content in final tails. This formula applies to flotation circuits where there is only one metal of interest. When there are two concentrate streams containing metal a and metal b involved as illustrated in Figure 1, equations can be written to provide metal recoveries in terms of assays alone by "three-product" formulas (Taggart, 1945):

$$R_a = \frac{100c_{1a}[(f_a - c_{2a})(c_{2b} - t_b) - (f_b - c_{2b})(c_{2a} - t_a)]}{f_a[(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)]} \quad (2)$$

$$R_b = \frac{100c_{2b}[(c_{1a} - f_a)(f_b - t_b) - (c_{1b} - f_b)(f_a - t_a)]}{f_b[(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)]} \quad (3)$$

Where R_a and R_b are recoveries of metal a and b, respectively. Other variables are as follows:

f_a and f_b are metal a and b content in flotation feed

c_{1a} and c_{1b} are metal a and b content in concentrate stream 1

c_{2a} and c_{2b} are metal a and b content in concentrate stream 2

t_a and t_b are metal a and b content in final tails

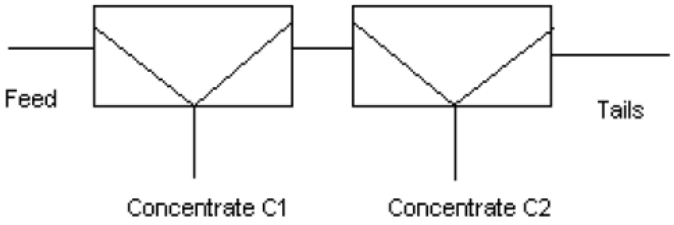

Figure 1. Flotation circuit with two concentrate streams.

When more product streams are introduced into recovery calculation, the formula becomes increasingly complicated. This is usually the case in real world applications where several concentrates are produced, for example in Cu-Zn-Pb flotation.

2.1 Accuracy of the Recovery Calculation

Saloheimo and Kongas (2001) present a method for estimating error when recovery is calculated according to the "two-product" formula.

When the equation for "two-product" formula (1) is differentiated, standard deviation for recovery can be obtained as follows:

$$\Delta R = \sqrt{\left(\frac{-t(f-t)}{f(c-t)^2}\Delta c\right)^2 + \left(\frac{ct}{f^2(c-t)}\Delta f\right)^2 + \left(\frac{-c(c-f)}{f(c-t)^2}\Delta t\right)^2} \quad (4)$$

Usually it can be assumed that c>>t, c>>f and f>>t for the produced metal, and the equation simplifies to

$$\frac{\Delta R}{R} \approx \frac{t}{f}\sqrt{\left(\frac{f}{c}\frac{\Delta c}{c}\right)^2 + \left(\frac{\Delta f}{f}\right)^2 + \left(\frac{\Delta t}{t}\right)^2} \quad (5)$$

From this formula it can be concluded that feed and tails have an equal effect to the accuracy of the calculated recovery whereas the concentrate accuracy has a smaller effect and is usually negligible in the calculation.

Because metal content in the tails stream is the lowest, this will be the most challenging stream measure accurately. When on-stream analyzer measurements are used to calculate recovery, it must be ensured that the most sensitive measurement technology is used and that the analyzer is properly calibrated. Table 1 illustrates effect of final tails measurement accuracy to error in recovery calculation.

Table 1. Accuracy of recovery calculation

	Metal content	Relative accuracy	Relative accuracy
Feed	1.50 %	3 %	3 %
Final concentrate	23 %	3 %	3 %
Final tails	0.12 %	5 %	10 %
Calculated recovery	92.5 %		
1-sigma error in recovery		0.47 %	0.84 %

Recovery calculation errors indicated in the table above serve well to emphasize the importance of the on-stream analyzer accuracy in the final tails stream. However, when practical usability of real-time recovery calculation is evaluated, the recovery figure calculated according to on-stream analyzer measurements should be compared to actual recovery figures measured by a metallurgical laboratory according to composite shift samples.

This brings out several new considerations. On-stream analyzer measures each sample point every 5…10 minutes. Composite shift sample is collected once per shift. These samples reflect averages over several hours and the composite includes also dimension of mass flow rate; changes in the process stream flow rate are relative to the amount of sample.

Spot samples measured by the on-stream analyzer every 5…10 minutes reflect momentary state of the process in each sample point. If recovery is calculated

according to these assays, delays between different sample points (e.g. phase difference between flotation feed and final tails) will have a significant effect to recovery calculation accuracy and thus these delays need to be eliminated by phase shift processing of analyzer measurements.

Figure 2 illustrates how real-time recovery calculated according to on-stream analyzer measurements corresponds to actual recovery that is calculated according to composite shift samples every 8 hours.

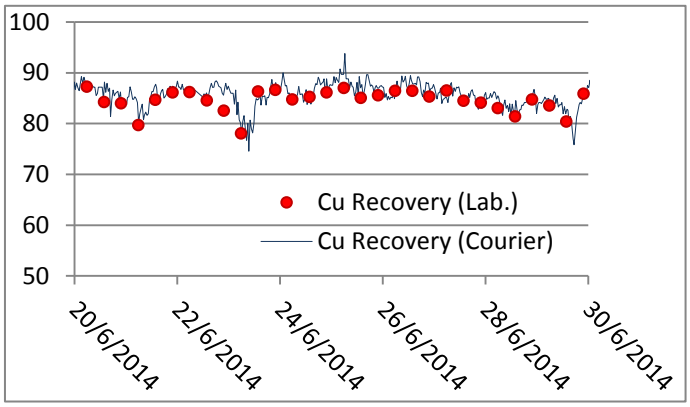

Figure 2. Recovery calculated according OSA vs. laboratory recovery (10 day period)

Generally it can be said that real-time recovery follows quite well the actual laboratory recovery during this period of 10 days. Relative error of real-time recovery compared to laboratory recovery is illustrated in Figure 3. Average relative error during this period of 10 days was 1.7% while being all the time below 6%.

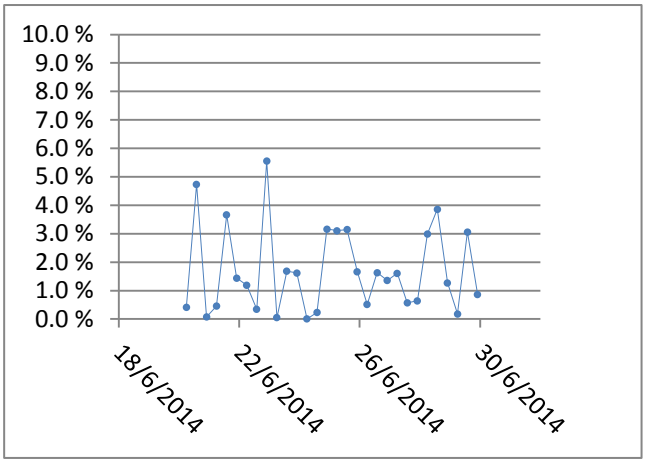

Figure 3. Relative error of OSA recovery compared to laboratory (10 day period)

However, during this period of 10 days the process was running on relatively steady feed rate and thus there was not much variation in flow rates of different streams according to which recovery was calculated. Figure 4 illustrates relative error of real-time recovery compared to laboratory recovery during a longer 3 month period which corresponds better to normal variable operating conditions. Average relative error during this 3 months period was 3.3% and from time to time error was over 10%.

It can be concluded that methods to improve real-time recovery calculation are needed in order to make a reliable to tool for plant personnel.

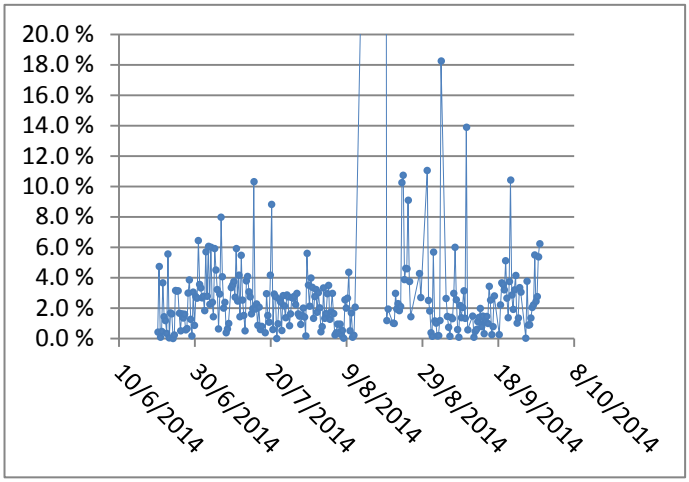

Figure 4. Relative error of OSA recovery compared to laboratory (3 months period)

3 IMPROVING REAL-TIME RECOVERY ACCURACY

Wills (1986) describes a method to improve accuracy of plant assay data by means of mass balancing. This method and its derivatives are widely used in minerals processing plants when recovery is calculated according to composite shift samples.

Calculations are relatively laborious to execute manually and thus Wills recommends use of microcomputers for these calculations. Development of information technologies has enabled several new computational technologies that were not feasible earlier. A modern on-stream analyzer for example contains enough computing power that even highly demanding calculations can be executed

locally by the analyzer CPU without auxiliary hardware.

Vasebi et al. (2012) describe several data reconciliation methods that are especially suitable for real-time execution. Bazin and Franklin (1996) describe actual implementation of real-time mass balancing application in Noranda Minerals concentrator plant in Canada.

3.1 Real-Time Data Reconciliation by Means of Steady State Mass Balancing

The real-time data reconciliation for on stream analysis results can be used to reduce the impacts of random errors. The data reconciliation improves reliability and accuracy and produces estimates that are best fits for the process model. Process model can represent the process ranging from static or steady state mass conservation constraints that calculate the process equilibrium to dynamic models that account process variation over time.

Mass balancing real time assays by steady state methods is a simple procedure for data reconciliation. The process is described by mass conservation constraints easily defined by using plant flowsheets. This solution provides good results when the inventory variations in the process are low compared to the measurement errors.

In case of process is more dynamic and the precision of the mass conservation estimates are less accurate than the measurements, the limitations of static models can be improved by handling the process inventory variation or node imbalances as random variables without increasing the model complexity.

3.2 Calculation of mass balancing adjustment components

A steady-state mass balancing process model can be developed by reducing the plant flowsheets into a series of nodes. Nodes can be either separators where input separates to two outputs or junctions where two inputs join to one output. Assuming that the process is in steady state conditions, the mass of the feed to a separating node is F and the two products C and T, and the material balance of the node is,

$$F = C + T \tag{6}$$

When each of the streams is assayed by metal content, the material balance can be written to

$$Ff = Cc + Tt \tag{7}$$

In ideal component balance where the feed F is assigned to 1 the unknown tails T can be defined by feed and concentrate.

$$F = 1 \tag{8}$$

$$T = 1 - C \tag{9}$$

The material balance is thus

$$f - Cc - (1 - C)t = 0 \tag{10}$$

But in reality there are inaccuracies in sampling and in assaying, an error e is generated in component balance.

$$f_i - Cc_i - (1 - C)t_i = e_i \tag{11}$$

$$e_i = (f_i - t_i) - C(c_i - t_i) \tag{12}$$

Where i represents a particular component. For a series of k components, the sum of errors produced is:

$$\sum_{i=1}^{k} e_i = \sum_{i=1}^{k}(f_i - t_i) - C\sum_{i=1}^{k}(c_i - t_i) \tag{13}$$

The sum of squares of the errors, SSE, is:

$$SSE = \sum_{i=1}^{k} e_i^2 \tag{14}$$

$$SSE = \sum_{i=1}^{k}(f_i - t_i)^2 + C^2\sum_{i=1}^{k}(c_i - t_i)^2 - 2C\sum_{i=1}^{k}(f_i - t_i)(c_i - t_i) \tag{15}$$

SSE cannot have zero value at any value of C but the minimum can be found by differentiating the SSE with respect to C, when:

$$\frac{\partial SSE}{\partial C} = \frac{\partial \sum e_i^2}{\partial C} = 0 \tag{16}$$

$$\frac{\partial SSE}{\partial C} = 2C\sum_{i=1}^{k}(c_i - t_i)^2 - 2\sum_{i=1}^{k}(f_i - t_i)(c_i - t_i) = 0 \tag{17}$$

The best fit value of C is then:

$$\hat{C} = \frac{\sum_{i=1}^{k}(f_i - t_i)(c_i - t_i)}{\sum_{i=1}^{k}(c_i - t_i)^2} \tag{18}$$

Where $\hat{C}$ denotes the estimate of C.

Using the method of Lagrange multipliers it is possible to define the estimates for each component subject to the equality constraints:

$$\widehat{f_i} = (f_i - f_{ia}) \quad (19)$$

$$\widehat{c_i} = (c_i - c_{ia}) \quad (20)$$

$$\widehat{t_i} = (t_i - t_{ia}) \quad (21)$$

$$\widehat{f_i} - \hat{C}\widehat{c_i} - (1 - \hat{C})\widehat{t_i} = 0 \quad (22)$$

$$(f_i - f_{ia}) - \hat{C}(c_i - c_{ia}) - (1 - \hat{C})(t_i - t_{ia}) = 0 \quad (23)$$

Where a represents the adjustment of the assayed component.

By subtracting the equation (12) from (23), the error for each component can be defined by adjustment values:

$$e_i = f_{ia} - C c_{ia} - (1 - C)t_{ia} \quad (24)$$

$$e_i - f_{ia} + \hat{C}c_{ia} + (1 - \hat{C})t_{ia} = 0 \quad (25)$$

The sum of squares for adjustment values SSE_a, can be minimized by subject to the constraint equation for e_i by finding the critical points of Lagrangian function:

$$SSE_a = \sum_{i=1}^{k}(f_{ia}^2 + c_{ia}^2 + t_{ia}^2) \quad (26)$$

$$L(f_{ia}, c_{ia}, t_{ia}, \lambda_i) = SSE_a + 2\lambda_i \sum_{1=1}^{k}(e_i - f_{ia} + \hat{C}c_{ia} + (1 - \hat{C})t_{ia}) \quad (27)$$

Where λi is the Lagrange multiplier for the component *i*. At any critical point of function *L* the partial derivates of *L* with respect to f_{ia}, c_{ia} and t_{ia} are zero:

$$\frac{\partial L}{\partial f_{ia}} = 2f_{ia} - 2\lambda_i = 0 \Rightarrow f_{ia} = \lambda_i \quad (28)$$

$$\frac{\partial L}{\partial c_{ia}} = 2c_{ia} + 2\lambda_i\hat{C} = 0 \Rightarrow c_{ia} = -\lambda_i\hat{C} \quad (29)$$

$$\frac{\partial L}{\partial t_{ia}} = 2c_{ia} + 2\lambda_i(1 - \hat{C}) = 0 \Rightarrow t_{ia} = -\lambda_i(1 - \hat{C}) \quad (30)$$

From equations (25), (28), (29) and (30) we now have for Lagrange multiplier:

$$e_i = \lambda_i\left(1 + \hat{C}^2 + (1 - \hat{C})^2\right) \Rightarrow \lambda_i = \frac{e_i}{1+\hat{C}^2+(1-\hat{C})^2} \quad (31)$$

The adjustments for each component are thus:

$$f_{ia} = \frac{e_i}{1+\hat{C}^2+(1-\hat{C})^2} \quad (32)$$

$$c_{ia} = \frac{-\hat{C}e_i}{1+\hat{C}^2+(1-\hat{C})^2} \quad (33)$$

$$t_{ia} = \frac{-(1-\hat{C})e_i}{1+\hat{C}^2+(1-\hat{C})^2} \quad (34)$$

4 REAL-TIME RECOVERY CALCULATION MODULE

In principle, real-time recovery can be calculated according to formulas (2) and (3) by applying mass balancing adjustment components as indicated in formulas (19), (20), (21), (32), (33) and (34).

This is a method that is commonly used by plant metallurgists for mass balancing of composite shift sample results. When this method is applied for real-time application, several assumptions need to be reconsidered.

Mass balancing assumes steady state conditions and that material inflows equal material outflows as per equation (6). In case of 8 hour composite samples this is typically a safe assumption. In case of on-stream analyzer samples with as high as 5 minute sample rate, effect of process dynamics need to be taken into account.

When real-time recovery calculation feature was implemented into Courier on-stream analyzer, several possibilities accommodate effect of process dynamics in recovery calculation was evaluated. During the evaluation following design parameters were considered:

- Accuracy of the recovery calculation
- Robustness of the model in variable process conditions
- Generality of the model i.e. possibility to utilize the model in various flotation circuit configurations
- Amount of configuration parameters i.e. ease of use
- Visualization of results

Target was to implement a recovery calculation module that is relatively easy to

configure for most typical flotation circuit configurations so that it would give accurate enough (1-2% rel.) recovery reading in variable process conditions.

It was concluded that for typical Cu-Zn-Pb applications, an extension up to four products was required. For polymetal applications, a reservation for more product formulas was acknowledged but these calculations were not implemented in the first version of the module.

To consider process dynamics with minimal complexity in configuration, parameters describing phase difference between different process streams were needed. Flotation residence time describes phase difference between the feed and final tails. For intermediate streams, there is a possibility to configure estimated residence times separately.

During the evaluation process, it was found that use of direct mass-flow measurements in the recovery calculation has a great potential to improve on-line recovery calculation accuracy in unstable process conditions, for example during radical change in flotation feed rate. For this reason recovery calculation module was accommodated with a possibility to utilize information from existing mass-flow measurement field instrumentation. To enable this feature, a two-way communication mechanism between the DCS and the OSA was implemented.

During the development it was acknowledged that visual reporting of the real-time recovery is essential in order to enable maximal use value for plant operators and metallurgists.

One commonly used method to visualize performance of a flotation process is to use grade-recovery curve. It was acknowledged that in addition to current on-line recovery, this chart has to visualize also historical development of the process in order to give better overall view of the situation.

One of the challenges in visualization is the sheer amount of grade-recovery data over period of time. For this reason different tones of grey color was used to indicate density on most commonly visited dots on grade-recovery chart thus giving a visualization about actual position of the grade-recovery curve itself.

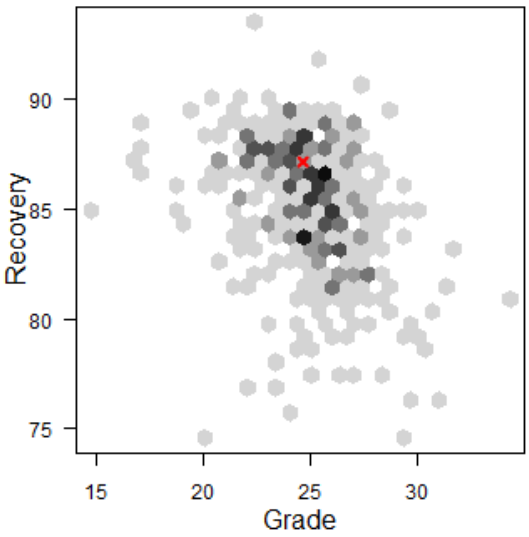

Figure 5. Grade-Recovery visualization of the real-time recovery module.

The red X describes the most recently measured grade-recovery. Grey dots indicate density of historical grade-recovery measurements.

5 RESULTS

Figure 6 illustrates the same data as in Figure 4 after the data has been reconciliated. Three assays were used from each stream for balancing the masses. The recovery was calculated using equation (2) with mass balance adjustment components (32), (33) and (34).

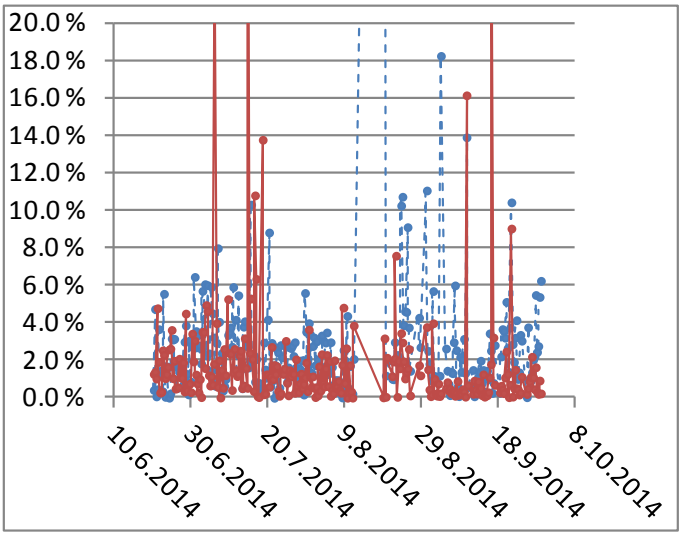

Figure 6. Relative error of OSA recovery compared to laboratory (3 months period).

Real time calculation without mass balancing in blue dotted line and recovery calculated using mass balancing data reconciliation in red line

Applying the data reconciliation methods to the data from the 3 months period the average relative error was reduced to 1.8% from 3.3%. The median error was reduced from 2.0% to 1.0%.

Table 2. Accuracy of recovery calculation with and without mass balancing

	Without mass balancing	With mass balancing
Average relative error	3.3 %	2.0 %
Median relative error	2.1 %	1.1 %

The accuracy of real-time recovery calculation can be improved by applying steady-state mass balancing methods. The reliability of the calculation could possibly be improved further by applying dynamic models for data reconciliation.

6 CONCLUSIONS

Calculation of real-time recovery based on OSA measurements brings useful information for plant operators about current state of the process. The most straight-forward way to calculate real-time recovery is to apply a "two-product" formula for OSA assay data from feed, concentrate and final tails.

Accuracy of real-time recovery calculation can be improved by utilizing a formula for three or more products. Further improvements can be achieved by utilizing data reconciliation methods based on static or dynamic process models.

However, in order to make real-time recovery calculation feasible in real world applications, configuration of calculation models must not be overly complicated.

Prediction of Final Concentrate Grade Using Artificial Neural Networks from Gol-E-Gohar Iron Ore Plant

S. H. Hosseini, M. Samanipour
Islamic Azad University, Tehran South Branch, Tehran, Iran

ABSTRACT In this study, the artificial neural networks methods were used to predict the iron, phosphor, sulphur and iron oxide content of final concentrate from Gol-E-Gohar iron plant, Kerman province, Iran. The particle size (d_{80}), iron, phosphor, sulphur and iron oxide percentages of run of mine (R.O.M) were used as the inputs for the network. Feed-forward artificial neural networks (FANNs), with 5-8-7-7-4 and 5-8-8-6-4 arrangements were used to estimate the final concentrate grade in both wet and dry magnetic separation process. The outputs of the models were the iron, iron oxide, phosphor and sulphur content of the final concentrate. It was achieved quite satisfactory correlations of $R^2 = 0.98$ in training and testing stages for wet magnetic process prediction. The proposed neural network model, as an alternative to the simulation method, can be used accuratelyto determine the effects of changes in feed and concentrate grade of Gol-E-Gohar iron ore plant in dry and wet magnetic process.

Keywords: Artificial neural network, estimation of ore concentrate grade

1 INTRODUCTION

Artificial intelligence tools have been used for many years in a number of mineral processing applications. These networks have been used different applications such as modeling for particle size analysis (Maxwell et al., 1995), simulation for particle shape quantification (Oja and Nystöm, 1997), assessment of flotation experiments (van Deventer et al., 1997; Cilek, 2002; Labidi et al., 2007) and the modeling of gold liberation from diagnostic leaching data (Petersen and Lorenzen, 1997).

The Gol-E-Gohar iron ore beneficiation plant is located around 55 km southwest of Sirjan, Kerman province, Iran. This plant is situated at the center of a triangle comprising the cities of Kerman, Shiraz and Bandar Abbas in Iran and is one of the major manufacturers of iron concentrate in Iran with capacity of 3.5 million tons annually (Ghasemi, 2004). The plant feed was provided from the Gol-E-Gohar iron mine which is located in Kerman province, Iran.

The iron ore, after drilling, blasting, loading the extracted ore, are transported by mining trucks to the plant. Then the extracted ore are transferred to gyratory primary crusher. The maximum feed size to gyratory crusher is 1.5 m (d_{max}) and d_{80} of gyratory crusher product is about 20 cm. After primary crushing, the crushed ore transfers to autogenous mills. The maximum size of AG mills product is 3 mm (d_{max}) and d_{80} of product is about 550 microns. The product of AG mills transfers to dry low intensity magnetic separator (LIMS). The output of LIMS will be 3 types of products including concentrate, tailings and middlings. The middlings will be regrinded in wet ball mills in next stage and will produce the iron concentrate using wet low intensity magnetic separator. The final concentrate will be transported to tailing dam after dewatering using filters and tickeners. Finally, dry and wet concentrate will be blended together and will be ready to send to the customers. Table 1 shows the chemical properties of final iron concentrate producing by Gol-E-Gohar iron ore plant with d_{80} of 60 microns and maximum moisture of 2%.

The input-output data was obtained from the Gol-E-Gohar iron plant. In order to

obtain the most suitable ANN models which predict the final iron concentrate grade, the performances of the models in terms of mean relative error (MRE) and mean absolute error (MAE) were calculated by the following equations:

$$\text{MRE}=\frac{\sum_{i=1}^{N}\frac{X_{predicted,i}-X_{observed,i}}{X_{observed,i}}}{N}\times 100 \qquad (1)$$

$$\text{MAE}=\frac{\sum_{i=1}^{N}\left|X_{predicted,i}-X_{observed,i}\right|}{N} \qquad (2)$$

Where Xi is the grade or particle size and N is the number of data points.

The aim of the present study is the assessment of Fe, FeO, P, S % of final iron concentrate from Gol-E-Gohar iron plant, Kerman province, Iran with changing the particle size (d_{80}), Fe, FeO, P, S % of the feed from Gol-E-Gohar iron mine, and simulate the process using neural network technique.

Table 1. Chemical properties of final iron concentrate in Gol-E-Gohar iron ore plant

Element or oxide (%)	Amount
Fe	67% min.
FeO	20% min.
P	0.05% max.
S	0.5% max.
CaO	0.6% max.
SiO_2	2% max.
Al_2O_3	0.5% max.

2 RESULTS AND DISCUSSION

The used multilayer perceptron (MLP) neural networks has 3 hidden layers. Five neurons in the input layer correspond to the percentage of Fe, FeO, P, S and d_{80} of the iron ore feed, and four neurons in the output layer correspond to Fe, FeO, P and S content for the final iron concentrate.

Figures 1and 2 depict the models 1 and 3 of feed-forward network with one input layer, three hidden layers, and one output layer, which were used for the prediction of final iron concentrate grade.

Data used to test the proposed approach are taken from the Gol-E-Gohar plant chemical analysis daily database. The database consist of the percentage of Fe, FeO, P, S and (d_{80}) of the feed (iron ore) and also Fe, FeO, P, S content of the final iron concentrate. A total of 219 sets of data sets were used in the predictions by ANN; 200 data sets for training and 19 sets for testing the network were used. The training process was stopped after 200 epochs (Figure 3). In each epoch, the entire training set was presented to the network and errors are calculated and used to adjust the weights in the network using sigmoid transfer function.

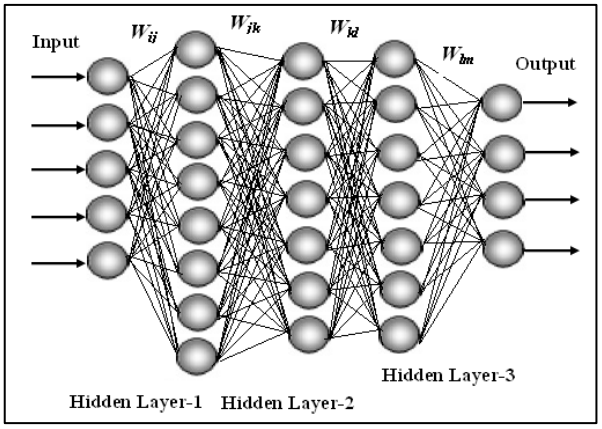

Figure 1. Multilayer perceptron neural network model 1 (5-8-7-7- 4)

Modeling was carried out in five stages according to the feed of different mills (wet or dry mills) and also the mixture of wet and dry iron concentrate. This was done in order to have a convenient comparison between the results and reliable prediction for the quality of final iron concentrate with the least error.

Table 2 shows the different stages of modeling according to the network structure and also the obtained correlation coefficients. As it can be seen, the highest correlation coefficient was observed in models of 1 and 3 for all training, testing, validating and prediction stages.The correlation coefficient value for the training set on both of models 1 and 3 were equal to 0.99. The correlation

coefficient for testing sets was 0.99 in both models of 1 and 3. The coefficient of determination value for the training set on both of models of 1 and 3 were 0.98. The test set that actually determines how good the model is shows that the models can estimate the outputs quite satisfactorily. Quite satisfactorycorrelation of 0.99 for prediction of iron concentrate grade was achieved. The quite satisfactory coefficient of determination 0.98 for prediction of iron concentrate grade was achieved. It was observed that the final concentrate grade could be predicted using the ANN model satisfactorily

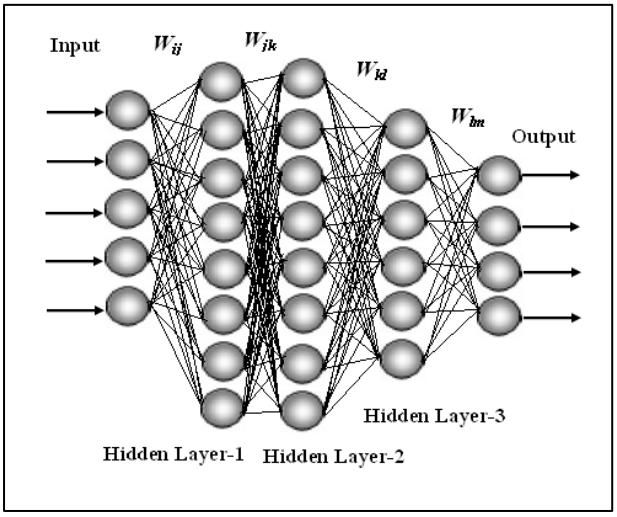

Figure 2. Multilayer perceptron neural network model 3 (5-8-8-6- 4)

Table 3 shows the prediction errors. Negative values of errors in Table 3 indicate that the prediction values and comparing with actual value. The performance of used function is the mean absolute error (MAE), the average absolute error between the network predicted outputs and the target outputs, that was 0.02, -0.23, 0, 0 for testing data in Fe, FeO, P and S % predictions for model 3, respectively. Figures 4-7 show the predicted data using FANN versus actual data in plant process. The R2 values for the testing sets were 0.96, 0.96, 0.90 and 0.94 in Fe, FeO, P and S % predictions, respectively. It was observed that the grade of final iron concentrate could be predicted using the ANN model satisfactorily.

However, the above mentioned results suggest that ANNs owing to their excellent nonlinear modeling ability are better alternative to the linear models for the prediction of final iron concentrate grade.

3 CONCLUSION

(1)Based on the results from this study, the three-hidden-layer ANN model is capable of predicting the Fe, FeO, P and S % of final iron concentrate subject to different conditions.

(2) The input- output data were obtained from the Gol-E-Gohar iron ore plant, and used in the simulation by means of artificial neural network. Feed-forward artificial neural networks with 5-8-7-7-4 and 5-8-8-6-4 arrangements were used to predict the grade of final iron concentrate.

(3) In the testing process, the proposed ANN models can estimate the outputs quite satisfactorily. The correlation coefficients (R) for testing sets are 0.98, 0.98, 0.95 and 0.97 in Fe, FeO, P and S assay predictions, respectively. The coefficient of determination(R^2) for testing sets are 0.96, 0.96, 0.90 and 0.94 in Fe, FeO, P and S assay predictions, respectively.

(4)The proposed approach should be useful to geologists, mining engineers and plant engineers for predicting the grade of different iron ore types and for suggesting suitable blending of feed materials to achieve the maximum recovery.

(5)The proposed neural network model accurately reproduces all the effects in prediction of final iron concentrate grade at Gol-e-Gohar iron ore plant.

(6)These studies on forecasting the grade of final iron concentrate could be new unexamined conditions that where ANN have never been used to predict of Fe, FeO, P, S % in final iron concentrate at Gol-e-Gohar iron ore plant.

(7) In the current work the accuracy of the models were enhanced by the selection of better network structures instead of selecting a larger data set.

ACKNOWLEDGEMENTS

The authors would like to thank Islamic Azad University, South Tehran Branch, Tehran, Iran for funding this project and also Gol-e-Gohar Iron Ore Company for their assistance in collecting the required data used in this study.

ABSTRACT To improve the quality of decision making in the mining operation, it is essential to find global optimum in problems with large dimensional scales. It is widely accepted that Long-term production scheduling (LTPS) problem is playing key role in mining projects to improve their performance by considering availability constraints while maximizing the project total profits during the period. Since production scheduling problems are NP-hard, there is need of improving scheduling methodologies to get good solution. This paper presents a hybrid model between augmented Lagrangian relaxation (ALR) and Genetic algorithm (GA) to solve the LTPS problem. We propose to apply the ALR method on the LTPS problem which to improve its performance speeding up the convergence and also, GA is used to update the Lagrangian multipliers. The results from synthetic data set show that the ALR method is effective in solving large- scale problem and generation a feasible solution then the traditional linearization method. Furthermore, the proposed hybrid strategy based on GA showed better performance in comparison to the available methods.

Keywords: Augmented Lagrangian Relaxation, Genetic Algorithm Optimization

1 INTRODUCTION

A problem that must be solved frequently by an orebodoy block model is to determine economically by what blocks will be removed to meet the forecasted processing decisions and operating constraints, over a long time horizon. The problem is commonly referred to as the Long-term production scheduling (LTPS) problem. The LTPS problem is a mixed-integer programming problem and is the class of NP-hard problems. Because of its size and NP-harness, the true optimal solution of the LTPS problem is normally difficult to obtain. Nevertheless, the high dimensionality and combinatorial nature of the LTPS problem curtail attempts to develop any rigorous mathematical optimization method capable of solving the whole problem for any real-size block model. Therefore, many research efforts have been focused on efficient LTPS algorithms for higher total production profit and computational time.

A first optimization model for this problem was proposed by Johnson [1] based on linear programming model by using Dantzig-wolf decomposition principles. Many

conventional methods were applied to solve the LTPS problem such as branch and cut method (BC) [2, 3] mixed-integer programming (MIP) [4-10], dynamic programming (DP) [11-15], classical Lagrangian relaxation (CLR) [16-20].

Aside from the above methods, there is another class of numerical techniques applied to LTPS problem. Specifically, there are Artificial intelligence (AI) [21-23], Genetic algorithm (GA) [24-27], Simulated annealing (SA) [28-29]. The GA, SA methods can search not only local but also global optimal solution. However, they are sensitive to the parameter setting and require a considerable amount of computational time for large problem size due to the large search space. Extensive surveys of different operation research techniques and modeling issues are provided by Espinoza et al. [30]. To reduce the search space in the large-scale problem, and therefore computational time, hybrid methods are much efficient than the single methods due to more production profit and faster computational time [31]. The hybrid methods are purported to incorporate more complicated constraints and are purported to have better quality solutions.

This paper proposes a hybrid method between augmented Lagrangian relaxation and Genetic algorithm (ALR-GA) to solve the open pit mines LTPS problem. ALR-GA is a combination of improved augmented Lagrangian relaxation and Genetic algorithm. The hybrid method uses the advantage of GA which can provide a near global solution combined with the advantage of ALR which can find a solution within a short time.

2 THE PROPOSED METHOD

During the past few decades, considerable attention has been focused on finding methods for solving the large-scale problems. At present, one of the potential approaches for solving proposed problems is the Lagrangian relaxation (LR) method. Within the LR method, there are two main approaches: the CLR and the ALR method [32, 33]. The basic idea of LR is to relax the complicating constraints by using Lagrangian multipliers. The relax problem is then decomposed into N subproblems. The search is an iterative algorithm that solves relaxed subproblems and updates Lagrangian multipliers according to the extent of violation of complicate constraints. The main drawback of CLR method is that there is duality gap between the solution of the Lagrangian dual problem and the solution of original problem, and often the quality of the final solution depends on the heuristic steps [34]. These difficult can be overcome by the ALR method, which is based on the linearization technique [35]. The ALR decomposition procedure is dependent on the initial estimates of the Lagrangian multipliers and on the method used to update the multipliers. On the other hand, stochastic optimization techniques such as GA start with the generation of randomly selected chromosomes as the initial population that encoded a set of possible solutions. GA can provide a near global solution but takes a long CPU time.

The ALR and GA method incorporates GA into ALR to update the Lagrangian multipliers and improve the performance of the ALR method within a reasonable CPU time. This hybrid method solves the open pit mine LTPS problem by relaxing the complicating constraints and using the dual optimization theory.

3 FORMULATION OF A LTPS PROBLEM

Long-term production scheduling model is used to predict production targets and ore material flow over several years, it is generally takes a simplified representation of the production and formulated as linear problem. The open pit mines LTPS model on the other hand is more detailed assuming that key decisions (processing decisions) have been made. To consider these two different decision-making targets, the simplest way is to formulate a full space optimization model, where in every period of the scheduling horizon, the availability

constraints are incorporated into the model. In this section, we formulate the LTPS problem as follows:

$$Maximize \quad Z = \sum_{ijk\in\Gamma}\sum_{t}^{T}\sum_{d}^{D}\frac{NV_{ijk}^{td}}{(1+r)^{t}}\cdot b_{ijk}^{td} \tag{1}$$

S.t

$$\sum_{ijk\in\Gamma}\left(\overline{\alpha}_{ijk}-L_{\overline{\alpha}}^{t}\right)\cdot Q_{ijk}^{o}\cdot b_{ijk}^{td}\geq 0 \qquad for\ all\ t,d \tag{2}$$

$$\sum_{ijk\in\Gamma}\left(Q_{ijk}^{o}\cdot b_{ijk}^{td}\right)\leq U_{o}^{t} \qquad for\ all\ t,d \tag{3}$$

$$\sum_{ijk\in\Gamma}\left(Q_{ijk}^{o}+Q_{ijk}^{w}\right)\cdot b_{ijk}^{td}\leq U_{w\&o}^{t} \qquad for\ all\ t,d \tag{4}$$

$$\sum_{t=1}^{T}\sum_{d}^{D}b_{ijk}^{td}=1 \qquad for\ all\ ijk\in\Gamma \tag{5}$$

$$b_{k}^{td}-\sum_{y}^{Y}\sum_{r=1}^{t}b_{y}^{rd}\leq 0 \qquad for\ all\ t,k,d \tag{6}$$

In the model being built, the following indications were accepted:

ijk: is the block identification number, *ijk=1,2,…,* Γ.

Γ: is the total number of blocks to be scheduled.

t: is the scheduling periods index, *t=1,2,…,T.*

T: is the total number of scheduling periods.

d: is the processing type of the block (i.e. *d*=1, 2,…, *D*)

D: is the number of processing type.

NV_{ijk}^{td}: is the net value to be generated by mining block *ijk* in period t if processed as type *d*.

r: is the discount rate in each period.

b_{ijk}^{td}: is the binary variable equal to = $\begin{cases}1 & if\ block\ n\ is\ extracted\ at\ period\ t\ as\ processing\ type\ d\\ 0 & Otherwise\end{cases}$

Q_{ijk}^{o}: is the ore tonnage in block *ijk*.

Q_{ijk}^{w}: is the waste tonnage in block *ijk*.

$\overline{\alpha}_{ijk}$: is the average grade of block *ijk*.

$L_{\overline{\alpha}}^{t}$: is the lower bound average grade of material sent to the mill in period *t*.

U_{o}^{t}: are the upper bound total tons of ore processed in period *t*.

$U_{w\&o}^{t}$: is the upper bound total amount of material (waste and ore) to be mined in period *t*.

Y: is the total number of blocks overlaying block *k*.

K: is the index of a block considered for extraction in period *t*.

y: is the counter for the *Y* overlaying blocks.

In the above model, the objective function (1) is the total profit over the scheduling horizon. Therefore, the objective function is expressed as the sum of net value of the extracting blocks taking into account discount rate. The constraints of the above can be divided into operational and physical constraints. Eqs. (2) to (5) represent the operation constraints, among them, Eq. (6) represent physical constraint.

Among the constraints of the LTPS problem, Eq. (2) limit the average grade of the material sent to the mill to a certain value. Constraints (3) ensure that the milling capacities hold. This upper bound is necessary to secure a smooth feed of ore. Constraints (4) relate the actual available equipment capacity for each period. This upper bound is total amount of material (ore and waste) to be mined in period. Constraints (5) enforce that a block is removed in one period only. Constraint (6) is the wall slope restriction on the basis of *Y* constraint for each block per period.

3.1 Decomposable Structure with Reformulation

Observing the special constraint structure of the open pit mines LTPS problem as shown in section 2, we can reformulation the problem into a decomposable structure through the processing targets. Let us refine the LTPS problem way.

$$Max\ Z=\sum_{ijk\in\Gamma}\sum_{t}^{T}\sum_{d\notin p}^{D}\frac{NV_{ijk}^{td}}{(1+r)^{t}}\cdot b_{ijk}^{td}+\sum_{ijk\in\Gamma}\sum_{t}^{T}\frac{NV_{ijk}^{tp}}{(1+r)^{t}} \tag{7}$$

$$\sum_{ijk\in\Gamma}\left(\bar{\alpha}_{ijk}-L^{t}_{\bar{\alpha}}\right)\cdot Q^{o}_{ijk}\cdot b^{tp}_{ijk}\geq 0 \qquad for\ all\ t \tag{8}$$

$$\sum_{ijk\in\Gamma}\left(Q^{o}_{ijk}\cdot b^{tp}_{ijk}\right)\leq U^{t}_{o} \qquad for\ all\ t \tag{9}$$

$$\sum_{ijk\in\Gamma}\left(Q^{o}_{ijk}+Q^{w}_{ijk}\right)\cdot b^{td}_{ijk}\leq U^{t}_{w\&o} \qquad for\ all\ t,d \tag{10}$$

$$\sum_{ijk\in\Gamma}\left(Q^{o}_{ijk}+Q^{w}_{ijk}\right)\cdot b^{tp}_{ijk}\leq U^{t}_{w\&o} \qquad for\ all\ t \tag{11}$$

$$\sum_{t=1}^{T}\sum_{d\neq p}^{D} b^{td}_{ijk}=1 \qquad for\ all\ ijk\in\Gamma \tag{12}$$

$$\sum_{t=1}^{T} b^{tp}_{ijk}=1 \qquad for\ all\ ijk\in\Gamma \tag{13}$$

$$b^{td}_{k}-\sum_{y}^{Y}\sum_{r=1}^{t} b^{rd}_{y}\leq 0 \qquad for\ all\ t,k,d \tag{14}$$

In the problem reformulation (7) we have made a compact representation of the availability constraints (2) and (3) as (8) and (9) for the sake of processing type. Also, constraints (4) and (5) are decomposed with respect to the processing type as (10) – (13). We use $p \subseteq \{1,2,\ldots,d\}$ to represent set of block indices of those blocks processed as type p. Consequently, part 1 of the objective function is used for maximizing the total discounted economic value not meeting processing targets while part 2 is used for maximizing the total expected net present value of meeting processing targets using processing type p. In this particular formulation, it is considered that there are processing capacity constraint and blending grade constraint for processing type p in each period.

4 LTPS BASED AUGMENTED LAGRANGIAN FUNCTION

The complexity of the large-scale combinatorial optimization problems motivates the use of decomposition techniques. Obviously, CLR has been widely studied for the constrained optimization problem. The major concept of CLR is to distinguish the set of complicating constraints of a general integer program and to incorporate them into the objective function in a Lagrangian fashion by adding penalty coefficients to them so to guide the search toward reducing the amount of constraints violation [33, 36]. Based on powerful duality theorem, we know that if all the constraints are convex and all the variables are continuous, the optimum of primal problem will equal the optimum of the dual problem. However, a duality gap might obtain in the presence of integer, which means that the optimal solution to the dual problem will be exactly less than the true optimum of primal problem.

Based on the above reasoning, we used an ALR technique, where can effectively generate feasible solution for the original problem; based on the augmented Lagrangian function proposed by Andreani et al. [37].

With the above reformulation, the resulted model (7) is decomposed into a wasting subproblem and a number of processing subproblems once the coupling constraints (9)-(13) are relaxed. In this work, the augmented Lagrangian method is applied to solve the open pit mines LTPS problem.

The original maximization objective is equivalent to the minimization a revised objective function. Here, we specify the objective as:

$$Min \qquad \sum_{ijk\in\Gamma}\sum_{t}^{T}\sum_{d}^{D} - Z(b) \tag{15}$$

Specifically, equality and inequality constraints (9)-(13) are relaxed and the following augmented Lagrangian relaxation problem is obtained:

$$L(b,\lambda,\mu,\upsilon,\sigma) = Min \quad \sum_{ijk\in\Gamma}\sum_{t}^{T}\sum_{d}^{D} - Z(b) +$$
$$\left[\sum_{t=1}^{T}\sum_{d}^{D}\lambda^{td}\cdot(b_{ijk}^{td}-1)+\sum_{t=1}^{T}\sum_{d\notin p}^{D}\lambda^{tp}\cdot(b_{ijk}^{tp}-1)\right]+$$
$$\sigma\cdot\left[\sum_{t=1}^{T}\sum_{d}^{D}(b_{ijk}^{td}-1)^2+\sum_{t=1}^{T}\sum_{d\notin p}^{D}(b_{ijk}^{tp}-1)^2\right]+$$
$$\left[\sum_{t=1}^{T}\sum_{d}^{D}\upsilon^{td}\cdot(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{td}+\sum_{t=1}^{T}\sum_{d\notin p}^{D}\upsilon^{tp}\cdot(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{tp}\right]+ \quad (16)$$
$$\sigma\cdot\left[\sum_{t=1}^{T}\sum_{d}^{D}\left[(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{td}\right]^2+\sum_{t=1}^{T}\sum_{d\notin p}^{D}\left[(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{tp}\right]^2\right]+$$
$$\sum_{t=1}^{T}\mu^{tp}\cdot(Q_{ijk}^{o}\cdot b_{ijk}^{tp})+\frac{\sigma}{2}\sum_{t=1}^{T}(Q_{ijk}^{o}\cdot b_{ijk}^{tp})^2$$

The objective function of the relaxed problem can be rewritten as follows:

$$L(b,\lambda,\mu,\upsilon,\sigma) = Min \quad \sum_{ijk\in\Gamma}\sum_{t}^{T}\sum_{d}^{D} - Z(b) +$$
$$\sum_{t=1}^{T}\sum_{d}^{D}\left\{\begin{array}{l}\lambda^{td}\cdot(b_{ijk}^{td}-1)+\upsilon^{td}\cdot(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{td}+\\ \sigma\cdot\left[(b_{ijk}^{td}-1)^2+[(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{td}]^2\right]\end{array}\right\}+$$
$$\sum_{t=1}^{T}\sum_{d\notin p}^{D}\left\{\begin{array}{l}\lambda^{tp}\cdot(b_{ijk}^{tp}-1)+\upsilon^{tp}\cdot(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{tp}+\\ \sigma\cdot\left[(b_{ijk}^{tp}-1)^2+[(Q_{ijk}^{o}+Q_{ijk}^{w})\cdot b_{ijk}^{tp}]^2\right]\end{array}\right\}+$$
$$\sum_{t=1}^{T}\mu^{tp}\cdot(Q_{ijk}^{o}\cdot b_{ijk}^{tp})+\frac{\sigma}{2}\sum_{t=1}^{T}(Q_{ijk}^{o}\cdot b_{ijk}^{tp})^2 \quad (17)$$

In order to minimize the Lagrangian function with respect to the Lagrangian multipliers, the adjustment of Lagrangian multipliers must be done carefully. Most references to adjust Lagrangian multipliers use a combination of subgradient method and various heuristics to achieve a rapid solution. In this paper, we use the Genetic algorithms to adjust the Lagrangian multipliers and improve the performance of Lagrangian relaxation method.

5 APPLICATION OF GA TO MULTIPLIERS UPDATING

As mentioned before, ALR is an iterative method. At each iterative, multipliers are updated, subproblems are optimally solved to obtain dual solution, and primal problem is updated by heuristics as suitable. As we know, subgradient optimization method is commonly used to solve non-differentiable problems by taking a fixed step size in direction of a subgradient [38]. Unfortunately, this method do not always provides good feasible solutions because Lagrangian relaxation is very sensitive to Lagrangian multipliers.

In this section, the Lagrangian multipliers are updated using a GA approach to overcome the convergence problems with ALR. Genetic algorithms are stochastic, parallel search algorithms based on theory of natural selection and the process of evolution [39, 40]. These algorithms start with a set of possible solutions randomly selected in the solution space as a population. Each possible solution is represented as a chromosome and evaluated for its fitness calculated using the objective function. After evaluating the fitness of each population member, a subsequent generation of population is generated by applying genetic operators, such as selection, crossover and mutation, to individual in the current population. Detailed application of the ALR-GA method is given for LTPS problem in section 5.1 to 5.2.

5.1 Generation of Random Lagrangian Multipliers

The process starts with the generation of a population of chromosome. In a genetic population, each chromosome comprises a number of genes and is encoded corresponding to a possible solution of the optimization problem. The popular methods of encoding a chromosome include binary encoding, real number encoding and integer permutation encoding. A chromosome in the ALR-GA method corresponds to an encoded normalized Lagrangian multipliers matrix, shown in Fig. 1.

$\lambda_1^1, \upsilon_1^1, \mu_1^1$	....	$\lambda_{12}^1, \upsilon_{12}^1, \mu_{12}^1$
⋮	....	⋮
$\lambda_1^T, \upsilon_1^T, \mu_1^T$	....	$\lambda_{12}^T, \upsilon_{12}^T, \mu_{12}^T$

Figure 1. The binary representation of a chromosome.

The advantage of using Lagrangian multipliers matrix as the encoded parameter is that the number of bits of chromosome will be entirely independent of the number of blocks. The more encoding bits therefore, the higher the resolution and the slower the convergence. In this paper, we use 12 bits to represent Lagrangian multipliers. The decoding of the encoded normalized Lagrangian multipliers can be expressed as:

$$\lambda_{decode}^{t} = \sum_{i=1}^{12} \lambda_i^t \cdot 2^{-i} \qquad \lambda_i^t \in \{0,1\} \tag{18}$$

$$\upsilon_{decode}^{t} = \sum_{i=1}^{12} \mu_i^t \cdot 2^{-i} \qquad \upsilon_i^t \in \{0,1\} \tag{19}$$

$$\mu_{decode}^{t} = \sum_{i=1}^{12} \eta_i^t \cdot 2^{-i} \qquad \mu_i^t \in \{0,1\} \tag{20}$$

Translating normalized, to real Lagrangian multipliers are calculated as follows:

$$\lambda^t = \lambda_{\min} + \lambda_{decode}^{t}(\lambda_{\max} - \lambda_{\min}) \tag{21}$$

$$\upsilon^t = \upsilon_{\min} + \upsilon_{decode}^{t}(\upsilon_{\max} - \upsilon_{\min}) \tag{22}$$

$$\mu^t = \mu_{\min} + \mu_{decode}^{t}(\mu_{\max} - \mu_{\min}) \tag{23}$$

Where, $\lambda_{\min}$, $\upsilon_{\min}$ and $\mu_{\min}$ are the minimum value of the input variable, $\lambda_{\max}$, $\upsilon_{\max}$ and $\mu_{\max}$ are the maximum value of the input variable.

5.2 Application of GA Operators

5.2.1 Selection

The evolution of a GA population is based on the natural selection and the survival of the fittest. In our implementation, this is achieved using the roulette wheel parent selection [39]. The chance of a chromosome to be selected for reproduction is proportional to its fitness.

5.2.2 Crossover

Crossover produces solutions by the recombination of the parent chromosomes. The operator in its classic form selects one or more crossing points in the parent chromosomes adopt a new crossover technique known as “uniform crossover” which exchange bits between the parent chromosomes to create two new offspring chromosomes by a randomly generated mask. The scheme of “uniform crossover” is shown in Fig.2. In the random mask, the “1” represent bit swapping and “0” denotes bit unchanged.

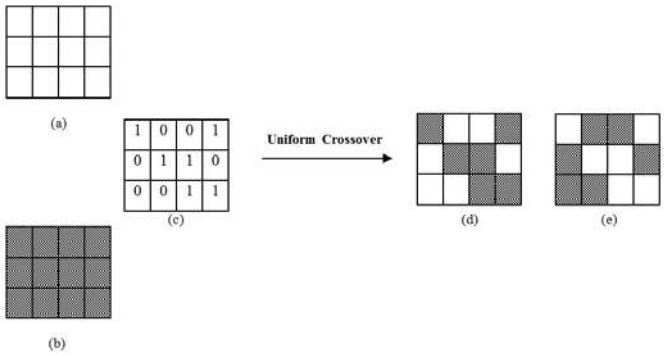

Figure 2. Uniform crossover operator: (a) is the parent chromosome1; (b) is the parent chromosome 2; (c) is the random mask; (d) is the offspring chromosome 1; (e) is the offspring chromosome 2.

5.2.3 Mutation

The mutation operation is aimed to introduce new genetic material into an existing individual. It adds diversity to the genetic characteristics of the population.

5.2.4 Fitness

Since ALR-GA method uses the relative duality gap as its basis of the convergence rule. The fitness function of the chromosome is expressed as follows:

$$FIT = \frac{1}{1 + K \cdot (\frac{F_{\max}}{F_r} - 1)} \tag{24}$$

Where:

K: is the scaling coefficient.

F_{max}= is the maximum of F_r within population.

$$F_r = \frac{1}{the\ relative\ duality\ gap} = \frac{1}{\varepsilon}$$

6 THE FRAMEWORK OF THE PROPOSED HYBRID METHODOLOGY

The proposed hybrid method is fulfilled in two stages (as shown in Fig. 3). The first stage is fulfilled, which formulate an augmented Lagrangian function proposed by Andreani et al. [37], updating the Lagrange multipliers and penalty parameters. Following this, the second stage is the constrained global maximization of the mentioned ALR function, in which a new stochastic method near to the optimal maximum is found using the GA. The framework of the proposed hybrid method can be described as in Fig. 3. The steps of methods are as follows:

Step1. Define coding type and the length of individual string.

Step2. Define Genetic algorithms operation parameters.

Step3. Generate a population of chromosomes, (Lagrangian multipliers).

Step4. Decoding individual string to get different values of multipliers.

Step5. Calculate the constrained maximum of Lagrangian function and convert it into fitness.

Step6. Perform reproduction operator according to the fitness.

Step7. Perform crossover and mutation operators to obtain a new chromosome in order to minimize Lagrangian function.

Step8. If the termination criterion has satisfied, then stop; otherwise return to step (4).

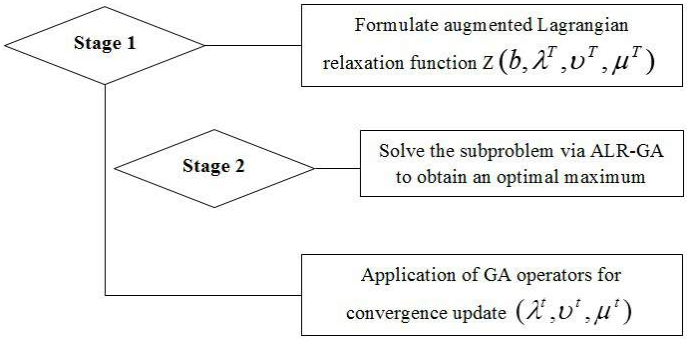

Figure 3. The framework of the proposed hybrid method.

7 CONCLUSION

To address the problem of Long-term production scheduling in open pit mines, a hybrid method between augmented Lagrangian relaxation and Genetic algorithm is proposed in this paper. Based on the special structure of the optimization model, new variables and coupling constraints for the processing decision variables are introduced, the coupling constraints are then relaxed and the resulted augmented Lagrangian relaxation problem is solved through hybrid technique. We propose a new strategy based on optimization of the Lagrangian multipliers and compare its performance with traditional approximation based subgradient method. Genetic algorithm is used to update the Lagrangian multipliers. The advantage of using normalized Lagrangian multipliers as the encoded parameter is that the number of bits of chromosome will be entirely independent of the number of blocks and only dependent of number of periods and processing type. This is particularly attractive in large scale problems.

ABSTRACT Green iron oxide pellets are indurated with thermal treatment in pelletizing plant to achieve sufficient mechanical properties and to be used in iron-steel industry. In the first stage, the pellets are dried with hot air coming from the firing unit. High heat transfer makes the evaporation rate exceeding the outgoing steam rate from the pellets and as a result, increasing the inner pressure of the pellets and fragment. On the other hand, low heat transfer causes low production rate. Using the related equations and considering the pellets' moisture and porosity and applying the pellets' condition on parameters such as specific heat capacity and heat conductivity, an acceptable standard is achieved for simulation. The current work has focused on investigating the pellets' drying process to achieve the optimized condition and consequently, lowering the energy consumption and increasing the process efficiency. Simulating by ANSYS Fluent software, the velocity and temperature of the gas are studied to reach the optimized condition.

Keywords: Heat transfer, navier-stokes, pellet drying, simulation

1 INTRODUCTION

Initial load of both blast furnace and DRI (direct reduction iron) plants should have the required permeability to allow the gasses pass through them uniformly and with a high rate. Since the iron concentrates are in powder form, they make a compressed form which closes the penetration ways. By using the iron concentrate as initial load, additionally, the fine particles of ore across with gasses exit the furnace as dust. The iron concentrate powders should pass an agglomeration process in which the particles sizes grow and therefore, the load permeability and reduction rate increase and the exiting materials as dust through the furnace decrease (Eisele and Kawatra, 2003). Pelletizing provides uniformly sized and almost spherical pellets with sufficient mechanical strength in wet and dry conditions. In wet pellets, moisture content and plasticity are so important to get sufficient bed permeability. For instance, if the plasticity of wet pellets is higher than normal range, the permeability of pellet bed in drying zone on travelling grate will be affected adversely. If they are not plastic enough, they will become fragile or will not have sufficient wet pellet strength to survive on travelling grate. Therefore optimum wet strength and plasticity is important and can be controlled by changing the addition dosage of binder during wet pellet formation (Ljung et al., 2008). Thus, most pelletizing plants have been built near the iron mines.

The pellets' geometric is so that the air passes through them and consequently, the resistance on gas flow is less than briquettes (Meyer, 1980). Today pellets have been a main input of blast furnace (Ljung et al., 2011).

1.1Pelletizing Process

Low grade iron ores with impurity gangue minerals containing silica and alumina must be upgraded to an acceptable level of iron content. Concentrates, due to their fine sizes, are not suitable to be directly charged to the iron-making processes such as the blast furnace. Hence, an agglomeration technique should be applied to fine concentrate. The most commonly employed one is pelletizing in iron ore industry. In pelletizing, iron ore, water and a binder are balled in a mechanical disc or drum to produce agglomerates (Process Description of Gol–E-Gohar, Sivrikaya and Arol 2010, Sivrikaya and Arol 2012). Pelletizing of fine particles consists of a variety of stages such as drying to remove the moisture and grinding to acquire the suitable grain size. The mixed iron concentrates (with additives such as bentonite, lime and sludge) are fed in to the pelletizing discs. Then the green pellets transfer to indurate machine to indurate and to achieve the required mechanical, physical and metallurgical features for steel making plants (Figure 1).

Since the measurement and control in the machine are intricate, the process control is too complicated and a matter of debate. The indurating process generally consists of three main stages; (1) drying, (2) induration and sintering at 1200-1350 °C and (3) cooling the pellets before going to stockpile. The air passes through the steel grates within the machine. Fig. 1 depicts schematic of typical straight-grate induration system. The machine consists of seven regions; updraft drying (UDD), downdraft drying (DDD), preheating (PH), firing (F), after firing, cooling 1 (C) and cooling 2 (C2). Six fans are installed in different areas of the machine to circulate the air within the machine.

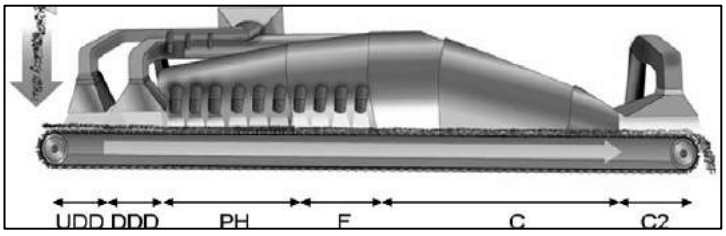

Figure 1. Schematic of assembly line of pelletizing (Ljung et al. 2011).

1.2Drying Green Pellets

In drying stage, the moisture which inhabits the green pellets' porosities evaporates by hot air (300-330 °C). Passing the air through the first layer of pellets, the air absorbs the moisture and reaches the saturation state. The drying gasses are cooled from initial state (300-330 °C) to saturation point. While passing the saturated air through the upper pellet layers which are green and cool, some of air water liquidates on the pellets. These layers will receive high moisture that leads to dropping the pellets' strength and a high plastic deformation occurs in the layers. To overcome this problem a combination of downdraft and updraft drying is applied. The down pellet layers are dried and their temperature increases in updraft drying. In the next stage, the downdraft drying carries out and the top layers are heated and dried. So, the saturated gasses flow from downer layers of hot dried pellets without cooling to saturation point. The initial drying gasses temperature is so that no thermal shock is applied on pellets. If the heating occurs very fast, the cracks appear on the pellets and pellet fragment takes place. Anyway, the pellets are places on a palette to move to different areas of indurating machine (Process Description of Gol–E-Gohar)

The current study is on modeling the heat transfer as well as fluid velocity in drying process by Computational Fluid Dynamic (CFD) method. The aim is well done and initial gasses of various temperatures and flow rates are used and modeled.

2 EXPERIMENTAL

2.1 Transport Equations

Considering the fluid's temperature, velocity, viscosity etc., the fluids are divided into two main categories; laminar and turbulent. The laminar theory is employed in this study. The Navier-Stokes equations for incompressible fluids at basic mode can assume the fluid Newtonian and extract various features. The equations, in which the modelling is done based on them, are as follow:

$$\frac{\partial \rho}{\partial t} + \nabla.(\rho u) = 0 \quad (1)$$

Equation 2 is used for momentum:

$$\rho \frac{\partial u}{\partial t} + \rho u.\nabla u = -\nabla p + \nabla.\left(\mu(\nabla u + (\nabla u)^T) - \frac{2}{3}\mu(\nabla.u)I\right) + F \quad (2)$$

The dominant equation for heat transfer in fluids is:

$$\rho C_p \frac{\partial T}{\partial t} + \rho C_p\, u.\nabla T = \nabla.(k\nabla T) + Q \quad (3)$$

and in solids:

$$\rho C_p \frac{\partial T}{\partial t} - \nabla.(k\nabla T) = Q \quad (4)$$

The relation between heat and temperature gradient is considered as:

$$q = -k\nabla T \quad (5)$$

The Reynolds equation is used to analyze the fluid flow and is as follows:

$$Re = \frac{\rho U L}{\mu} \quad (6)$$

where ρ, u, T, C_p and k are the density (kg/m^3), the velocity (m/s), the temperature (K), the specific heat at constant pressure (J/kg K) and the thermal conductivity (W/m K) of the surrounding fluid. Furthermore, Q is the energy source term (W/m^2) and μ is the dynamic viscosity (kg/m s).

Table 1 describes the used materials' properties.

2.2 Model Geometry & Boundary Conditions

ANSYS software was used to simulate the geometry and to model. Employing this software, first the model geometry is drawn. For this purpose, an 18*60 mm chamber and a semi-circular pellet with a 6 mm radius and 18 mm higher from the chamber bottom is considered. The cross section is divided in half and then rotated for convenience in calculation. The model is simulated in three-dimensional as mentioned.

Table 1. Values of pellet parameters used as the base case of simulation.

Parameter	Value
Density of magnetite	5175(Kg/m^3)
Density of water	998(Kg/m^3)
Density of air	0.633 (Kg/m^3)
porosity	25 (%)
Pellet moisture content	8 (%)
Thermal conductivity	3.75(W/m K)
Specific heat capacity of magnetite	700 (J/Kg K)
Specific heat capacity of water	4190(J/Kg K)
Specific heat capacity of air	1009(J/Kg K)

Using ANSYS facilities, the model is meshed for simulation in the next stage (Figure 2).In the last step, the boundary conditions are applied (Figure 3). The pellet's structure and the surrounding are required to build the model. The pellet is considered as a homogeneous sphere with a radius of 6 mm. The system is symmetric and using the symmetric axis, a rectangular chamber with specified dimensions is considered. It is assumed that the existing air present in this area is the effective air on the pellet's temperature. According to the defined pressure over the top and down of the chamber, the simulation condition is kept near the surrounding's real condition. It is seen that the gas velocity is used in the documents; but, in this paper, to use more precise data, the pressure difference of the chamber is calculated and used according to pressure and velocity relation (Equation 1). The simulations were carried out with the commercial software ANSYS Fluent v14.0, which is based on Finite Volume Method (FVM).

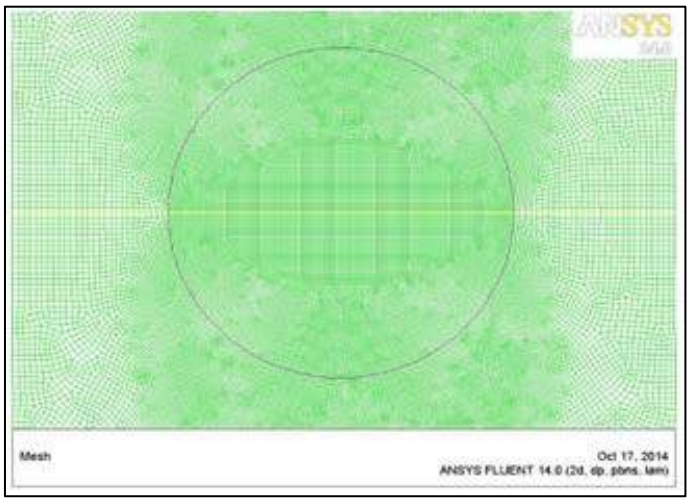

Figure 2. Mesh of the simulation around pellet with symmetry

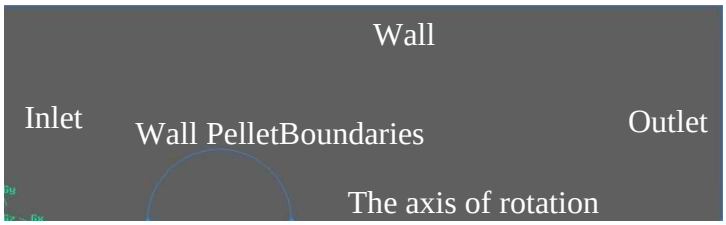

Figure 3. Model geometry with boundary conditions.

2.3 Initial and Boundary Conditions

The boundary condition is necessary to solve the equations. Different states of the system are investigated by applying various boundary conditions in this study. These data are tabulated at Table 2.

The pellets are made from magnetite ore and the initial temperature of the system is considered 70°C. The real fall in pressure is between the top and down of the pallets; however, the simulation calculations are based on a single pellet. So the real initial condition is different from the considered one.

3 RESULT AND DISCUSSION

Velocity profile is calculated for various pressure differences: 5, 10, 15, 55 and 65 Pa; and the results of the calculation for the pressure difference of 15 and 55 between two sides of chambers are reported in Figure 4-a and Figure 4-b. Due to the constant flow of gas, in areas where pellet reduces the speed of gas and lowers gas flow rate consequently, it is necessary the gas speed increases in the vicinity of pellet and the total flow rate remains constant in that case. As a result, gas velocity is increased in those areas. In other case, it is obvious that at low gas velocities, gas velocity is nearly constant in all areas of the chamber before reaching the pellet. But the velocity in these areas could vary by increasing the total velocity. As a result, pellet could change the velocity inside the chamber in a wide range. As it is obvious in Figure 4, by increasing the entrance gas velocity, the area behind the pellet, where the gas velocity is lower, becomes smaller. So it could be concluded that by increasing the entrance gas velocity, heat transfer through the back arch of the pellet can be done better. In addition, velocity of the layer near the pellet is approximately constant. As it is shown in Figure 2, by increasing the inlet and outlet pressure and the velocity as a result, the heat transfer rate gets higher and these changes are linear.

Table 2. Boundary conditions in constant pressure and temperature

Grid no.	$T_{in}(^{\circ}C)$	$\Delta P(pa)$
1	100	10
2	150	10
3	200	10
4	250	10
5	300	10
6	350	10

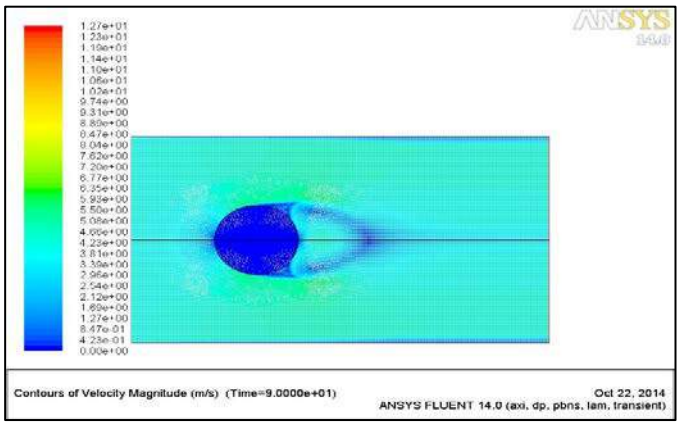
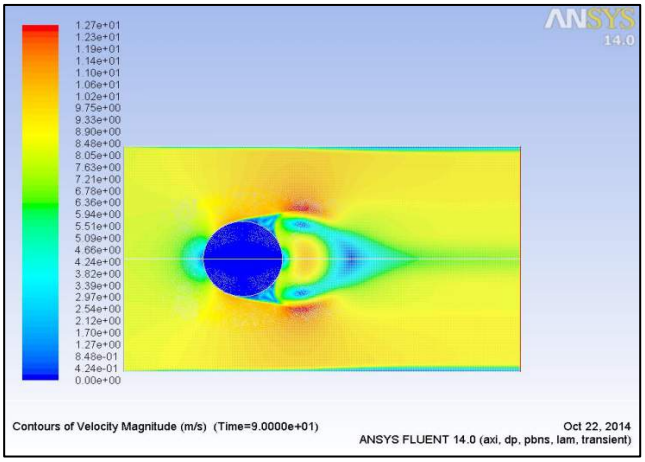
8	200	35
9	200	55



(a)



(b)

Figure 4. Velocity magnitude for flow at ΔP a) 15 Pa b) 55 Pa.

Temperature profile calculated in different temperatures is shown in Table 2. The results in which the pressure difference between two sides of the chamber is 15 Pa, initial pellet temperature is 70 °C and the entrance gas temperature is 200 °C, after 60, 120, 240 and 280 seconds are shown in figures 5-a, b, c, d. As it is obvious in Figure 5, the pellet temperature is low at first step and results in lowering the gas temperature contacts with pellet surface. This could affect the drying rate of other pellets that are placed on top layers by lowering the drying rate. Additionally, pellets' temperature is increasing up to entrance gas temperature.

Figure 6-a shows the pellet cross section of the shown temperature profile in Figure 6-b. According to temperature gradient, it is seen that the temperature variation at inside the pellet is reducing in time. All aforementioned results revealed the fact that in drying process, in order to avoid temporal stress, crack or even fragment, the first step of the drying procedure should be done very accurately. The entrance gas temperature should be low at first and could be increased gradually, so pellets would be properly prepared for next steps of the pelletizing procedure.

Moreover, other temperature profiles are calculated for different boundary conditions. The effects of gas entrance temperature and pressure difference between two sides of the chamber for single point inside the pellet with lower temperature are shown in Figures 7 and 8. As can be seen in the mentioned Figures, the results are matched properly with related equations.

As can be seen in Figure 7, the region inside the pellet where consists the lowest temperature is increased linearly with increasing the entrance gas velocity.

Figure 8 shows that the effect of entrance gas temperature is greater than entrance gas velocity which is increased linearly. In addition to, the pressure difference between 20 and 50 Pa is the range for changing the condition from layer flow to turbulence flow, which is not considered in calculations.

4 CONCLUSION

For a system containing a single pellet and a cylinder as the chamber, an analytical simulation is carried out to calculate fluid flow and heat transfer and the results are as follow:

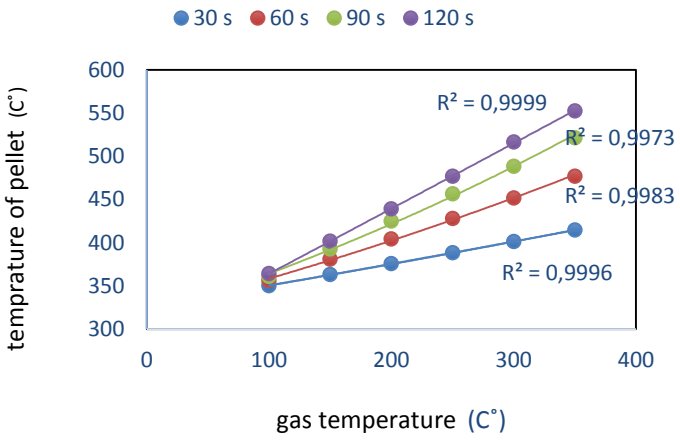

Figure 8. Effect of the gas temperature on minimum temperature of pellet at different times.

The pellet has influence on gas velocity in different areas of the chamber and as a result, affects other pellets' drying process.

- Increasing initial gas temperature increases the internal pellet temperature linearly.
- As the temperature difference inside the pellet is more at first steps of drying process and the possibility defect creation, more attention should be paid in these steps.
- The temperature effect is more considerable compared to the effect of the pressure on heat transfer inside the pellet.

ACKNOWLEDGEMENT

The authors would like to acknowledge the R&D center of Gol-E-Gohar Iron Ore Co. for contribution of the plant data for assessment of the model.

GIS and Topography Applications

Comparative Analysis of Coordinates of Mine Traverse Points Determined on the Basis of Polygon and Tachymetric Traverse

A. Ganić, A. Milutinović
University of Belgrade – Faculty of Mining and Geology

ABSTRACT Determination of spatial coordinates of mine traverse points is to be performed on the basis of measurements of directional angles by applying gyrus method, by measuring lengths on both sides as well as differences in altitude between traverse points, with defined number of measurements repetition. Measurements, organized in this way, provide the required accuracy of points coordinates within the mine traverse in order to carry out all necessary mining works. The use of electronic instruments and the implementation of simple measurement method may provide sufficient accuracy to carry out certain mining activities to a limited extent. The paper displays comparative analysis of spatial coordinates of mine traverse points determined on the basis of measurements within polygon traverse by applying gyrus and tachymetric measurement method at the closed-down lead and zinc mine "Crveni Breg" on the Mountain Avala near Belgrade in the Republic of Serbia.

Keywords: Polygon, tachymetric, gyrus

1 INTRODUCTION

Traverses and level lines build up through underground mine chambers and structures. They consist of points that have their coordinates and altitudes within the same coordinate system, in which the points of the physical Earth's surface are located as well. In this way, underground mine chambers are geo-referenced and their spatial position can be compared with natural and artificial structures located above mining works or within the zone of their influence. Understanding of actual interactions between structures on the terrain surface and underground structures is very significant primarily in terms of safety and protection of people and structures, but also for the purpose of the development of mine pursuant to the designs (Borshch-Komponiets et al., 1989).

Coordinates and levels of traverse and bench points are not measured directly but rather indirectly, by way of calculation, on the basis of measured angles, lengths and differences in level in those traverses. Polygon traverses and level lines in underground mine chambers most often belong to the category of so called open traverses. This means that they end in points that have no known coordinates and levels, whereby this eliminates the possibility to determine actual accuracies of measured parameters within traverses, their correction and, with corrected results, calculation of the most probable values of unknown coordinates and levels of points.

In order to increase the accuracy of measurement, and thereby the accuracy of calculated coordinates and levels of points, measurements are to be repeated several times. This increases the accuracy of measurement but the time necessary to carry out those measurements increases as well.

By using modern electronic instruments, such as total station, time required to carry out measurements can be significantly reduced without significant loss of the accuracy of measurement (Schofield and Breach, 2007). To this end, experimental measurements were carried out at the closed lead and zinc mine "Crveni Breg" on the mountain Avala near Belgrade that belongs to the Faculty of Mining and Geology.

2 EXPERIMENTAL MEASURING AT THE "CRVENI BREG" MINE

The lead and zinc mine "Crveni Breg" was opened in 1886/87 by the group of Serbian capitalists. The French Association of Industry and Mining acquired rights to extract ore at this mine in 1906, when two adits, i.e. horizons were opened, on levels +247m and +195m. With periodic interruptions, ore extraction at the "Crveni Breg" mine continued till 1953, when the mine was definitely closed down.

In the meantime, four additional horizons were opened, on levels: +165m, +135m, +130m and +85m, so that at the moment of closing, there were 6 horizons, 10 inter-horizons, 2 vertical shafts connecting all horizons, several raises and chambers at the mine. Total length of all horizontal and vertical chambers is approximately 6045m. The lowest four horizons were flooded, and because of caving, the first two horizons on levels +247m and +195m are only partially passable and safe.

Furthermore, in 1953, the "Crveni Breg" mine was placed at the disposal of the Faculty of Mining and Geology in Belgrade. As a school mine, it is used for performance of field work and practice.

Experimental measurements were carried out in the so called "lower adit" on level +195m. Mine traverse (Figure 1), which is at the same time level line as well, consists of 17 points and its length is 359.83m. Average length of traverse legs is 22.49m and they range between 6.48m and 64.29m.

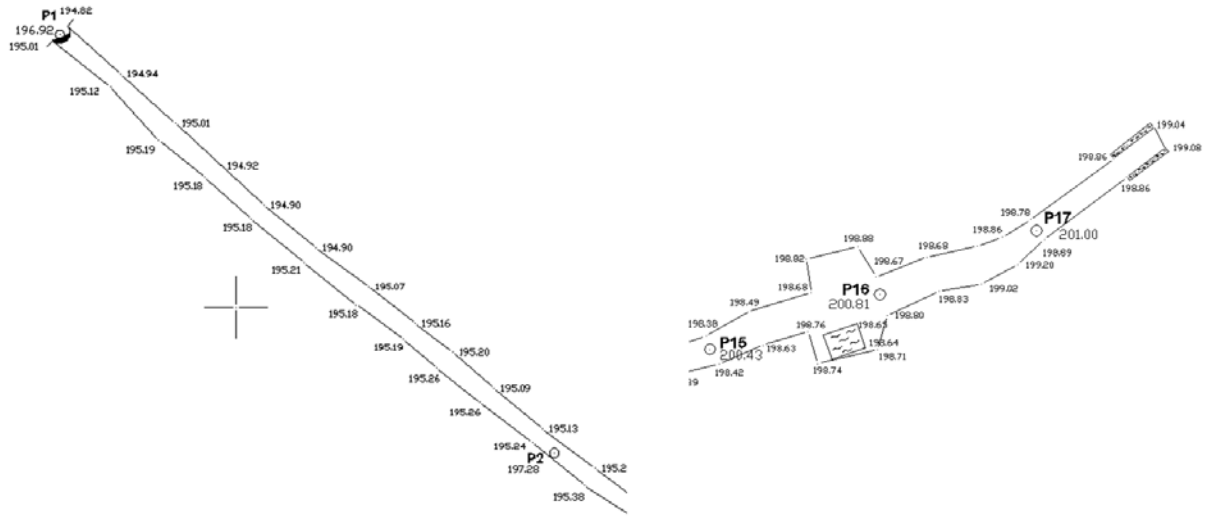

Figure 1. Beginning and the end of the mine traverse at the school mine "Crveni Breg"

During the experiment, angles and lengths within traverse and differences in level within level line were measured first. Angles were measured in two gyruses, and lengths with two repetitions "forward – backward". Differences in level were measured by geometric leveling, the method of leveling from the middle, as well as with two repetitions "forward - backward". Measurements of angles and lengths were carried out by using total station Topcon GTS-226. Specified accuracy of this instrument is ±6" for measuring directions and ±5mm+5ppm when measuring lengths. Differences in level were measured by leveling instrument Carl Zeiss NI-025 with automatic leveling. Pursuant to averaged results of measurements, coordinates and levels of points at the traverse, i.e. level line were calculated.

Thereafter, measurements were carried out at traverse, this time, though, measurements were carried out as if this was tachymetric traverse. This implied that angles (horizontal and vertical) are measured by simple method, only once and only at one position of telescope, and lengths in only one direction. On the basis of those

measurements, coordinates and levels of points in the mine traverse were recalculated. The results obtained according to both methods of measurement are shown in Table 1.

Measurements at traverses and level lines are more accurate that at tachymetric traverses. Therefore, the coordinates and levels of points obtained at traverses and level lines also have conditionally true values when compared with their values obtained by tachymetric measurements. All measured parameters are burdened with accidental errors, so that the differences of coordinates and levels of the same points have no distinctly constant trend. However, when observing spatial differences of positions of points obtained by different methods of measurement $\Delta_{N,E,H}$, it may be generally stated that there is an indicator of the increase in difference in view of accumulation of errors resulting from the lower accuracy of tachymetric measurements.

Table 1. Comparative overview of coordinates of points at the mine traverse

Point	Traverse/Leveling			Tachymetric traverse			Difference			
	N [m]	E [m]	H [m]	N [m]	E [m]	H [m]	Δ_N [cm]	Δ_E [cm]	Δ_H [cm]	$\Delta_{N,E,H}$ [cm]

P15	8968.93	1122.70	200.43	8968.89	1122.71	200.42	-4	+1	-1	4.2
P16	8972.68	1134.28	200.81	8972.63	1134.30	200.80	-5	+2	-1	5.5
P17	8977.04	1144.95	201.00	8976.99	1144.96	200.98	-5	+1	-2	5.5

When analyzing the results of measurements on angles and lengths, it was observed that the average difference of measured angles is 4.6" which corresponds to the internal accuracy of total station. At the same time, 11 angles differ from each other by less than 5", and maximum difference is 17". Average difference between the same lengths is 1.1cm, whereby seven lengths differ from each other by less than 1cm, and maximum difference is 2.6cm. The difference between the same lengths is larger than the internal accuracy of total station, so it could be concluded that the lengths are the reason for the displayed differences between the coordinates of points.

An additional analysis of spatial error of coordinates at the terminal point of the mine traverse has shown that almost entire error of the terminal point is the consequence of badly measured lengths within the traverse (Dmitrić, 2012). The reason for this is the fact that the reflector signaling could not be carried out qualitatively.

3 APPLICATION OF TACHYMETRIC TRAVERSE AT UNDERGROUND MINES

The analysis of the results obtained shows that when carrying out measurements by applying tachymetric traverse by means of electronic total station, certain tasks in field of mining surveying at mine traverses may be solved. Those are primarily measurements where high accuracy of measurement is not required, i.e. the determination of spatial coordinates is not required:

- at traverses with smaller lengths,
- executing shorter breakthroughs,
- connection of inter-horizons where there is possibility of independent checking,
- in excavation chambers,
- in temporary mine chambers etc.

Figure 2. The layout of the level +494m at the bauxite mine "Kosturi" Srebrenica

The Figure 2 shows the level layout +494m with scale 1:500 from design documentation of the underground bauxite mine "Kosturi" Srebrenica (Faculty of Mining and Geology, 2009). The designed bench passage EH-494-2 is cca 450m long and its function is to be preparation mine chamber for excavation of bauxite ore by applying the method of caving in of lateral and roof parts of the massif (Milutinović et al., 2010). Considering the length of the bench passage, its temporary character and accuracy required when constructing it, the usage of tachymetric traverse for marking directions is justified when constructing this mine chamber.

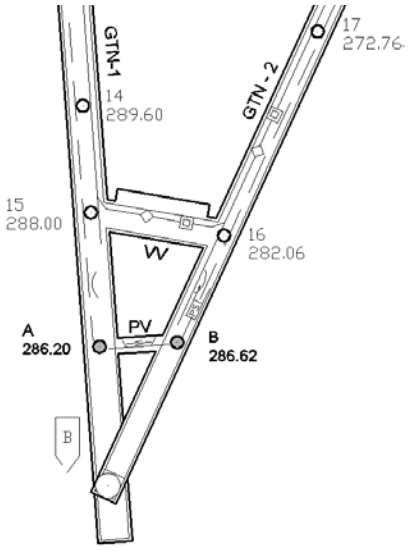

Figure 3. The detail of the layout of the brown coal mine "Soko" Soko Banja

The Figure 3 shows the detail of the design of underground brown coal mine "Soko", Soko Banja (Mining Institute Belgrade, 2002). The underground chambers (GTN-1, VV, GTN-2) shown, represent opening chambers and they are located in such working environment (limestone) where the usage of electronic measuring instruments is permitted. Considering the properties of working environment and requirements to carry out short breakthrough having the function of the transversal connection "PV" for the purposes of coal conveying (points A-B), it is constructed by marking the breakthrough direction from point "A" on the basis of data from tachymetric traverse (points 14-15-A).

4 CONCLUSION

Measurements in tachymetric traverse are carried out by applying simple method including measurements without repetition and with only one position of telescope. Therefore it is possible that such measurements are burdened with gross errors that significantly impair the results obtained. The possibility of gross errors occurrence eliminated at measurements that are being repeated. The application of tachymetric traverses, i.e. measurements in mine traverses, require therefore special attention when carried out. The usage of electronic total stations in underground traverses has the advantage over usage of classical surveying instruments because of elimination of errors occuring while reading directions and entering results. The result of this is also the quality of the directly obtained spatial coordinates of the surveyed points.

Afore-stated findings imply the need that special attention must be paid to centring the instrument and signalling the points as well as the necessity for quality sighting when carrying out those measurements. At that point the occurencies of gross errors in the results of measurements may be eliminated with large certainity, so that in cases stated in this paper or similar, tachymetric traverse may be applied as the method to determine spatial coordinates of points within the mine traverse and to solve mining and surveying tasks.

The advantages of this measurement metod are primarily the shorter time required to carry out measurements, and therefore shorter possible disruption of production causing higher economic efficiency of the production at the mine.

Diffusion of Geograpgic Information System at Municipalities in Istanbul

M. Çavur, M. Özturan, C. Karaduman
Boğaziçi University, Management Information System, İstanbul

A.B. İçli
Bilkent University, Electric-Electronic Engineering, Ankara

ABSTRACT This study aims to develop a better understanding of diffusion of Geographic Information Systems within municipalities and examines the infrastructure of İstanbul municipalities and whether they are ready for this technology or not. This study uses two research methods: The first one comprises interviews with the experts of GIS in Turkey. The second one comprises questionnaires conducted with Geographic Information Systems - related departments of İstanbul municipalities. Data collected online have been analyzed by using descriptive statistics, reliability tests, Anova and regression to test the hypotheses. One of the findings is that almost half of the municipalities implement Geographic Information Systems without a vision or a plan for the future. Another finding is that Geographic Information Systems is mainly used to perform registration and maintenance functions instead of supporting the decision-making process. Finally, there is an optimistic expectation of municipalities regarding the use of Geographic Information Systems in the future.

Keywords: Geograpgic Information System (GIS), Istanbul municipalities

1 INTRODUCTION AND OUTLINE OF RESEARCH

Using information technologies (IT) and information systems (IS) is a very common and compulsory issue in all sectors nowadays. Since geographic information system (GIS) is a kind of information technology which enables us visualize, question, analyze, interpret, and understand data in many ways that reveal relationships, patterns, and trends in the form of maps, globes, reports, and charts, it is being used inevitably by all sectors. Municipalities are one of the governmental organizations which use GIS mostly to collect, store, use and evaluate data related to geography.

Due to the reasons mentioned above, municipalities need a new tool or a technology to deal with those data in order to increase their efficiency. The only tool and technology to meet their requirements is GIS tool. Using such tools and techniques, municipalities reduce their work load and time spent. Also, they provide better services and make more profits. On the other hand, they have to share data and information with other governmental organizations and citizens. Therefore, they have to obey some rules and regulations enforced by the governmental organizations to bring standardization and to have high quality data and information. Also, to be more competitive, they serve those data to their citizens and in this way, they provide better services to their citizens. Because of those regulations, social requirements and special reasons, not only municipalities but also all governmental organizations, which are dealing with spatial data and information, have to use GIS technologies.

The objectives of the study are to understand the diffusion of GIS at municipalities in İstanbul, to determine failure and success factors during implementation, to find out required infrastructure for a successful GIS implementation, to understand the problems related with GIS diffusion and finally to

figure out the future expectations of İstanbul municipalities from GIS.

In the literature there are many studies about "Implementation of GIS in a Municipality" in Europe, Canada, Australia and USA, but there are only a few studies about that topic in Turkey. For this purpose, interviews with experts and surveys with municipalities were conducted to study about "The Diffusion of GIS at Municipalities in İstanbul". The interviews were held with three different groups which are academicians, employees in private sector and IT/IS managers in municipalities. The questionnaire was held online with the Metropolitan Municipality of İstanbul and 39 İstanbul districts and the data collected were analyzed through various statistical methods using SPSS 15.

2 BACKGROUND

In this section, data, information, knowledge and GIS terms are discussed in order to have a clear understanding of the study.

2.1 Data, Information and Knowledge

Data is converted into information after processing. According to Hicks (1993), information is a processed version of data which is meaningful to a decision maker. Data are meaningless without processing and interpretation. Therefore, it should be converted into a new form that is easier to be understood by the users. In this way, the user can understand and use information for their purposes and make decisions with respect to this information. Evaluating data provides a healthier decision for the decision-maker.

Longley et al. (2001) assert that information is distinct from data in terms of selection, organization and preparation for a specific purpose. Information serves some ideas which means an interpreted version of data. As can be seen from the definitions, it is clear that the words data and information have different meanings. The relation between reality, data, information and knowledge is complex (Figure 1).

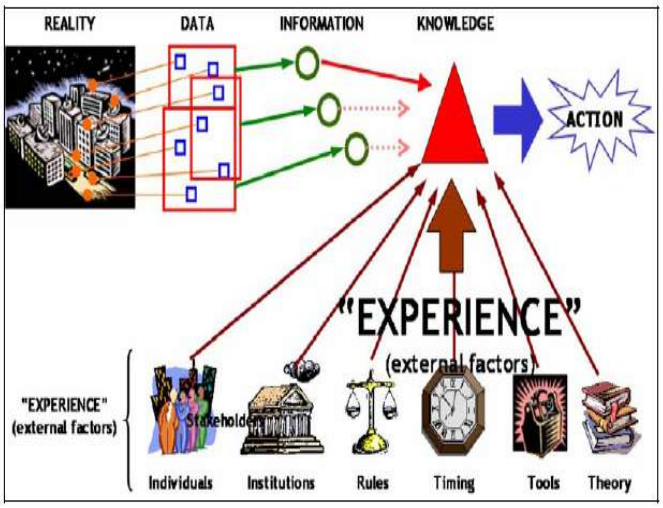

Figure 1. The relation between data, information, and knowledge. (Carrera, 2004)

2.2 Geographic Information System (GIS)

Since GIS is an interdisciplinary method of solution for different areas, there are varying types of GIS definitions with respect to different perspectives. Each profession uses a specific part of GIS extensions or modules; therefore they have different definitions for GIS.

De Man (1988) and Carter (1989) affirm that GIS are perceived as distinctive instances of information system. This is the purest definition of GIS. Indeed, it is clear that information is very important for GIS. GIS mainly consists of two different types of data which are called spatial (geographical) and non-spatial (non-geographical), and has a relational database between these two types of data and has been accepted as a remarkable information system tool.

Dangermond (1988) maintains that GIS comprise five rudimentary parts: data, hardware, software, procedure and people. One wants to use technologies mainly to benefit from them. Indeed, using GIS brings many advantages to governmental and private organizations. Time, efficiency and money are the main advantages of GIS for organizations. Carter (1989) stresses that implementation of GIS requires an organizational structure which combines technology, database, expertise and ongoing financial support. It is for certain that GIS will also bring some financial advantages in time for the organizations using GIS.

3 LITERATURE SURVEY

In the diffusion cycle, the technology is to be accepted and implementation phase is to be achieved following the satisfaction of the citizens or end users. Investing more money, time and people for a new technology brings about more success and implementation evolves into to adoption. Last stage is to develop and invest some more money for a new technology. It means that the new technology is the part of that governmental organization which has to use this technology. After this stage, the new technology not only provides intangible satisfaction for management, end users and citizens; but also provides some tangible benefits. The resources can be used more efficiently and costs of services to the organization are reduced. In accordance with the ideas of Medlin (2001) and Parisot (1995), Rogers' diffusion of innovations theory is the most suitable way of exploring the adoption of technology in higher education. There are five steps of diffusion of a new innovation (Figure 2).

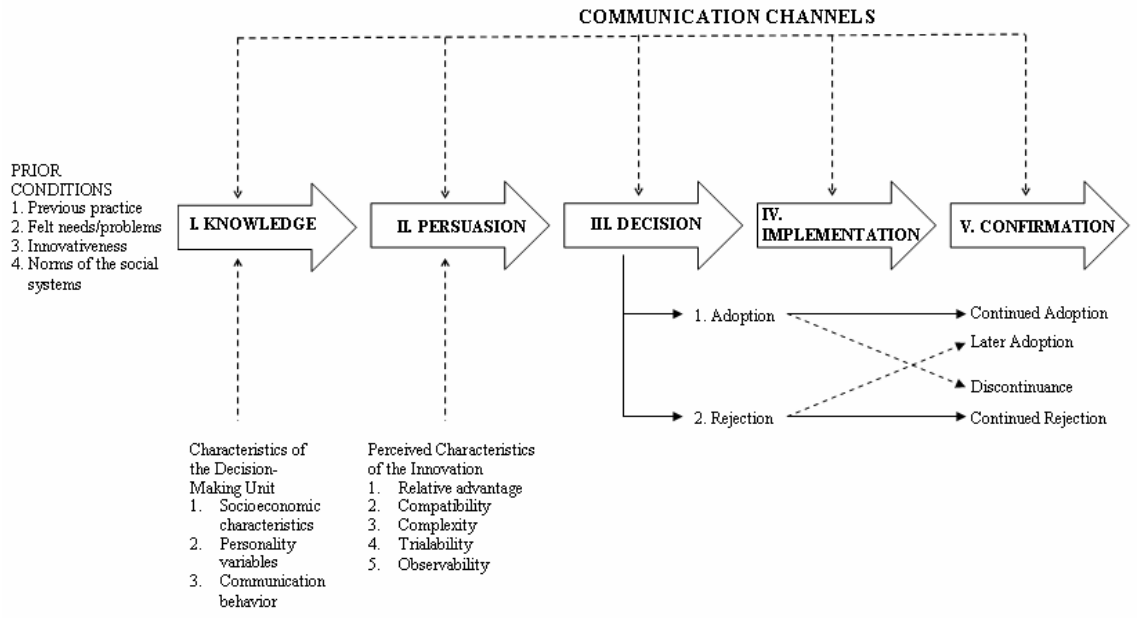

Figure 2. A Model of five stages in the innovation-decision process (Rogers, 2003)

3.1 The Diffusion of GIS at Municipalities in Istanbul

Istanbul is the largest city in Turkey. According to the address-based birth recording system of the Turkish Statistical Institute, the population of the metropolitan municipality, which corresponds to 17.98% of Turkey's population, is 13.26 million as of 2010 and this places Istanbul as the third largest city in Europe after Moscow and London. Since it is the largest and the most crowded city , management of Istanbul is a difficult task. For this reason, it had been divided into different districts throughout history. 8,156,696 people live in the European side and 4,416,867 people live in the Asian side. According to Istanbul Nufus ve Demografik Yapi [Population and Demographic Structure of Istanbul] (n.d.), there are 25 municipalities on the European side and 14 municipalities are on the Asian side.

Municipalities are the representatives of government which encounter with citizens mostly. Their main purpose is to provide better services to citizens pertaining to fresh water, electricity, real estate, tax, natural gases, sewage and more. The complexity of tasks, such as distribution and control of power, fresh water and natural gas, sewage, telephone, school and hospital networks, has been forcing municipalities to find a way to organize these tasks. Besides, some problems about these tasks that are mentioned above occur. For instance, traffic accidents, natural hazards and fire incidents all force the municipalities to come up with fastest and the most efficient solution. In

order to organize these tasks and overcome related problems, appropriate tools and techniques are needed. At this point, GIS is accepted as one of the best solutions for municipalities nowadays.

The awareness for this technology began at the beginning of 1990s; however, it was started to be used at the beginning of 2000s. Municipalities of bigger cities' with respect to their populations, such as Ankara, Bursa, Istanbul, Izmir and Konya, started to exploit the advantage of this technology firstly. However, smaller municipalities have not used it effectively due to lack of awareness and budget. Yomralioglu (2002) says that only some municipalities, such as in Istanbul, Bursa, Ankara, Izmir, Aydin and Antalya, utilize GIS more realistically than the rest.

It is clear that only 4% municipalities attempt to exploit that technology effectively. Should a further research on exploitation of this technology conducted, the percentage will surely increase.

Yomralioglu (2002) challenges the key drives of municipalities, that is awareness of thematical, topographical and administrative structure of all provinces, and adds other motives such as accomplishing health, security, population, communication and road networks, etc. In addition, municipalities actively use GIS especially in solving important local problems such as urban planning, land development, urban management, supervision, and tax collection.

4 THEORITICAL MODEL AND HYPOTHESIS

4.1 Problem Statement

Today, almost all sectors are dealing with GIS technology in one way or another. When these sectors are divided into different parts with respect to their usage level, it is found out that governmental organizations use GIS technology more heavily than private sector. If a comparison is made among governmental organizations, it is seen that municipalities use GIS tools and software mostly with respect to others. Almost all departments use GIS technologies directly or the products of GIS technologies indirectly.

Although municipalities are governmental organizations, they are independent within their internal affairs and policies in Turkey. Therefore, they can easily accept and implement new systems or projects for their use and enjoy the advantages without dealing with too much bureaucracy. There is no competition among municipalities, so they can support each other with their experiences.

4.2 Aim and Objectives

The aim of this study is to explore the usage and diffusion level of GIS at municipalities in İstanbul and opinions of their employees about the following issues:

- Development of GIS at municipalities in İstanbul
- Research about GIS implementation at municipalities in İstanbul and Turkey
- Failure and success factors during implementation of GIS at municipalities in İstanbul based on literature survey, expert opinion and survey results
- Type of infrastructure required for a successful GIS implementation at municipalities in İstanbul
- Kind of problems that may occur during GIS implementation at municipalities in İstanbul
- Anticipation of the future of GIS in the short term (5 years) and long term (10 years) at municipalities in İstanbul

4.3 Key Questions

Based on the objectives, the following research questions are prepared;

- What are the main requirements to implement GIS at municipalities successfully?
- What are the failure and success factors for municipalities during implementation of GIS?
- What kind of purposes are there for using GIS at municipalities?

- What kind of problems may occur during implementation of GIS projects at municipalities?
- Through which processes is GIS implemented at municipalities in İstanbul?
- What are the driving forces for GIS implementation in a municipality?
- What are the strategies that municipalities apply during the implementation process of GIS?
- Who are the actors and what are their roles during implementation of GIS?
- What does GIS bring to a municipality?
- What is the future of GIS at municipalities in İstanbul?

4.4 Hypothesis

Based on the aim and objectives, the following hypotheses are determined (Table 1). Each hypothesis is analyzed with different test.

Table 1. Hypotheses about Diffusion of GIS at Municipalities

NO	HYPOTHESES
H1	There is a relationship between the level of knowledge about GIS and geography- related areas with the success level of GIS diffusion.
H2	There is a relationship between the usage frequencies of GIS in municipalities' departments with the success level of GIS diffusion.
H3	There is a relationship between the levels of acceptance of GIS projects with the success level of GIS diffusion.
H4	There is a difference between municipalities with different longitude of use of GIS in terms of the success of GIS diffusion.
H5	There is a difference between municipalities with different population groups in terms of the success of GIS diffusion.
H6	There is a difference between municipalities with different numbers of employee groups in GIS departments in terms of the success of GIS diffusion.
H7	There is a difference between municipalities with different number of employee groups in municipalities that use GIS tools in terms of the success of GIS diffusion.
H8	There is a difference between municipalities with different satisfaction levels of GIS applications in terms of the success of GIS diffusion.

5 RESEARCH METHODOLOGY

The methodology of this research consists of two important stages. The first stage comprises interviews with the experts of GIS. The second stage comprises a survey focusing on local municipalities of İstanbul

5.1 Interviews

Interviews, which were held with end users, consultants, technical users, developers and managers of municipalities responsible for GIS department or projects, were conducted using face-to-face method.

5.2 Questionnaire

The research was conducted during the spring semester of 2010-2011 by means of a questionnaire which had been developed based on previous researches and theories as well as interviews with GIS experts. Municipalities in İstanbul were decided to be of concern in this study because İstanbul is considered an important research area. Although many of the municipalities use GIS technologies, some municipalities have not used GIS technologies as of the publication date of this study. The questionnaire, which covers the GIS-related departments in municipalities, includes five sections and a total of 36 questions. The questionnaire is distributed to the municipalities in İstanbul via Internet.

6 ANALYSIS AND FINDINGS

6.1 Interviews

In this part, summarized opinions of interviewees are reported under five main headings: overview of GIS, purpose and usage of GIS at municipalities in İstanbul, main problems related with GIS diffusion at municipalities in İstanbul, future of GIS for İstanbul municipalities, and criteria for a successful GIS implementation.

6.2 Purpose and Usage of GIS at Municipalities in Istanbul

- The order of priority in using GIS, in order of first priority to last, is emergency issues such as people in a difficult conditions, fire, ambulance, etc. then citizens, and finally institutions. From parcel-sale and social aid to flooding and property analysis are for what GIS is utilized.
- GIS is about spatial information but MIS is about human information. With the perfect integration of both, it provides services to

citizens with maximum performance. For example, handicapped or educated citizens can easily be followed by the integration of MIS and GIS. In this way, more accurate decisions about them can be made.

- The workload of employees of municipalities in İstanbul has been decreased with the use of GIS. Therefore, this convenience surely is reflected on the citizens. They are now enjoying faster services with higher quality. Since the number of complaints has been decreased, the management is satisfied with this new system.
- GIS is used in every task including numbers, such as road and real estate information. Briefly, it is used in everything that includes geography at municipalities in İstanbul.
- The communication between external institutions and municipalities in İstanbul has increased; so the number of mistakes has decreased. For example, determination of the rate of incomplete declaration and defective buildings is now easier thanks to the usage of GIS at municipalities in İstanbul. In this system, the problems that used to be solved in 3-5 days are dealt with one click.
- Since municipalities are not service-oriented organizations, they use CAD tools just to create maps. Therefore, they waste their time with these tools. Almost 90% of them use CAD tools instead of GIS tools.
- All matters that require the use of spatial analysis are of interest, especially the control of numeric identification, creation of a new numeric identification numbers, problem identification, detection and correction of false addresses, National Address Database System (UAVT) updates, queries of demographic data, and selection of the most appropriate site.

6.3 Main Problems Related with GIS Diffusion at Municipalities in İstanbul

In this part, the interviews are reported with respect to each problem area that has occurred during the diffusion process of GIS. The main problems are as follows:

- Management
- Bureaucratic
- Citizens
- Employee Resistance
- Time
- Budget
- Data
- Infrastructure
- Other Problems

6.4 Future of GIS for İstanbul Municipalities

In this part of study, the future of GIS for municipalities in the short term (5 years) and in the long term (10 years) is discussed.

- GIS is being developed along with the Internet technology, mobile and band communications. To this extent, developments in aerial technology, 3D, video, and cell phone processing units will have a direct impact on GIS adopted by social networks.
- Actually, the users of GIS stay away from databases. There is an increasing trend of using spatial servers, which are the center of GIS management, along with the classical database applications.
- GIS will inevitably be used not only in municipalities but also in all governmental organizations; however, they are not ready in terms of culture and the quality of employees. It is believed that GIS will be used in the daily lives of citizens and municipalities in the near future.
- The importance of local governments and the stress of European Union are increasing every day. For these two reasons, the use of GIS is inevitable for all municipalities in Turkey.

6.5 Criteria for a Successful GIS Implementation

In this part, the criteria for a successful GIS implementation are summarized as follows:

- Management Support
- Perception of Employees
- Data
- In/Out-Sourcing
- Infrastructure
- Bureaucracy

- Project Updates
- Time

6.6 Questionnaire

In this study, data are collected using online questionnaires administered to municipalities in İstanbul and analyzed by using descriptive statistics, reliability tests, linear regression analyses, and ANOVA to test the hypotheses and provide findings. In addition, some graphical representations are used to explain the use of GIS at municipalities in İstanbul.

33 participants (82%) accept that ease of CAD usage is one of the most cited advantages of GIS tools.

21 municipalities (%53) examine successful projects before GIS implementation.

17 municipalities (%43) are planning to invest more money for development of several applications in the future.

Non-user municipalities have several expectations regarding the features of GIS tools. 5 of them (%71) claim that "Reasonable Budget", "Support of Top Management" and "Availability of Useful Digital Data" are the most important reasons that force municipalities to use GIS in the future. On the other hand, only 1 of them (14%) claims that there should be more functional GIS products.

14 municipalities (%35) state that IT/IS department is responsible for GIS tools and projects.

The data indicate that 39 municipalities (%98) outsource GIS projects to consultancy firms. Also, 20 municipalities (%50) outsource GIS projects to private companies. On the contrary, 10 municipalities (%25) implement GIS projects in-house. Finally, they believe that the effect of universities and governmental organizations on municipalities' decision is worthless.

6.7 Reliability

A commonly accepted rule of thumb for describing internal consistency by using Cronbach's alpha is shown as $\alpha>0.7$. To test each hypothesis, reliability analysis is conducted. After finding Cronbach's α (alpha) value

for each piece of data, regression analysis is made for the data whose Cronbach's α value is higher than 0.7 . The Cronbach's α (alpha) value for each piece of data is above the threshold (Table 2).

Table 2. Cronbach's α (Alpha) Value for each Data

Hypothesis	Number of Item	Cronbach's α (Alpha)
Knowledge about GIS-related areas	7	0.777
Frequency of GIS usage	8	0.770
Acceptance of GIS projects	12	0.867

6.8 Linear Regression Analysis

Linear regression analysis is used for specifying the one to one relations between two or more different variables. The linear regression's dependent variable is the success in diffusion of GIS and the independent variables vary. Regression analysis is used to test Hypothesis 1, 2 and 3.

According to the F statistics significance (Sig.) values, all of the constructs are meaningful because they are below 0.05, which means that these constructs can be accepted as statistically meaningful with the confidence level of %95 and the GIS diffusion success can be explained by the related hypotheses (Table 3). The R2 values for the significant constructs show the percentage of the variance in GIS project success which is explained by the related hypotheses. B values indicate the path coefficients which mean that 1 unit change in the related independent variables will affect the GIS project success by the proportion of B values.

Hypothesis 1: Table 3 shows the result of regression analysis for Hypotheses 1. Knowledge factor about GIS-related areas explains %33 of the variance in diffusion success, and has a positive impact by the

proportion of 1.466 on GIS diffusion success.

Hypothesis 2: The result of regression analysis for Hypothesis 2 explains the frequency of GIS use by the departments of municipalities (Table 3). The significance value for this relation coefficient is less than 0.01 (Sig= 0.000); therefore, it can be concluded that there is a significant relationship between success scores and the frequency of GIS use at municipalities. Please note that the relationship is positive: as the intensity of GIS use at municipalities increases, the success in GIS diffusion increases. Therefore, our hypothesis is supported: as usage of GIS increases, so does success in the diffusion.

Hypothesis 3: For GIS diffusion to be successful, acceptance factor of GIS projects explains %54 of the variance and has a positive impact by the proportion of 0.486 on GIS diffusion success (Table 3). It is shown that there is a positive relationship between success and knowledge about GIS-related areas.

Table 3. Linear Regression Analysis of Hypotheses

Hypothesis Explanation	R^2	*Sig.*	*B*	*Hypothesis*	*Hypothesis Acceptance*
Knowledge about GIS-related areas	0.331	0.001	1.466	H1	Accepted
Frequency of GIS usage	0.619	0.000	0.624	H2	Accepted
Acceptance of GIS projects	0.535	0.000	0.486	H3	Accepted

Hypothesis 4: To test Hypothesis 4, ANOVA analysis has been conducted so that GIS diffusion success is differentiated according to their usage time. The data indicate that some municipalities have been using GIS tools and application for long time, but some other municipalities are more successful in garnering benefits from GIS projects (Table 4).

Table 4. ANOVA for Duration of Use of GIS and Success in GIS Diffusion

		Mean	**F/t Value**	**Sig.**
Hypothesis 4 (Rejected)	0-1 year	3.7326	F=0.291	0.881
	1-2 years	4.3032		
	2-5 years	3.9746		
	5-10 years	4.0500		
	10-30 years	3.8750		

It can be seen that the hypothesis is rejected since the significance value (.881) is higher than .05. Therefore, there is no difference among using various GIS tools for different durations in terms of their average success.

Hypothesis 5: To test Hypothesis 5, ANOVA analysis has been conducted so that GIS diffusion success is differentiated according to the number of inhabitants in a specific municipality. Larger municipalities in Istanbul are indeed using GIS techniques but there is no concrete relation between the size of municipalities and GIS success (Table 5). Even if they are the early adopters of GIS, it does not give rise to a successful diffusion. It can be concluded from Table 7 that the largest group of GIS users, who use GIS in several departments at least, is between 50.000 and 150.000. On the other hand, relatively smaller organizations implement GIS in GIS-related departments rather than in the entire organization.

Table 5. ANOVA for Population Groups of Municipalities and Success in GIS Diffusion

		Mean	**F/t Value**	**Sig.**
Hypothesis (Rejected)	Less than 20,000 people	3.3750	F=0.377	0.823
	20,000-50,000 people	3.6303		
	50,000-150,000 people	4.1771		
	150,000-300,000 people	3.9531		
	300,000-500,000 people	4.0021		
	More than 500,000 people	4.0010		

It can be seen that the hypothesis is rejected since the significance value (.823) is higher than .05. Therefore, there is no difference among using various GIS tools in terms of population groups living in a specific municipality.

Hypothesis 6: In addition to the size of municipalities, it is worthwhile to examine

the number of GIS users in municipalities to see whether there is an effect on success of GIS diffusion or not. To test Hypothesis 6, ANOVA analysis has been conducted so that GIS diffusion success is differentiated according to the number of employees in GIS departments of municipalities. Similar to the finding regarding direct users of GIS, the total number of GIS users, no matter if they use it directly or indirectly, have no effect on success of GIS diffusion (Table 6).

Table 6. ANOVA for Number of Employees in GIS Department and Success in GIS Diffusion

		Mean	F/t Value	Sig.
Hypothesis 6 (Rejected)	Less than 5 employees	3.9624	F=0.773	0.662
	6-10 employees	3.5122		
	11-50 employees	4.4216		
	More than 50 employees	4.5000		

It can be seen that the hypothesis is rejected since the significance value (.662) is higher than .05. Therefore, there is no difference among the number of employees working in GIS-related departments in terms of success in GIS diffusion.

Hypothesis 7: To test Hypothesis 7, ANOVA analysis has been conducted so that GIS diffusion success is differentiated according to the number of employees using GIS in a municipality.

Table 7. ANOVA for Number Employees in Municipalities and Success in GIS Diffusion

		Mean	F/t Value	Sig.
Hypothesis 7 (Rejected)	Less than 25 employees	3.5744	F=1.984	0.147
	26-50 employees	4.0751		
	51-100 employees	4.6741		
	More than 100 employees	4.3438		

The data indicate that the hypothesis is rejected since the significance value (.147) is higher than .05 (Table 7). Therefore, there is no difference among the number of employees in municipalities using GIS in terms of their success in GIS diffusion.

Hypothesis 8: To test Hypothesis 8, ANOVA analysis has been conducted so that GIS success is differentiated according to the satisfaction of GIS projects at municipalities. Satisfaction and success are strongly correlated with each other. If there is satisfaction about new tools or techniques, they will inevitably be successful at the end (Table 8).

Table 8. ANOVA for Satisfaction Levels of GIS Applications and Success in GIS Diffusion

		Mean	F/t Value	Sig.
Hypothesis 8 (Accepted)	Poor	1.6250	F=22.352	0.000
	Fair	3.9792		
	Good	3.8685		
	Very good	4.6317		

It can be seen that the hypothesis is accepted since the significance value (.000) is lower than .05. Therefore, there is a difference among satisfaction levels of municipalities with GIS in terms of their success in GIS diffusion.

7 CONCLUSION, IMPLICATIONS AND LIMITATIONS

This study intends to develop a better understanding of the nature and success of GIS diffusion at municipalities in Istanbul. An extensive survey has been conducted about GIS, diffusion process of GIS, the usage of GIS and the future of GIS. The objectives are to determine the benefits of GIS use and the barriers to adoption at municipalities in Istanbul. Success and failure factors, as well as a better understanding of development of GIS diffusion in time, were identified. Then, the interviews are held with the experts of GIS in the field. After the survey and interviews, diffusion of GIS is analyzed in detail, hypotheses are framed and a questionnaire was generated and delivered to municipalities in the online environment. At the end of data gathering process, descriptive statistics, reliability tests, regression and ANOVA analyses are performed by using SPSS 15 with data collected from 40 municipalities. Since Istanbul is the largest city in Turkey with its population of nearly 15 million people, the questionnaire is focused on municipalities in Istanbul. All

municipalities have participated in this study. Based on the research findings of analyses in previous sections, the conclusions are as follows:

- Since GIS tools have concrete superiority over CAD tools, GIS is useful and should be used in all departments by all municipalities in Turkey.
- Almost all departments of municipalities should use GIS tools for some applications.
- Awareness is a key factor for a successful implementation but education is the least important factor to affect success. Examining successful projects and successful municipalities are the most important factors which should be evaluated very carefully before implementation.
- In implementing GIS systems, some municipalities just buy a system from a supplier end introduce this into the organization.
- Budget, managerial support, useful data and number and quality of employees are key factors for non-user municipalities to use GIS in the future.
- Technical departments and GIS-related departments within a municipality take the initiative to implement GIS tools in their departments and the entire organization.
- Municipalities are not the only decision-makers.
- Live projects will be successful eventually which refers to the acceptance of that project and cultural norms at municipalities.
- Knowledge and experience exchange should be increased among municipalities.
- Because of their requirements and power, municipalities are perfect organizations to use GIS tools.
- Municipalities mainly perform registration and maintenance functions instead of support in the decision-making process.
- Another important conclusion is that half of the municipalities, which have started to implement GIS, accomplish this without a vision or a plan for the future.

An important failure factor to implement GIS is the fact that 49% of the GIS users do not have a policy.

7.1 Success and Failure Factors

The diffusion process of IT/IS technologies increases the interaction between organizations and citizens. IT/IS technologies will be accepted and diffused in a governmental organizations if its advantages are proven. Before and after implementing IT/IS technologies, the advantages and disadvantages of them should be clearly defined.

Success factors, as a summary of findings of questionnaires, are as follows:
- Determination and support of the management and the organization
- Desire to accept changes
- Examination of successful projects and municipalities
- Personnel capacity and education
- The leader who puts GIS on the agenda
- Accurate consultant selection
- Budget
- High quality of data
- Live projects

Failure factors, as a summary of findings of questionnaires, are as follows:
- Low quality and redundant data
- Time not decided upon carefully
- Not enough personnel
- Neither attention nor support of the management.
- Not enough budget
- Departmental barriers
- Changes of tasks

Rockfall Hazard Zonation based on Weights of Evidence Modeling of the Doroud –Andimeshk Railway Track, NW Iran

H. Hassani, M. Gholinezhad
Amirkabir University of Technology, Faculty of Mining and Metallurgical Engineering, Tehran, Islamic Republic of Iran

ABSTRACT A significant proportion of national and infrastructure investment is devoted to construction activities in nature. These funds must be selected with sufficient confidence to ensure survival and duration of vital interest. In this study, after collecting information including slope angle, lithology, fault length, river length, road length, rainfall, earthquake and vegetation, the packed cell map is processed in Geographical Information System (GIS). Finally, Rockfall Hazard Zonation (RHZ) in Doroud-Andimeshk railway is presented. The zonation map of the area is prepared using the Mora-Varson method and is validated using the AHP method. The slope angle is obtained from a digital elevation map of the area. The1/25000 topography map is used to obtain the digital elevation map. The lithology map is prepared using the 1/100000 geological map. The fault length, road length, river length and vegetation are obtained from the Landsat satellite map. Rainfall and earthquake data are obtained from the meteorology center and geological survey of Iran. Finally, the area with high risk zones was introduced.

Keywords:Zonation map, GIS, Slope stability, Rockfall, AHP method, Doroud Andimeshk

1 INTRODUCTION:

Rockfall zonation map is the first step in any slope stabilization program (Chacon, 2006). Nowadays the application of GIS mapping, as a quick way to achieve sensitivity maps, has become widespread. Anbalagan (1996) concluded that identifying unstable zones and helping the planner to select development locations for the construction of roads and residential areas in the early stages of planning is very useful and improves safety (Chacon, 2006). Rockfall occur for two groups of reasons as shown in figure 1.

Ahmadi et al. (2004) used the multivariable regression method and the hierarchical analysis method to investigate which parameters significantly influenced the occurrence and extent of rockfall.

In this study, 7 parameters are investigated. The hierarchical analysis method appear to be more efficient than the multivariable regression methods at identifying significant factors (Ahmadi et al.2004).

In order to classify different causes of rockfall, methods such as the Mora-Varson and Kanagava have been employed. In this study according to structural conditions, lithological conditions, topographical conditions and climatological conditions of the studied area are evaluated to estimate effective factors on instabilities. Scoring of each parameter is done using network map. After collecting different information including slope angle, lithology, fault length, rivers length, road length, rainfall, earthquake and vegetation, data are processed in a packed cell map geographical information system and eventually the rockfall zonation map of Doroud–Andimeshk railway is presented.

2 STUDY AREA

The Doroud-Andimeshk railway, with a length of 215 kilometers is located in Lorestan and Khuzestan province in south of Iran. The Lorestan province is located in western of Iran and has rough topography. This railway is a part of the route that connects Bandare-Emam in the south to Tehran the capital of Iran. It begins from the Khuzestan plain and moves onto the sidelines of Dez River from the heart of

Zagros mountains. It has very long strategic bridges such astheTelezang bridge and Absirom bridge, Shahbazan bridge, Tooh bridge, Bishe bridge and Abmamon bridge. It has over 130 tunnels, with Tunnel 22 and Tunnel 23 having lengths of over 2500 meters being the longest railway tunnels in the Middle East and covering 60 kilometers of road. About 10000 passengers travel through this route each day.

The studied area is located in the Zagros structural zone including high Zagros, folded Zagros and the Khuzestan plain. The main faults in the area are the Zagros Fault, the Main young Zagros Fault, the main young Doroud fault and the Doroud fault. The area of jungles around Dez and Sezar watershed with a railway track parallel to these rivers is about 150000 hectares. In addition to these jungles, in the study area there are 250000 hectares of pasture. The Doroud-Andimeshk district vegetation is varied.

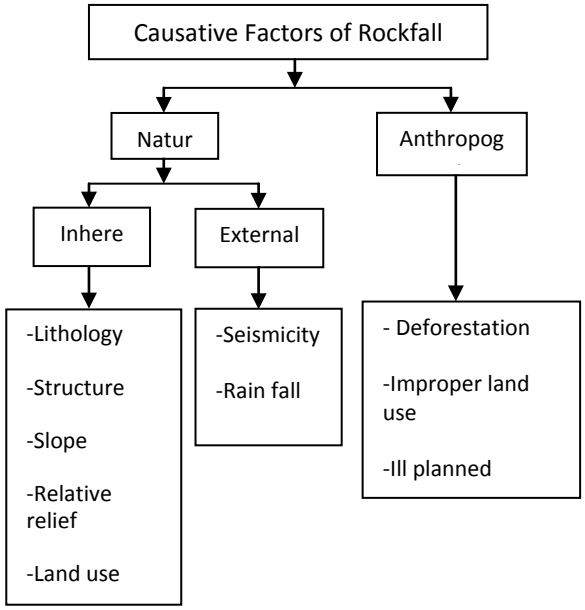

Figure 1. Flowchart showing causative factors of rockfall (Manoj and Anbalagan, 2010).

3 METHODOLOGY

3.1 Evaluation And Rating Of Affective Factors On Slope Domain Instabilities

Various factors such as topographical conditions, lithology, groundwater regime, tectonics land-use change, rainfalland vegetation may interact to cause an increase in slope instability.In this regard, the role of human activity on the slope's instability should be considered. Generally, factors that cause slope instabilityare classified into two groups, environmental and intrinsic factors. Intrinsic factors include the composition, texture and fabric of material and geometrical shape of the slope. Environmental factors include trenching, excavation, the rapid loss of water,rainfall, vegetation and weathering, freezing, vibrations and shock caused by earthquakes. In this study, all factors affecting the instability of slopes were evaluated. Seven factors are considered as significant influencesslope instability in the studied area. These factors includeslope angle, lithology, material, structural elements, rainfall and earthquakes.

3.1.1 Slope angle

The slope angle is one of the main factors influencing slope failures and can be divided into two categories: natural and artificial [4].

In order to classify slopes in the studied area, a 1:25000 topography map is used. To determine slope angle and slope strike in the studied area,the Digital Elevation Model (DEM)of the district is initially prepared from topography maps using ArcGIS. Then,the slope angle of the studied area is determined. In terms of angle,regarding slope angle, slopes are classified into five categories. Theoretically assuming all other factors being equal, the risk of rockfall in the area where slopes are greater is higher than other areas. Regarding the angle, slopes were classified into five categories.

Table 1. Effect of slope angle on instability of slopes. (F_I)

>45	36-45	26-35	16-25	5-15	**Slope angle(degree)**
Very high	**High**	**medium**	**low**	**Very low**	**Effect of instability on slopes.**
5	**4**	**3**	**2**	**1**	**coefficient**

3.1.2 Lithology

A combination of material's texture, fabricand slope materials, materials forming slopesplay an important role in stabilities and instabilities. Slopes having weak rocks with low shear strength are more likely to failure (Hassani, 2008).

Standard penetration test (SPT) is used to determine the permeability coefficient and inflation of formation. Different types of rock mechanic tests are used to determine porosity, water absorption, shear strength and compressive strength. Table 2 shows that existing materials in terms of behaviour and resistance slippage are generally classified into five groups.

Table 2. Five type of lithology in the studied area. From 1 to 5 the risk of failure is increasing

Group	Description
1	Massive limestone and thick limestone. Massive dolomite and thick dolomite. Conglomerate with silicic cement
2	sandstone and quartzitic limestone and sandstone having limestone. Siltstone and thin layers of limestone.
3	Marl limestone, clay limestone, quartzitic sandstones, piritic shales and massive limestones.
4	Shale, andesite, gipsy marl and gips.
5	Quaternary sedimentary, sand and gravel

3.1.3 River's length and Road's length

Analysing and evaluating the slope in the studied area due to limitations of ups and downs, in the road's design, excavation and trench design in the path is inevitable.Due to this operation result inthe creation of artificial slopes with a minimum dip of 45 degreesin the path.

Meteoric water is also another driving factor in creating instability of slopes. Due to the instabilities occurring in the area, the factors related to trench's length, stream's length and river's length have a decisive role. Accordingly, the density of roads and rivers have been ranked and listed in table 3.

3.1.4 Rainfall

The effect of rainfall in increasing the instability and slope's movement was investigated. The annual average rate of rainfall map of the past 40 years is used. The effect of rainfall is considered in the form of an increase of the soil's moisture due tothe rainfall increasing rate and in the form of factors causing earth movements. The effect of rainfall in slope instability is shown in table 4.

Table 3. Effect of road's length and river's length on instability**.**

>2250	1500-2250	750-1500	250-750	<750	River's length and road's length
Very high	High	Medium	Low	Very low	Effects on instability
5	4	3	2	1	(F_D)

Table 4. Effect of annual rate of rainfall in rockfall**.**

>600	500-600	400-500	300-400	<300	Rainfall(mm)
Very high	High	moderate	low	Very low	Rate of effect on instability
5	4	3	2	1	F_r

3.1.5 Earthquake

One of the driving factors increasing instability in the studied area is earthquakes. Earthquake's forces cause rupture and primary cracks in slopes. Lack of complete rupture and slip is lack of continuity of force and if the earthquake occurs for the second time, the depth and rate of the crack's opening will be increased. However, after the earthquake occurs, some other factors affect it and the weight of the mass causes completion of the earthquake effect on creating instability. Slopesaredirectly under the effect of earthquake's acceleration. The maximum horizontal acceleration that affects

the studied area is classified in table 5.

Table 5. Effect of earthquake relative risk (F_R).

Very high	high	moderate	low	Very low	Relative risk
5	4	3	2	1	F_R

3.1.6 Vegetation

Vegetation is an indirect factor on slope's stability. Barren slopes without vegetation have more potential to slide and fast erosion and instability to the forested area. In other words, meadows and forests decrease the erosion process. Roots penetrate the soil causing stability of slopes. Moisture in the soil mass is one of the important factors in reaching the mass to saturation and creation of earthquakes.The type and amount of vegetation is determined by the Landsat satellite images. Vegetation of the area was divided into five categories. The classification results are shown in table 6. Generally, by increasing the vegetation, the risk of falling rock decreases.

Table 6. Effect of vegetation (F_{Lc}).

low	Relatively low	Moderate	Relatively high	High	vegetation
5	4	3	2	1	(F_{lc})

3.2 Rockfall Hazard Zonation Map

To determine relative importance and influence of effective factors on the rockfall zonation map, the weighting method or scoring method is commonly used. In this method, based on engineering judgment and existing experience, each of the effective factors are given weight and score. During long and extensive studies on the sides of the railway in different parts of the studied area, the number of old and young rockfall were identified. The results of this part of the study were used as the calibration factor of this method in confirmation to identify factors of increasing the potential of rockfall in the studied area. Regarding the specific circumstances of the area, effective factors on instability of slopes, including lithology, slope angle, road and river,faults, rainfall, and earthquake were investigated. These factors together are in different conditions and due to the degree of relative risk of each of these factors, different influences on the instability of slopes is observed. The area was divided into a network of neat square cells with dimensions of 250*250 m^2 and on a scale of 1:25000 and using the results of classifying effective factors on instability, the instability's score for each unit was determined. Regarding the influence of the degree of each factor on slope instability, an appropriate coefficient with a rate of influence of each factor on slope instability was considered. Regarding the effective factors on slope instability, this general relationship for the studied area can be considered.

$$RHZ = (C_L \times F_L) + (C_I \times F_I) + (C_F \times F_F) + (C_D \times F_D) + (C_R \times F_R) + (C_S \times F_S) + (C_{LC} \times F_{LC}) \quad (1)$$

In the above formula, F_L=Lithology factor, F_i=slope angle factor, F_f=fault length factor F_D= road's length and river's length factor, F_{ir}=rainfall factor, F_s=earthquake relative risk, and $F_{LC=}$vegetation factor. C= coefficient that shows the importance of each factor on instability. Values obtained for C related to the each factor, shown in table 7.

Table 7. Values related to relative importance coefficient in the study area (C)

C_{lc}	C_s	C_r	C_d	C_f	C_i	C_l	coefficient
0.75	1.6	1	0.75	1.2	1	1.5	value

In exerting the coefficient in each of seven effective factors in slopes instability, value of lithology coefficient(c_l), slope angle,(ci), fault(c_f) road and river(c_d), rainfall(c_r), earthquake coefficient(c_s), and vegetation coefficient(c_{lc}) is determined and exerted in each unit.

3.3 Application Of AHP Method In Validation Of Coefficients

In the models such as linear programming, integer programming, nonlinear programming, allocation model and classical models, when decisions are analyzed based on several criterion, the results are acceptable and satisfactory. Regarding to the Multi-criterion decision models such as SAW, TOPSIS, Electere and AHP, the AHP method has been used for validation on this paper.

3.3.1 AHP method

The Analytic Hierarchy Process (AHP) is a multi-criteria decision making approach and was introduced by Saaty .The AHP has attracted the interest of many researchers mainly due to the nice mathematical properties of the method and the fact that the required input data are rather easy to obtain. The AHP is a decision support tool which can be used to solve complex decision problems. It uses a multi-level hierarchical structure of objectives, criteria, sub criteria, and alternatives. The data are derived by using a set of pair wise comparisons. These comparisons are used to obtain the weights of importance of the decision criteria, and the relative performance measures of the alternatives in terms of each individual decision criterion. If the comparisons are not perfectly consistent, then it provides a mechanism for improving consistency.

The Analytical Hierarchy Process or AHP was first developed by Professor Thomas L. Saaty in the 1970's and since that time has received wide application in a variety of areas. AHP has been applied for a vast number of areas, but it was not applied for the problem that has been taken up in this paper. Thomas L. Saaty (1980) has explained about Hierarchies, multiple objectives and Fuzzy sets . Patric T.Harker (1989) explained AHP in detail as an art of Science and Decision-making. R.Ramanathan and L.S.Ganesh (1994) used group preference aggregation methods employed in AHP by deriving members' weightages. AHP has been applied to many areas but problem chosen presently was not taken into consideration earlier in the literature.

3.3.2 AHP algorithms

It includes determining the goal, selecting important indicators, determining the options, and pair comparison matrix of indicators. Then, the paired comparisons matrix is normalized. To do this, each of the elements of the previous stage matrix is divided by the sum of the column. The matrix calculated by this method is called the normalized matrix. Then the relative weight of each index is calculated using the arithmetic average of each line of the normalized matrix. Then the paired comparisons matrix of options is determined and then the normalized matrix and relative weights are separately calculated for each index.

3.3.3 Option rating

Rating is done by multiplying the relative weight matrix of the index to the relative weight matrix of index and rating based on the number of multiplied matrix. At this stage rating is finished.

3.3.4 Calculation of incompatibility rate

Determine if there is compatibility between the paired comparisons or not.
Weight summation factor (wsv)= paired comparison matrix (D)*relative weights vector
WSV is divided by the relative weight of index to calculate compatibility vector.

3.3.5 Calculate the arithmetic mean

CV elements which are shown by:

- Incompatibility index calculation
- $II=(\lambda_{max} - n) / (n-1)$ (2)

N shows number of variables.

- Incompatibility rate calculation

$IR=II/IRI$ (3)

Which IRI is calculated from Ttable 8.

Table 8. IRI values based on number of variables

IRI	N
0	1
0	2
0.6	3
0.9	4
1.12	5
1.24	6
1.32	7
1.41	8
1.45	9
1.45	10

This operation is separately done for options and index. If IR is smaller than 0.1, then there is reasonable compatibility between the paired comparisons. In this study, the AHP method is used as rockfall and rockfall zoning in the Lorestan railway. First the relationship between parameters should be determined. Effective factors in rockfall are: B_1: lithology factor. B_2: slope angle factor, B_3: Fault length factor, B_4: Road length factor and river length factor. B_5: rainfall rate factor B_6: earthquake relative risk factor, B_7: vegetation factor.

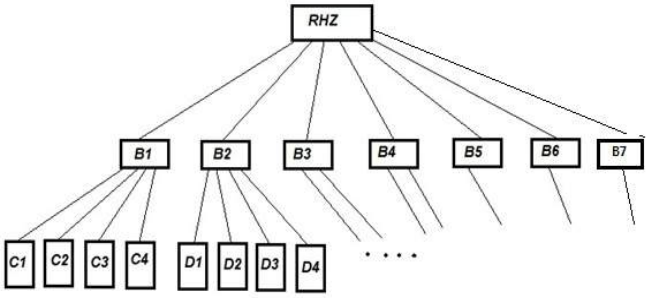

Figure 2. Flowchart of relationship between effective parameters in rockfall.

B coefficients show the importance of each effective factor on instability. Values are obtained in the studied area with regard to studies using research experiences and engineering judgments in the pattern area. In order to validate the coefficients, the stage related to the AHP method is done on the B coefficients. Results show that the AHP method confirms these coefficients.

3.3.6 Rockfall hazard zonation map (RHZ) in the Lorestan railway

In previous sections, each of the effective factors in instability and rockfall in the Lorestan railway in the packed cell map using ArcGIs is separately done. In this section, based on information and results obtained up to this stage, all information after processing with ArcGis is integrated in the packed cell map and the Rockfall hazard zonation map is obtained. Based on RHZ, the studied area is divided into five regions in terms of instability. 1- very high 2- high 3- medium 4- low 5- without risk. The number of cells in each region is shown in Figure 3.

Table 9. Risk ability rate (instability index) of slopes in the studied area.

Scores of five zones					**RHZ values**
24.42–27.15	21.69 – 24.42	18/96 – 21/69	16.23 – 18.96	13.5 – 16.23	
Very high	High	Medium	low	Without risk	Risk rate
13.06	85.625	260.75	291.43	93.54	Area (Km^2)
1.85	12.13	36.94	41.29	7.7	Cover percentage

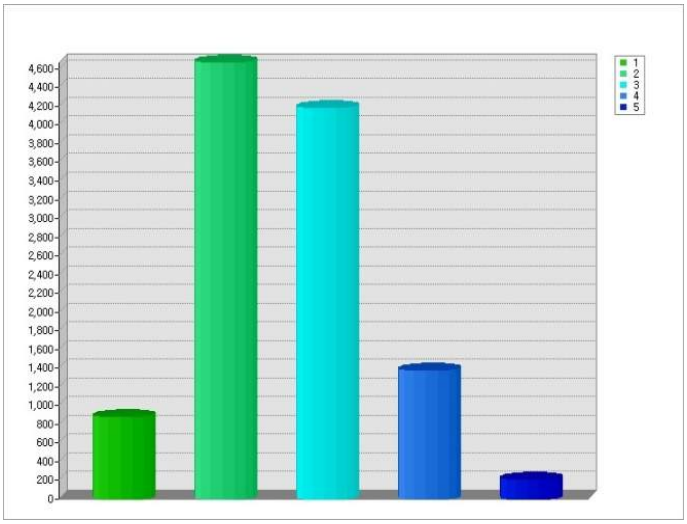

Figure 3. Graphs of cells in packed cell map of RHZ

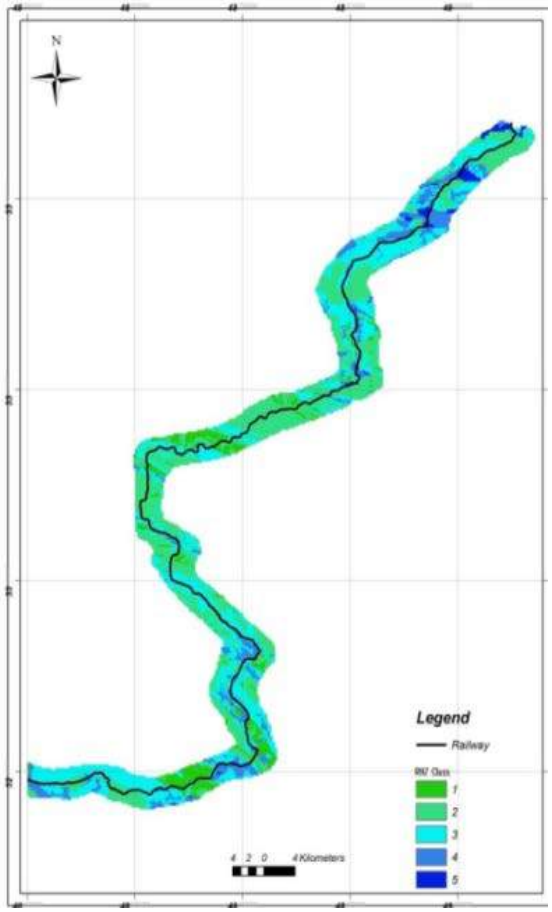

Figure 4. Rockfall zonation map in the studied area

4. CONCLUSION

The Rockfall hazard zonation map plan in Lorestan railway is an applicable developmental project, the results of which determine the regions with a potential of slope instability. Results obtained from this project can be the basis for selection of safe areas for construction of roads and railways. It is necessary that the studied area will be investigated in details and on larger scales. Rockfall is the result of a set of main and subsidiary factors and one factor can rarely cause this phenomenon alone. In forecasting and rockfall hazard zonation in a map, only the methods give good responses that have a real role on effective factors in this destructive phenomenon. In this study, with seven factors: 1- slope angle 2- lithology 3- fault's length 4- road and river length 5- Rainfal6- earthquake and 7- vegetation and using the Mora Varson's method the rockfall hazard zonation map was acquired and the map divided to 5 categories. Finally, the areas with moderate risk, high risk and critical risk were identified. After field checking and more studies, 43 risky points with moderate to critical hazard were determined and reported to Iranian railway research center.

5 ACKNOWLEDGMENT

We acknowledge those who helped us during this research, including the authority and management of the mining and metallurgy engineering faculty of Amirkabir University of Technology, and the railway research center of the Islamic Republic of Iran that helped us in collecting data and doing this research

Surface Displacement Monitoring - Using Satellite Insar for Mining Operations

D. Colombo
Tele-Rilevamento Europa TRE srl, Ripa di Porta Ticinese 79, 20143 Milano, Italy

ABSTRACT InSAR (Interferometric Synthetic Aperture Radar) uses satellite radar imagery to precisely measure ground deformation. TRE developed advanced techniques, PSInSAR™ and subsequently SqueeSAR™, as a standard monitoring tools in a number of applications: natural hazards, geothermal, oil and gas, mining, urban and infrastructures monitoring.

Thanks to its capability in detecting millimeter-to-meter level displacements over long periods and large areas, SqueeSAR™ analysis can be considered complementary to conventional geological and geomorphological studies in displacement detection and monitoring, supporting also the effectiveness of landslide and subsidence inventories at regional scale.

In this presentation, we would like to present some results obtained in the mining sector; as a matter of fact these data has been widely used in open pit operations for slope instability detection and to monitor waste piles and tailing ponds.

In order to give consistency to these statements, after a brief introduction on the capabilities of the technology, a set of examples will be presented taking into account lots of different displacement phenomena.

Some examples over mining areas are presented. In the case of open pit, the greater attention would be put on the immediate surroundings of the pit and on the nearby facilities (tailing ponds and waste piles); on the other hand, surface effects of underground mining - mainly in terms of subsidence - are being measured with millimeter accuracy.

Radar imagery can detect ground displacements that could threaten the integrity and safety of road and rail infrastructure (both at grade and elevated). By identifying natural and man-made ground measurement points, and using only remote sensed data, SqueeSAR™ maps millimeter displacements along the entire length of road and rail networks, aiding risk assessments and highlighting areas that may require maintenance.

1 INTRODUCTION

In the past, constant monitoring programs have been applied to small areas of current operations with the deployment of expensive ground based monitoring equipment. The cost of equipment and management of the complex data from multiple systems limited full mine site coverage. The increase in modern SAR satellites with better revisit times and ground resolutions has brought this technology to the forefront of monitoring mine site deformation on a constant basis. Advanced algorithms have brought processing times down and provide better precision. This paper addresses these advantages.

Over the last two decades, InSAR techniques progressively evolved from the use of differential interferograms (Massonnet et al., 1998; Carnec et al., 2000) to Persistent Scatterers Interferometry (Ferretti et al. 2001, Berardino et al., 2002; Werner et al. 2003; Costantini et al., 2008, Ferretti et al. 2011). PSI in fact overcomes limitations related to the atmospheric contributions affecting DInSAR standard technique and

allows to reach millimetre precision. Compared to conventional surveying methods, PSI provides higher spatial resolution at lower cost, being particularly convenient for wide areas monitoring. This is particularly true in urban and mining areas, where large number of reflecting features leads into a very dense distribution of measurement points (MP) (up to 100.000/km2).

After a brief technology overview, we present a case study over a mining site, where satellite InSAR has been used to detect and measure instabilities in the pit, over the tailings dams and the waste piles. Infrastructure monitoring is another main topic for PSI technique, both in mining areas and where tunnelling occurs; we present two case studies of metro lines tunnelling monitoring with SqueeSAR™, the first of PSI techniques, in different urban context. SqueeSAR™ has been already applied in several projects related to underground tunnelling (mainly TAV railway tunnels) and resulted to be a useful tool in all stages of a tunnelling project, from design to construction and management.

2 TECHNOLOGY OVERVIEW

InSAR Interferometric Synthetic Aperture Radar (InSAR) is a remote sensing technique that measures surface displacements. Radar sensors, mounted on dedicated SAR satellites, transmit radar signals toward the earth, some of which reflect off objects on the ground, bouncing back to the satellite. These back scattered signals are captured by the satellite's sensors and are used to compile radar images of the earth's surface. Both the amplitude and phase of the 'Back Scattered' signal are recorded.

The phase information from a pair of images is compared to detect very small changes in the surface profile. These changes relate to displacement that occurred between the acquisition dates of the pairs of images under analysis. (see Figure 1)

Advanced forms of InSAR, such as SqueeSAR™, process a large number of radar images to determine the displacement of radar targets over time. Stable targets can be naturally occurring features such as rock outcrops, or man-made objects such as buildings and artificial reflectors (referred to as Permanent or Persistent Scatterers) that maximize radar return strength and coherence (Ferretti et al., 2001, Ferretti et al., 2007). The processing of a long series of radar images (Figure 1) introduces a time factor that allows the motion history of a radar target to be observed (including non-linear motion), and increases measurement precision to millimetre level accuracy. This precision is achieved by applying advanced statistical algorithms to remove atmospheric 'noise' and orbital effects from the data. The SqueeSAR™ algorithm presents the unique feature of processing the weaker signals from spatially distributed targets covering several pixels (referred to as Distributed Scatterers), which significantly increases the density of measurement points in non-urban areas (Ferretti et al., 2010).

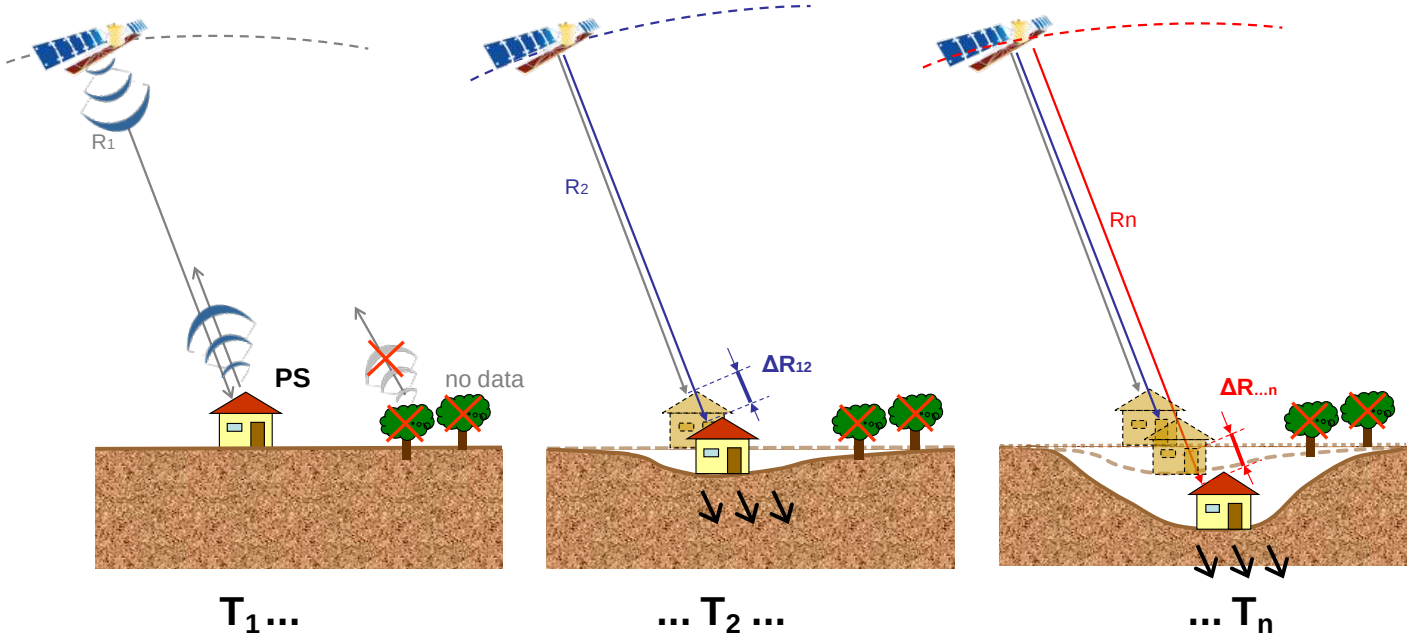

Figure 1. Basic concept of interferometric analysis: comparison between successive measurements of sensor-to-target distance, allowing ground displacement to be determined

2.1 Precision of Measurements

Error bars of SqueeSAR™ measurement are extremely complex to be estimated theoretically, before actually processing the data available (Colesanti et al. 2003). In fact, the precision of the displacement measurements depends on many different factors, such as: number of images used for analysis; spatial density of the measurement points (lower the density, higher the error bar); quality of the radar targets (signal-to-noise ratio levels); climatic conditions at the time of the acquisitions; distance between the measurement point and the reference PS; repeat cycle of the satellite (the lower, the better). An overall picture of the typical precision obtained by SqueeSAR™ analysis is provided in Table 1, which shows the values of standard deviation for average annual velocity, single measurement and positioning in terms of geographical coordinates (North, East, Height).

Table 1. Typical values of precision for a point less than 1 km from the reference point for a dataset of at least 30 scenes spanning a 2-year period

Precision (1σ)	C band satellite	X band satellite
Positioning (E-W)	7 m	4 m
Elevation (referred to ellipsoid WGS 84)	1,5 m	
Average annual velocity	<1 mm/year	
Single Measurement	< 5 mm/year	

3 MINING DEFORMATION MONITORING

Mining open pit operations require a reliable and efficient monitoring programme to assess the inevitable displacement occurring on pit walls and affecting most of the mining assets. Several geodetic tools (from Total Station to Ground based radar) are used to this purpose, and satellite InSAR proved to be a useful complement to usual survey techniques.

As an example of the information provided, a brief extract of a periodic report

is shown. In fact, together with industry standard databases, InSAR services rely on robust, custom-designed, reporting programmes; various update frequencies are available, depending on the Client needs, from weekly to semi-annual.

This monitoring example has been carried out over a very large copper (open pit) mine. The mine spreads for nearly 20.000 hectares, and it is well monitored with several in-situ sensors. This monitoring has been carried out during the first semester of 2013.

3.1 Bird's Eye View – Providing Information Over The Whole Mining Area

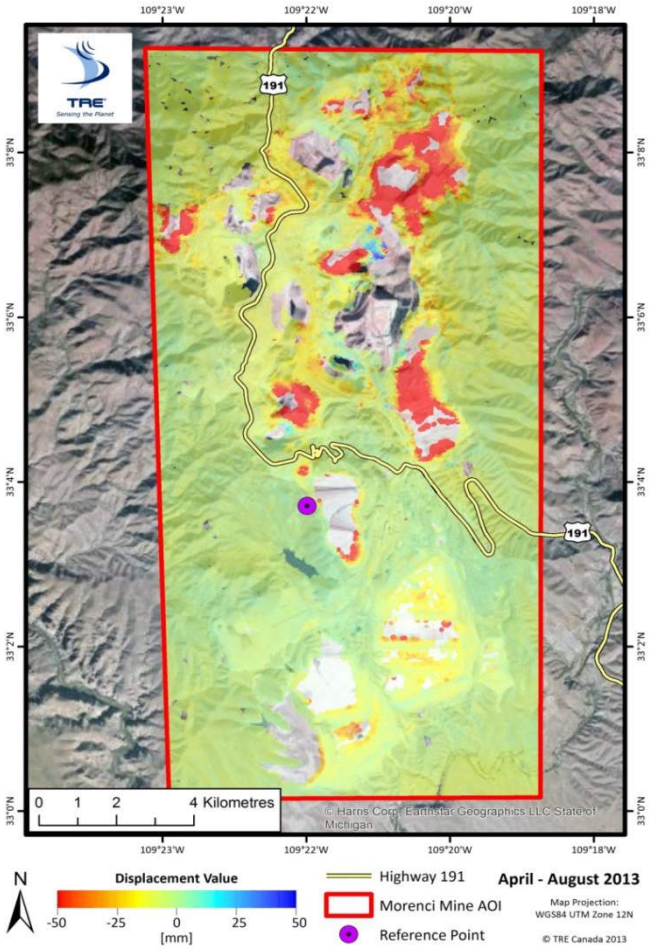

Figure 2. Cumulative displacement over the whole mining area.

Figure 2 shows the displacement occurred over the whole mining area during the accounted period (4 months).

The map has been obtained by means of the analysis of satellite images, hence without the use of any in-situ instrumentation: these set of data are then easily digested in modern GIS, allowing a convenient integration with other measurements.

This maps are produced every requested period (monthly to yearly). Among the various uses, they gained a great importance when planning for an instrumental monitoring programme.

3.2 In Pit Monitoring

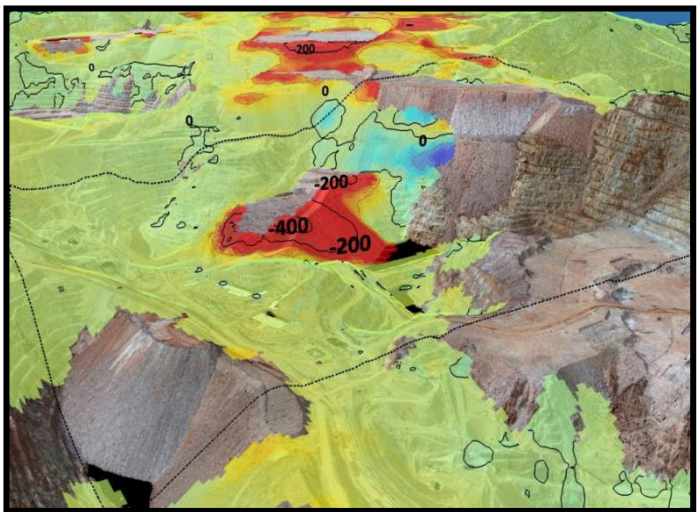

Figure 3. In pit zoomed view. Displacement unit: millimeter.

A simple zooming over the global map allows to identify and measure displacement occurring in the pit, assessing portion of the slope affected by not negligible displacement.

As these maps are not based on a material network of measurement point, an easy visualization of the displacement is achievable (Figure 3). In order to complement the displacement information, for every measurement point identified, a proper time series of displacement is provided (Figure 4).

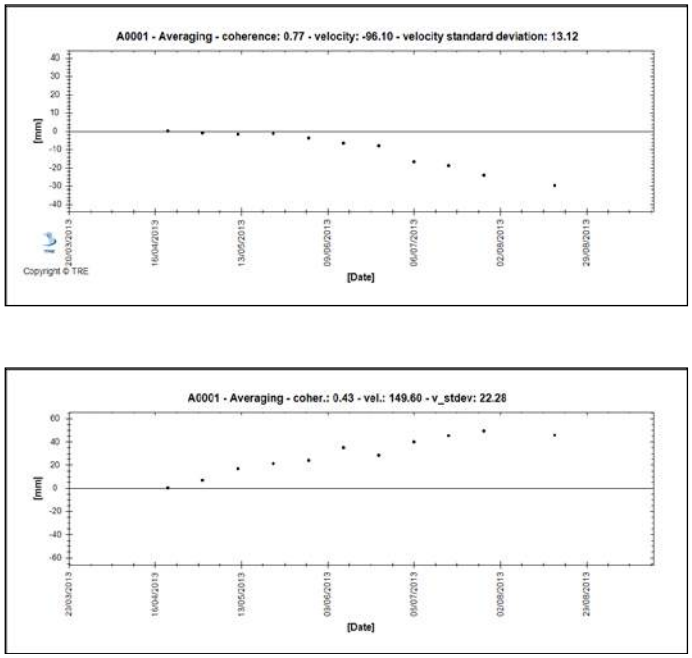

Figure 4. Time series of displacement. Examples in the pit.

3.3 Heap Leach Compaction

While the pit is usually well monitored, heap leaches and tailings dams are usually more difficult and hazardous to survey manually due to the harsh and dangerous environment. The particular structures in these areas do not fit the usual ground base instrumental monitoring strategy due to access and financial constraints.

Satellite InSAR, exploiting its unique aerial view (the line of sight is close to be vertical), provide and unprecedented tool to monitor such compaction phenomena.

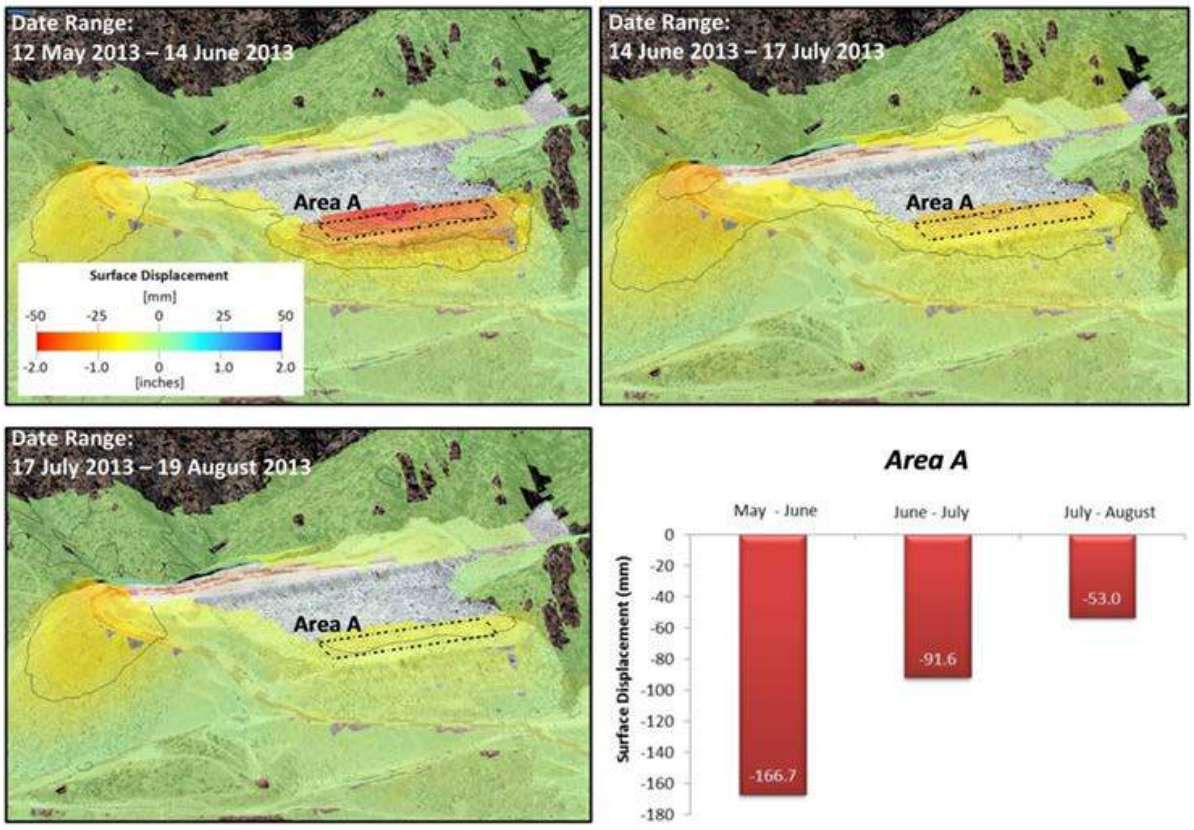

Figure 5. Compaction over heap leaches

3.4 Water Reclamation Facility: Cross-Section

Following the same approach, a dam that is in a water reclamation facility is an easy target for InSAR monitoring. In this particular case, the analysis of a cross section shows the area of displacement highlighting weak spots affecting the dam structure.

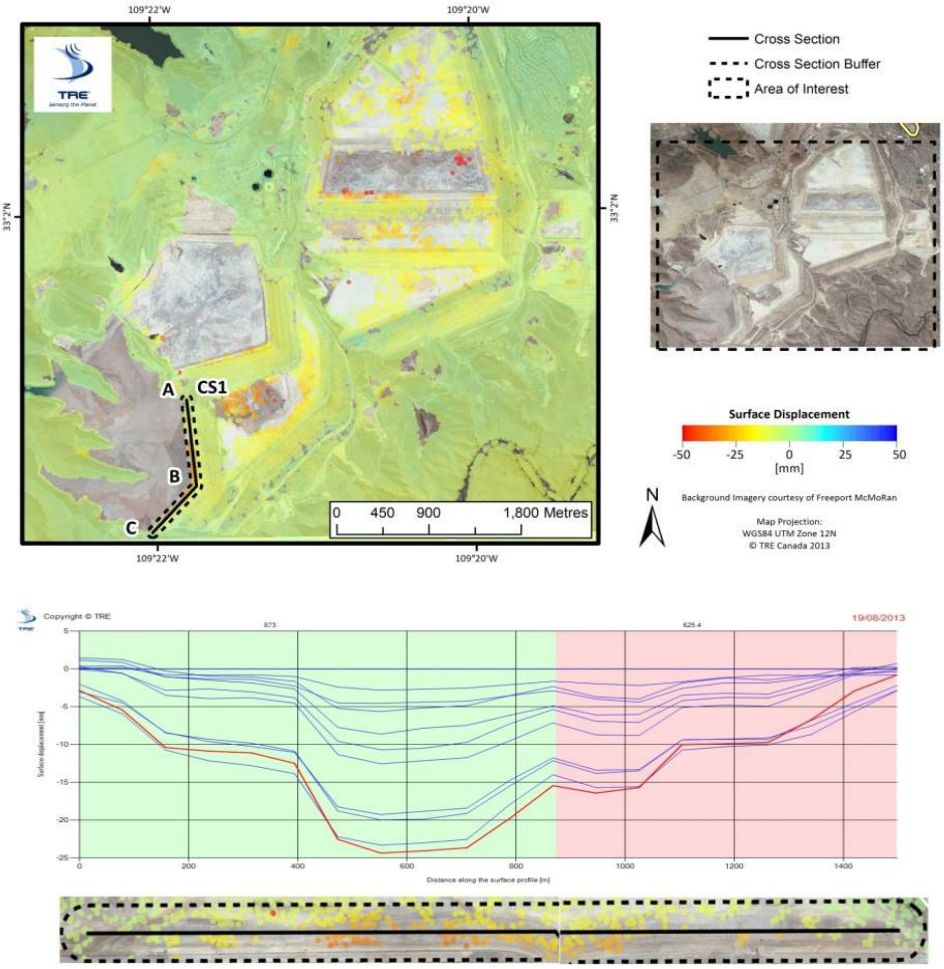

Figure 6. Water reclamation plant. Cross section of displacement over a dam

3.5 Third party Infrastructure

Mining activity may effect third party infrastructures, like railways or road, even if not directly used in the framework of upstream activity. This is the case of a major highway passing near the border of a pit, or in proximity of an instable waste pile. The first case is shown, where an evident sliding deformation affecting the mine rim triggers a deformation that spreads towards the highway (Figure 7).

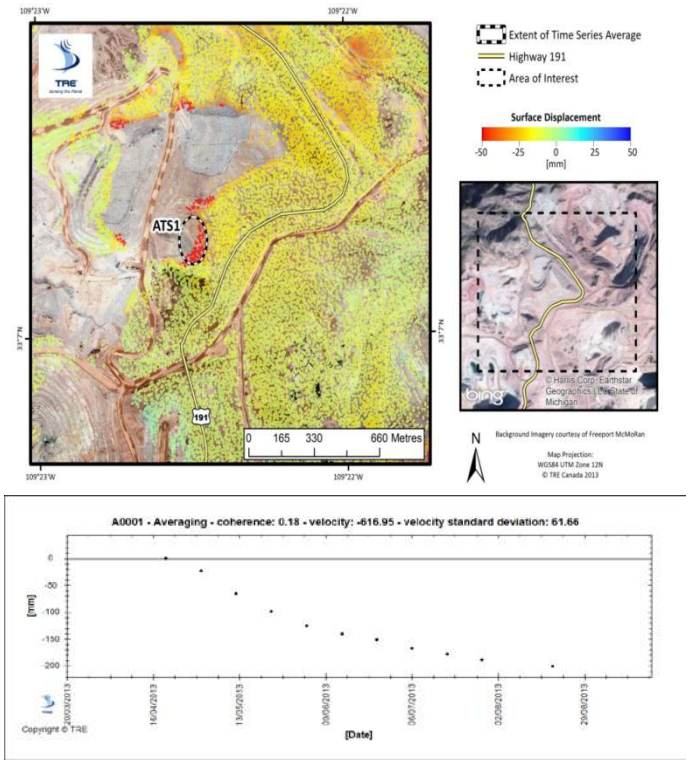

Figure 7. Third party infrastructure monitoring

4 APPLICATION IN SENSITIVE URBAN AREAS

The construction of new underground facilities inevitably interferes with existing surface buildings, even though potential ground movements have been greatly reduced thanks to the progress in the ability of tunnelling machines to cope with difficult ground conditions.

So, in urban areas, a remote monitoring systems that can detect settlements related to excavation activities can greatly assist contractors, designers and owner involved in the project.

In general it is recommended to carry out an historical analysis “ante-operam”, in order to have an overview of the area before the beginning of excavations. This is possible thanks to the availability of satellite data archives covering the last two decades (since 1992). This procedure will allows to plan a follow-up monitoring phase during the excavation and which should prolonged till the exhaustion of any long-term settlements.

4.1 Milan, Metro line 5

The M5 is a fully automatic light underground line, crossing the city of Milan (Italy) with a total length of 12.6 km.

The first stretch Bignami-Zara has been completed and is operating since February 2013. The second stretch San Siro-Garibaldi is under construction and will be operative for the Expo 2015.

In San Siro-Garibaldi stretch, a double track tunnel has been constructed using EPB machines. The tunnelling construction began in 2010 and was completed in 2013.

The SqueeSAR™ analysis of 120 high resolution radar images (TerraSAR X data) acquired from June 2008 to December 2012 identifies the TBM progress and its impact on the buildings above (Figure 8). Although the surface settlements are less than 1 cm, the precision of SqueeSAR™ data allows the detection of very small displacements without install any instrumentations on ground.

The time series (displacements over time) shown below highlight the effects of TBM progress during construction period (Figure 9).

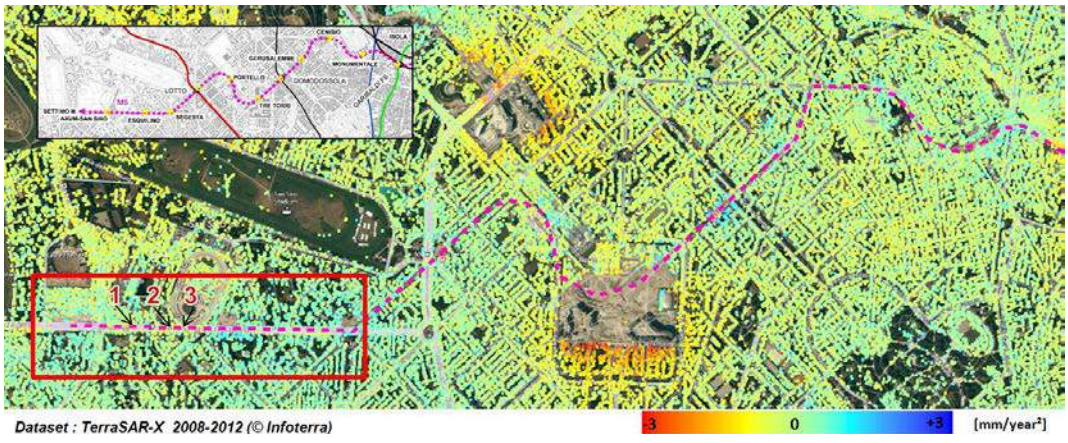

Figure 8. Milan: acceleration map [mm/year2] of measurement points identified from satellite.

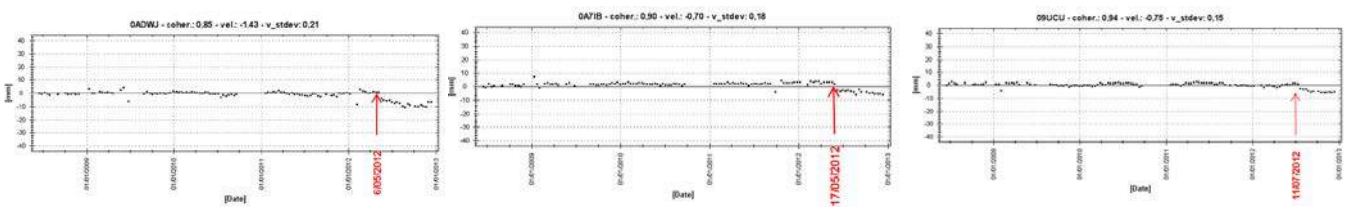

Figure 8. Time series (displacement over time) of measured points 1,2,3 respectively

4.2 Vancouver, the Canada Line

The Canada Line is a rapid transit line in the Metro Vancouver (Canada), servicing Vancouver, Richmond, and the Vancouver International Airport. The construction began in October 2005 and was completed in August 2009. Geological settings range from glacial till in the downtown area and along much of the line North of the Fraser River, to landfill along False Creek and the silt and clay deposits of the Fraser Delta in Richmond. These different conditions are likely to produce varied responses in the structures built on these terrains. The availability of archives of satellite data, provides the deformational behavior ante operam. Thereafter monitoring can be conducted during the construction phase and after the completion of the activities (long term monitoring), to follow in time the deformation. The study area was firstly analysed using 58 RADARSAT-1 images collected between 3 March 2001 and 18 June 2008, comprising ante-operam phase (2001-2005) and tunneling activities (2005-2008).

The historical analysis (Figure 10) highlights significant displacement rates in the area between the Sea Island Centre Station and the YVR-Airport Station.

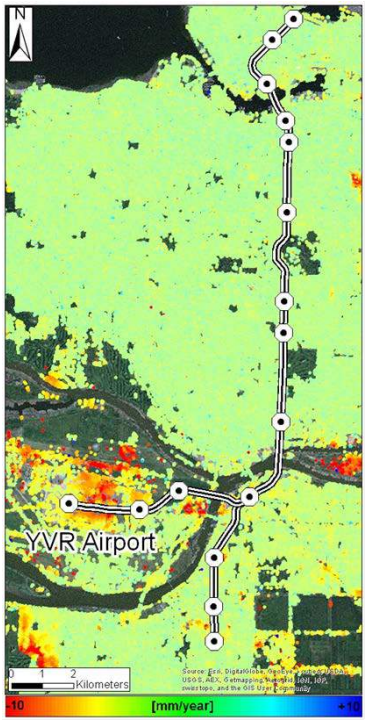

Figure 10. Canada Line: velocity map [mm/year] of measurement points identified from satellite. Monitoring time 2001-2008

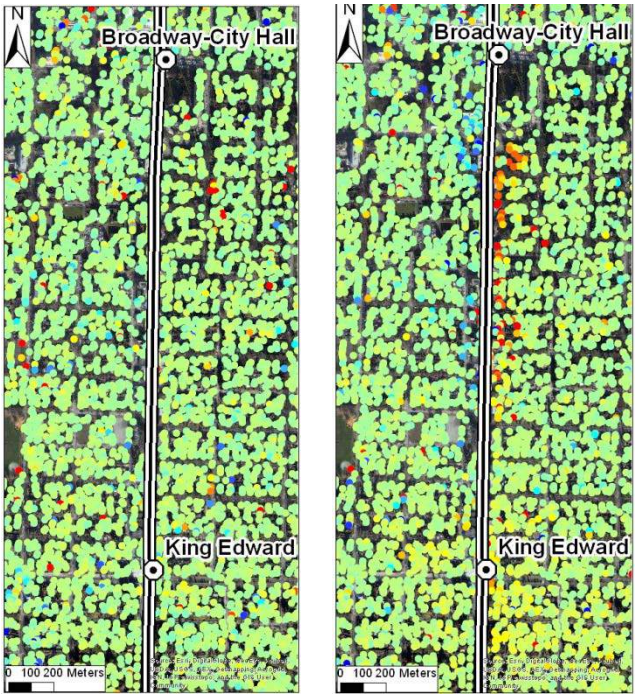

Figure 9. Average velocities map before (left) and after (right) the tunnelling activities

Nevertheless subsidence was antecedent the tunnelling activities, accelerations of about 1.5 mm/y2 have been measured during the construction. Furthermore, SqueeSAR™ data have been further analysed to detect changes in deformation trend, partitioning the time series accordingly before and after the event (in this case tunnelling). The time series analysis highlights acceleration in most of the measurement points along the Canada Line, between Broadway-City Hall and King Edward (Figure 11).

Blue and red points represent displacements toward tunnelling alignment. Differences in colours depend from satellite acquisition geometry.

Figure 12 shows that most of the measurement points in this area, reveals an acceleration in 2007, which corresponds to the year of beginning of tunnelling.

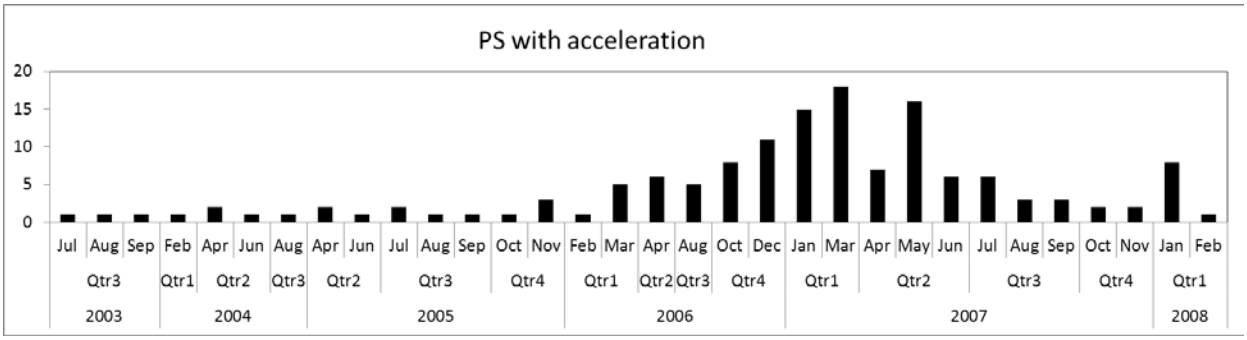

Figure 10. Histogram of measurement points between Broadway-City Hall and King Edward recording acceleration.

We observed a stable phase followed by a displacement‘s step of 2 cm in 2007, to the left and right side of the Canada Line (Figure 13) coinciding with the construction phase.

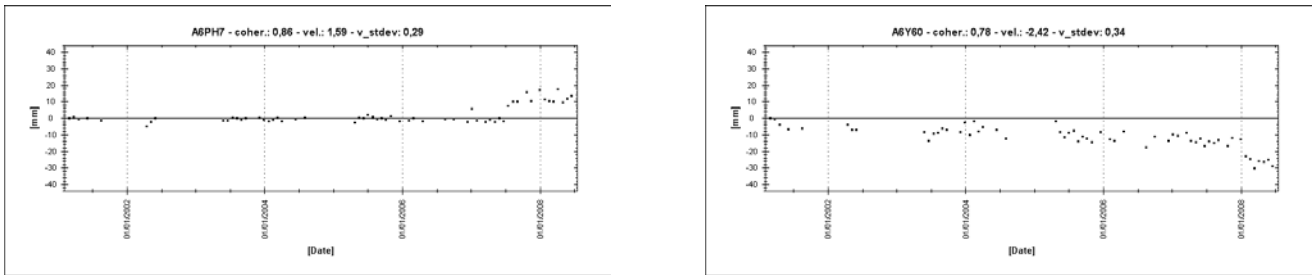

Figure 11. Time series of a Measurement Points to the left (a) and right (b) of the Canada Line

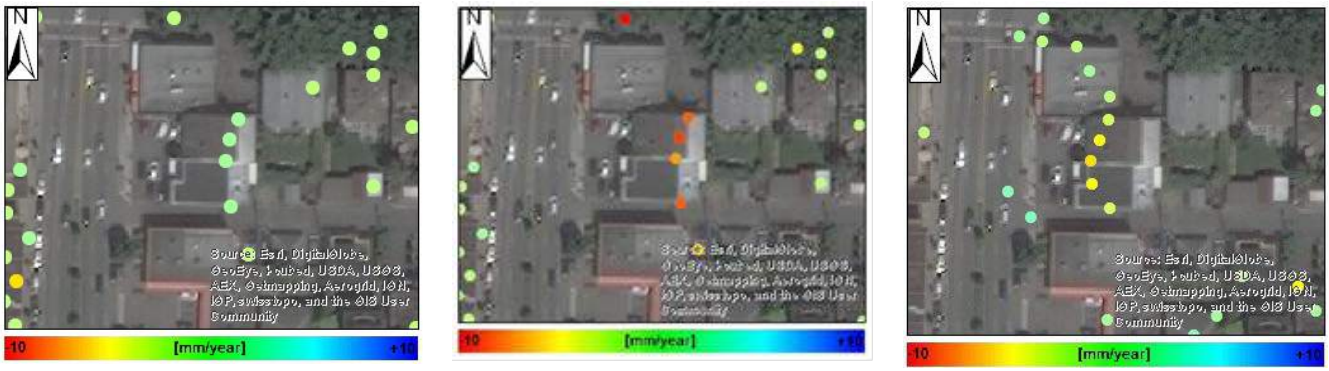

Figure 12. Velocities before the tunnelling , during, and 3 years later

Post-construction monitoring continues to verify the stability of long term displacements due to new construction near the transportation corridor. A data stack composed of 34 Radarsat-2 images, acquired from February 2009 and 11 March 2011, was processed with the SqueeSAR™ algorithm. Following this approach it was possible to assess the displacement before, during and after the construction works (Figure 14).

5 CONCLUSION

The technological advances in Satellite data specifications and InSAR processing techniques have brought deformation monitoring from space born platforms to the forefront of mine site and infrastructure applications. All mining assets can be monitored from a single sensor easing data compatibility issues across corporations and allowing a better understanding of the occurring phenomena. Moreover, the use of such measurement guide the deployment of network of sensors, both during the planning phase and the operational phase of underground and surface operations.

The Application of Weight of Evidence Method for Zn Mapping in Takhte-Soleiman, Iran

M. M. Oskouei, M. Bicharanlo
Sahand University of Technology, Iran

A. R. Jafari Rad
Islamic Azad University, Iran

ABSTRACT Decision making about the importance of each data layer (weights in integration procedure) and then integrated use of them to generate a potential map is usually challenging issue in mineral exploration. Actually all data layers like, geology, geophysics, geochemistry and etc. include significant information about deposit, but a comprehensive map resulted by their combination will be more helpful for target detection. This study aims to combine data layers of lithology, geochemistry and faults of Takhte-Soleiman district with the use of weight of evidence method in a geographical information system and then find the best locations for more detail explorations. Weight of evidence method was applied using eight known zinc indices in the study area. Values of W+ and W- and contrast were calculated for all data layers. In the case of the priority indication of regions around faults, in addition to W+ and contrast, other criteria like Capture Efficiency (CE) and index number change graph were applied. The computation of weight of evidence parameters on geological and geochemical maps, lead us to recognize three amphibolite, gneiss, and limestone beside geochemical zinc anomalies and their 100m distances as optimistic locations. Finally the zinc potential map was prepared by integrating of processed layers using W+ and W- in each point.

Keywords: Weight of Evidence, Mineral Potential Map, GIS, ArcSDM

1 INTRODUCTION

Application of conventional methods in mineral deposits exploration is costly and time consuming. Integration of different data layers in GIS will however reduce exploration costs and increase reliability of the detected targets. This will able one to combine and compare information from several layers like geological, structural, geophysical, geochemical characteristics and so on [1]. The mineral potentials are identified by weighting of evidences of any available map in order to assess various methods for their combination [2].Assigned weights are depended to evaluating their relationship with known mineral resources or reserves due to the subjective judgment of experts [3].

Weight of evidence is data driven approach that employs Bayesian theory to determine the significance of evidence. The method measures the spatial dependence between the evidence maps and obtained information from the well-known indices locations [4, 5]. The Bayesian in is, fact, a method based on probabilistic structure to combine a set of data. The main parameters in the approach are prior and posterior probabilities. The technique is applied aiming to determine the importance of various evidences and to combine them [2, 6]. This study aims using all available information (geochemistry, geology, and faults data layers) to identify Zn mineralization and to generate a potential map for the region (Takhte-Soleiman). The faults were extracted from the geological map of the study area and are illustrated in figure 1 in addition to the geochemical anomalies and known Zn indices in the region.

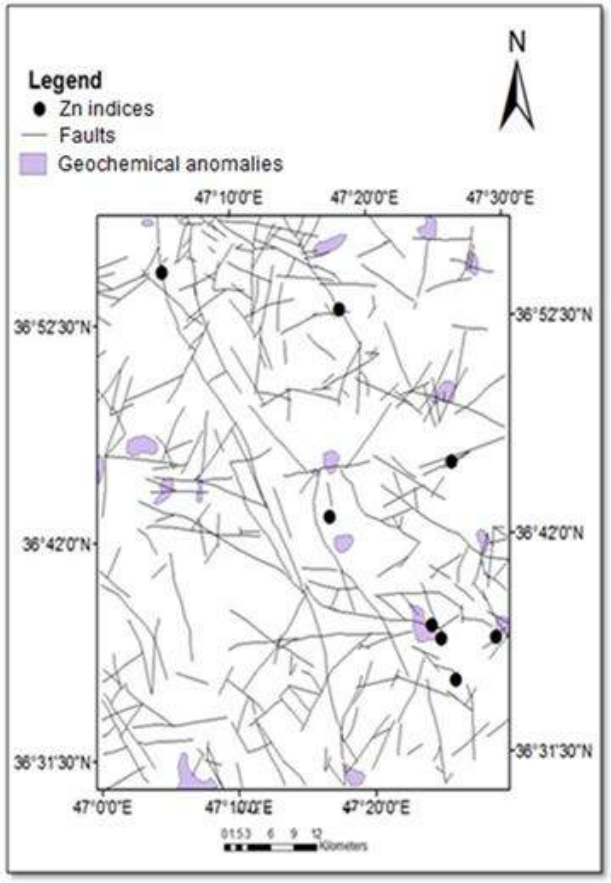

Figure 1. The map of geochemical anomalies, Zn indices, and faults in the study area

1.1 Study Area

The study area is covered by metamorphic rocks like schist, marble, gneiss and amphibolite having a North East - South West trend with a maximum altitude in the middle of the region. Generally, stratigraphy column from bottom to top consists of the Precambrian metamorphic rocks, the late Precambrian and Cambrian – Ordovician sedimentary rocks, the Palaeozoic metamorphic rocks, the Oligo-Miocene intrusive diorite, granodiorite, granite, sedimentary, and volcanic rocks, and younger Quaternary deposits. Lead and zinc mineralization were occurred in the area as a result of the returned hydrothermal fluids activities in different geological zones. These elements are appeared as sulphur-carbonate compositions in the veinlet system of marbles (Figure 2) [7].

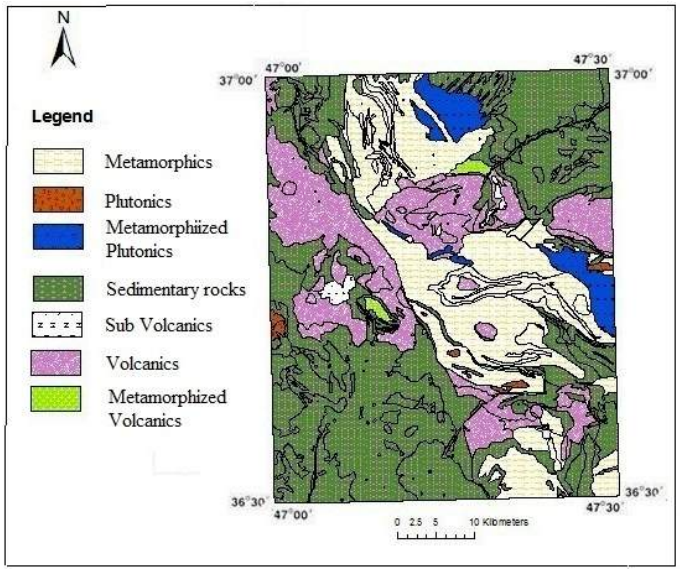

Figure 2. Geological map of the study area.

1.2 Data

All available information of the study area were used to identify optimistic locations for Zn mineralization and to generate a potential map. The geochemical, lithological, faults, and Zn recognized indices were employed to fulfil this task. The mentioned data layers were received from Geomatics division of the Geological Survey of Iran (GSI). The data driven Weight of Evidence (WofE) that is based on Bayesian probability theory was then applied using Zn indices.

2 METHODOLOGY

Agteberg (1990), Bonham Carter (1988), and Watson (1989) were among them who developed WofE for mineral potential mapping [2]. The method assigns “weights” (importance) for each data layer and to the units inside data layers using Bayesian theorem in a probability range of (0, 1) [8]. This theorem in exploration is expressed as updating the probability of a phenomenon like H in the case of E evidence to compute its posterior probability:

$$\boldsymbol{P(H \mid E)} = \frac{\boldsymbol{P(H)P(E \mid H)}}{\boldsymbol{P(E)}} \qquad (1)$$

Where $\boldsymbol{P(H \mid E)}$ is the posterior and *P(H)* is the prior probability of H before E observed evidence, and $\boldsymbol{P(E \mid H)}$ is the likelihood. The term *1/(P(E)* is independent of *H* and

considered as a normalization or scaling factor [6].

Converting the probability in the Bayesian theorem to "odds" will lead us to generate potential map using WofE. Odds is a probabilistic ratio of dividing the occurred probability *P(D)* by the not occurred probability $\boldsymbol{P(\overline{D})}$:

$$\boldsymbol{P(O(D)} = \frac{\boldsymbol{P(D)}}{\boldsymbol{P(\overline{D})}} \quad (2)$$

In the case of having more than one data layer and conditional independence of evidences, we can write:

$$\boldsymbol{O(D\ |E_1, E_2, \dots, E_n)} = \boldsymbol{O(D)} \prod_{i=1}^{n} \frac{\boldsymbol{p(E_i\ |D)}}{\boldsymbol{p(E_i\ |\overline{D})}} \quad (3)$$

Therefore:

$$\mathbf{log}_e[\boldsymbol{O(D\ |E_1, E_2, \dots, E_n)}] = \mathbf{log}_e[\boldsymbol{O(D)}] + \sum_{i=1}^{n} \mathbf{log}_e \frac{\boldsymbol{p(E_i\ |D)}}{\boldsymbol{p(E_i\ |\overline{D})}} \quad (4)$$

And according to the Agteberg modifications on the above Logit in the case of absence of the binary predicting maps:

$$\mathbf{log}_e[\boldsymbol{O(D\ |E_1, E_2, \dots, E_n)}] = \mathbf{log}_e[\boldsymbol{O(D)}] + \sum_{i=1}^{n} \mathbf{log}_e \frac{\boldsymbol{p(\overline{E_i}\ |D)}}{\boldsymbol{p(\overline{E_i}\ |\overline{D})}} \quad (5)$$

In the equations 4 and 5, the terms $\mathbf{log_e} \frac{\mathbf{p(E_i\ |D)}}{\mathbf{p(E_i\ |\overline{D})}}$ and $\mathbf{log}_e \frac{\boldsymbol{p(\overline{E_i}\ |D)}}{\boldsymbol{p(\overline{E_i}\ |\overline{D})}}$ are respectively positive and negative weights for ith prediction map remarked by W^+ and W^-. Dependence between recognized indices and the pattern of prediction of each evidence map will be calculated by contrast as

$C_i = W^+ - W^-$.

3 METHODOLOGY

Mineral Potential Mapping means detection of areas having a greater probability of mineralization for a specific element in the region [3]. Because of the need for integration of different layers for mapping, the following processes should be performed on all data layers:

a) Georeferncing of layers and verifying their same coverage

b) Preparation of the distribution of the Zn indices (8 indices shown in figure 1)

c) Deciding about the suitable cell size for converting vector to raster format

One of the most important parameters is the cell size when using GIS in raster format. The effect of cell size on the data driven methods is more than the knowledge driven algorithms [9]. The effective resolution for a map is equal to the minimum distance at which the spatial variation can be recorded. This is equal to the width of a line on a map (0.5 mm). However, a practical estimate of the cell size in meter will be achieved by multiplying of the scale denominator by 0.001 [10]. In this study, regarding to the 1:100000 scale of the maps, the cell size is 100 meter.

3.1 Faults

One of the best methods to determine the importance of surrounding areas and the relation of fault zones to intended mineralization is creating different buffers. The 100, 200 and 500 m distance buffers were then drawn to select the best distance using the weights of evidence for each one. The resultant weights and contrasts are illustrated to faults layer as an example in table 1. Finally, according to the calculated weights based on the indices locations, the 100 m buffer was selected as the best buffer. It means a distance of 100 meters buffers resolve better the study area [9, 10]. According to the graph in figure 3, the indices number increases gradually until 300m distance from faults and then sharply until 1100m, that after stays constant means no indices in the region farther 1100m. The fault map was then divided into three class as following:

1) Distances less than 300m (most favorable areas)

2) Distances between 300m and 1100m (favorable areas)

3) Distances greater than 1100m (unfavorable areas)

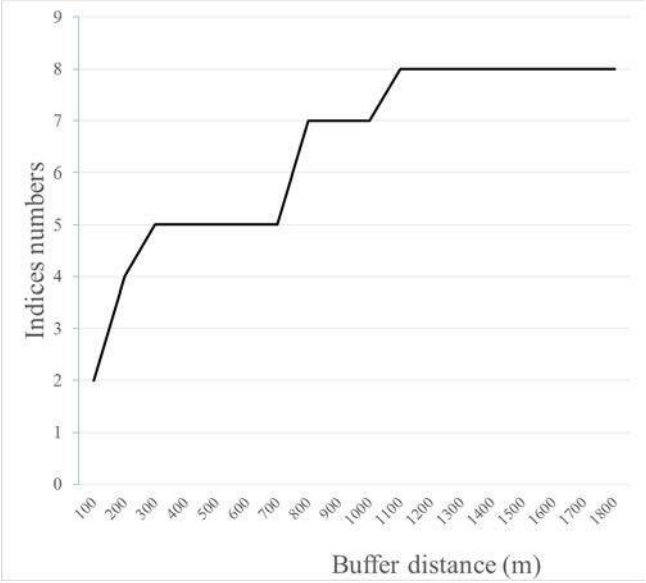

Figure 3. The number of proved indices inside different buffers.

Another indicator for optimum classification into three above mentioned classes (most favorable, favorable, and unfavorable) is *capture efficiency (CE)*. This parameter is resulted by dividing the square distance by the coverage of the related distance buffer:

$$CE = \frac{d^2}{a} \quad (6)$$

Figure 4 illustrates the calculated CE for various buffers. Regarding to the results the 1100 meter buffer has the highest value of CE. It means the 1100 meter distance of each fault is the boundary of favorable area the farther regions are not disposed for mineralization from faults systems view point.

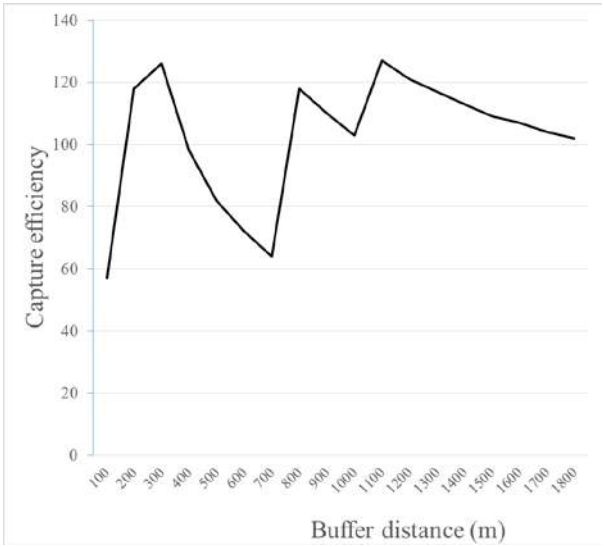

Figure 4. Calculated capture efficiency for different distances.

3.2 Geochemical Anomalies

The geochemical layer represents the Zn anomalies in the study area conducted by GSI. Each anomaly was considered as polygon and the geochemical layer was then binary encoded according to the presence or absence of the indices. The WofE weights were then calculated for the binary map. The calculation of the distance in which the positive relationship between the anomalies and indices has been increased is the next step. To this end buffers 100, 500 and 7500 meters around polygons were drawn and their weights were calculated. The results are shown in table 2.

3.3 Lithological Factor

The final objective in this part was to recognize the mineralization related rock units. The evidence weight of each unit was therefore computed and the units with positive weight and contrast were detected (amphibolite, limestone, gneiss, and an unknown unit). Different buffers (100, 200, 500, and 1000m) were then drawn for each unit. According to the calculated contrast and capture efficiency, the best buffer zone for each unit was selected as 100m for amphibolite and 0 for reminders.

Table 1. The calculated parameters for different buffers for faults layer using WofE

Buffer	Area	Indices No.	W^+	S_W^+	W^-	S_W^+
100	271.56	2	0.8055	0.7071	-0.1692	0.4083
200	524.09	4	0.8412	0.5	-0.4503	0.5
300	756.54	5	0.6972	0.4472	-0.608	0.5774
400	967.42	5	0.4513	0.4472	-0.4733	0.5774
500	1158.87	5	0.2707	0.4472	-0.3331	0.5774
600	1329.92	5	0.1331	0.4472	-0.1887	0.5774
700	1484.24	5	0.0233	0.4472	-0.0376	0.5774
800	1622.77	7	0.2705	0.378	-0.978	1.0000
900	1744.57	7	0.1981	0.378	-0.8146	1.0000
1000	1855.27	7	0.1366	0.378	-0.6386	1.0000
1100	1955.17	8	0.2165	0.3538	-5.0531	10.0000
1200	2045.3	8	0.1714	0.3538	-4.8429	10.0000
1300	2125.03	8	0.1331	0.3538	-4.6112	10.0000
1400	2197.64	8	0.0995	0.3538	-4.3399	10.0000
1500	2264.00	8	0.0698	0.3538	-4.0048	10.0000
1600	2324.31	8	0.0435	0.3538	-3.5556	10.0000
1700	2379.76	8	0.0199	0.3538	-2.819	10.0000
1800	2430.68	8	0.0013	0.3538	10.322	14.1421

Table 2. The calculated parameters for different buffers around geochemical anomalies

buffer	area(km2)	indices number	contrast
100 (most favorable)	57.56	1	2.32
500 (favorable)	116.01	3	4.68
7500 (unfavorable)	2475.76	8	-8.00

4 CONCLUSION

The integration of resulted weighted maps was performed using ArcSDM module in ArcGIS. This aims to compute posterior probability for the region and then detection of areas with higher probability for detail exploration. Determination of the layers weights was done using their W+ and W- for calculating posterior Logit and then posterior odds and finally posterior probability [2]. The resultant map of the computed posterior probability is shown in figure 5. The brighter parts of the map refer to the most favourable regions and the grey and dark parts represent favourable and unfavourable areas respectively. The known indices can be effectively used in application of WofE for mineral potential mapping. Despite the relatively low number of indices in the study area, it was able to predict high potential locations according to other conducted studies. The excessive number of indices will however result in more accurate potential map. Conditional independence between data layers reveals that an integration method is necessary for decision making.

ABSTRACT In this study, the possibility of usage of image processing methods to measure porosity of porous building stones is investigated. Porosity is one of the most important parameters for evaluating and classifying natural stones, because porosity affects other properties directly or indirectly. Image processing aided porosity testing has a potential being a good nondestructive testing method. Diyarbakir basalts were selected for this investigation. The conventional porosity test method and offered image processing method were applied ad the results were presented. The correlation coefficient between conventional and offered methods is calculated as 0.66. Several valuable results for future studies to improve the study have been observed.

Keywords: Image processing, porosity estimation, porous basalt

1 INTRODUCTION

There are several tests and parameters for evaluating natural building stones such as specific gravity, uniaxial comprehensive strength, hardness, slip resistance, tensile or bending strength, water content, ultrasonic P wave velocity, and thermal conductivity. With these test results, natural building stones can be classified or evaluated from different points of view.

Porosity is also very important parameter for this aim and can be measured with different ways. As a definition porosity is the ratio of pores or micro voids to total volume. Porosity as a feature is important for natural building stones because it may affect some other features of natural stones directly or indirectly such as water content, unit weight, p-wave velocity and thermal conductivity. Therefore it is important to measure a porosity value of a building stone to obtain pre-information about its other features.

In some cases, applying conventional rock mechanics tests is not easy or forbidden (for example testing historical buildings), so that we have to use non-destructive test methods.

Image analysis and image processing techniques which are very famous in last decades have very wide range area of utilization. Basically, image processing is the realization of almost all of the performances of the human visual system by computers. These performances include color or tone detection, object and edge detection, image segmentation and rendering, and image classification and identification (Jaehne, 1997). Image processing methods involve many techniques such as the acquisition, digitization, segmentation, and enhancement, classification, recording, and re-calling of images using different numerical sub-methods (Akkoyun, 2010) and there are several studies in literature about porosity estimation by using image processing (Yetkin et.al., 2012; Zeil et.al., 2008; Grove and Jerram, 2011; Cuningham et.al., 2004) and others.

In this study, possibility of usage of image processing methods to measure porosity value of porous building stones is investigated. Diyarbakir basalts were

selected for this investigation because these basalts are the most common building stone type in Diyarbakir province for both historical and modern buildings. Almost all historical buildings were built with basalts in Diyarbakir and any of non-destructive method would be very important for investigating these buildings.

2 THE METHOD

Porosity is one the most important features for evaluating natural stones, because it affects other important features of natural stones so that it may possible to estimate other related features of stones by using its porosity value.

As the method of this study we consider taking photos of porous stone samples to apply image processing techniques. The main idea is that the porous parts have darker pixels than other parts of stones so that this color differences may let us to calculate the ratio of dark parts over total pixels.

First, the colorful pictures are turned into grayscale pictures so that the pictures have only 25 different color codes from 0 (black) to 255 (white) which mean simpler form comparing to colorful form (Fig1 and Fig2).

Figure 1. Standard Lena picture-colored

Figure 2. Standard Lena picture -grayscale

After that the pictures are scanned and some statistical data about color values are obtained such as mean value of color codes of pixels, and number of total pixels. By this way porous parts of stone have dark pixels (smaller color value), but other parts of stone have light pixels (bigger color value) comparing to porous parts.

Image processing methods involve different statistical and mathematical calculations applying into color values. One of these methods is thresholding. Thresholding is the simplest method of image processing and mainly it means turning a grayscale image (has 256 colors) into a binary image (has only 2 color) (Fig3). After thresholding, image has on two colors; 255 for black and 0 for white (Fig4).

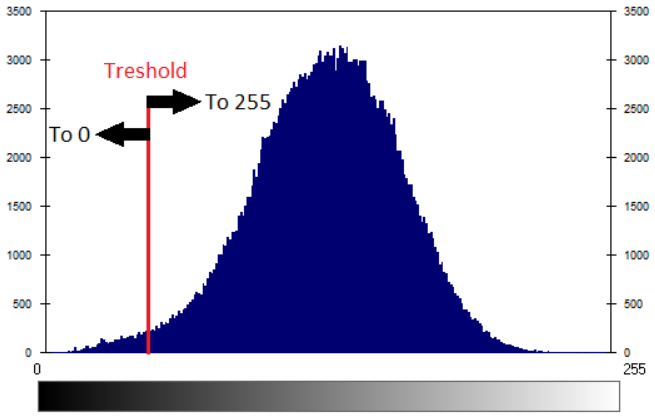

Figure 3. Color histogram and thresholding

Figure 4. Standard Lena picture -binary color

The most important point at this point is to determine the right color value to apply it as threshold point so that porous and non porous parts of stone may have different color values a 255 and 0. With this way, porous parts are represented by black pixels and finally, the last step is to calculate black pixels. The ratio of black pixels over total pixels represents ratio of porosity.

3 THE CASE STUDY

As a natural building stone, Diyarbakir basalts were selected. Diyarbakir basalts have been used for ages as natural building stone in this province and its hinterland. These basalts were used for the city walls, historical buildings, the churches and the mosques. On the other hand, basalts have been used for years in modern buildings, in walls and as pavement in city center.

The samples were obtained from porous basalts and prepared for scanning their images (Fig5).

Figure 5. The porous basalt samples

After that, the density values were calculated, then porosity values of the samples were measured. Then, in order to obtain digitized files of the samples, they were scanned by using scanner. In this step we have colorful pictures.

Following step is to turn the colorful pictures into grayscale forms. In this form, some statistical values which will be used for next step were calculated. The next step is to determine the thresholding level of the pictures so that porous parts and other parts of the pictures can be separated. After that, the pictures turned into binary files which have only black (porous) and white (other) parts (Fig6). In order to apply image processing methods, a new developed computer program (Akkoyun, 2010) was used.

Another part of the study is to measure the porosity values of the basalt samples by using conventional methods. Indirect method is used to calculate the porosity of the basalts. First, the samples were left in water for 24 hours and weights of saturated samples were measured, then after the drying step, weights of fully dried samples were measured. The differences were calculated as void volume and the ratio of this volume over total volume is calculated as porosity.

$P=Vp/Vt$

Where p is porosity,
Vp is voit volume of sample and
Vt is total volume of sample.

Figure 6(a). The original file of the sample

Figure 6(b). The grayscale form of the sample

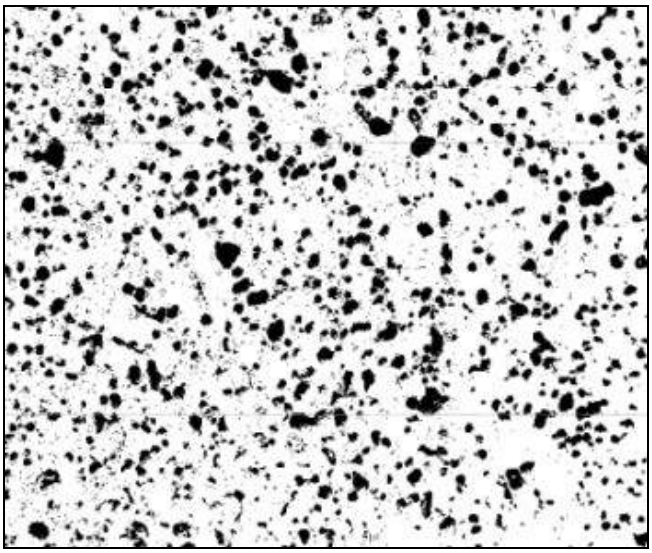

Figure 6(c). After the thresholding process

The porosity values of the samples which were calculated with both conventional and image processing method are given in Table1. The correlation between conventional and offered methods is given in Fig7.

Table1. The porosity values of the samples

Sample No	Porosity (conventional)	Porosity (image processing)
1	3.64	3.58
2	3.76	3.40
3	3.46	3.19
4	3.15	3.56
5	3.48	4.01
6	4.86	4.91

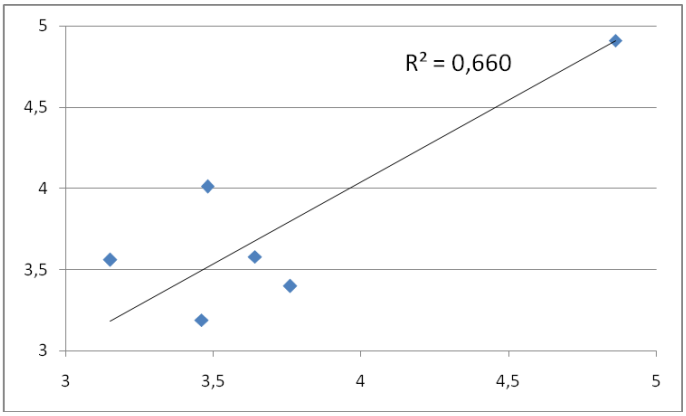

Figure 7. The correlation chart of the methods

4 THE RESULTS AND CONCLUSIONS

In this study, possibility of usage of image processing methods to measure porosity value of porous building stones is investigated. Here are the results of this study;

- Porosity is one of the most important parameters for evaluating and classifying natural stones, because porosity affects other properties directly or indirectly.
- Image processing aided porosity testing has a potential for being a good nondestructive testing method.
- Obtaining process of digital images and its conditions are crucial important as it is in every image processing study.
- The correlation coefficient between conventional and offered methods is calculated as 0.66 which is not high enough.
- Determining and selecting the threshold level is the most important part of his study and this level affects directly porosity calculations.
- One of the problems was color of the natural stone, basalt has dark colors in general and porous parts have also dark color so that it is no easy to recognize them and determine the thresholding color level. So that, relatively light stones such as travertine may have better results.
- The thickness of the samples are important, this study deals with stone's surface, but porosity is kind of

3D phenomena so that the third dimension must be considered.

- As future work, testing many samples having different thickness for one specific stone type it may possible to find a sufficient relationship between conventional and offered method.

Air Quality During Excavation Of Tunnels In The Rijeka Motorway Bypass

M. Klanfar, D. Vrkljan
University of Zagreb, Faculty of mining, geology and petroleum engineering, Zagreb, Croatia

ABSTRACT The main sources of dangerous and harmful gases during the excavation of tunnels are blasting operations and application of diesel equipment for loading and transport of excavated rock. Full-face driving of parallel pipes of three tunnels was conducted in the Rijeka Motorway Bypass by blasting operations and the use of diesel equipment. The quality and quantity of air was monitored in accordance with the technical conditions in the workspace of the tunnels. The concentration of harmful and hazardous gases, along with oxygen, was monitored by active continuous measuring with portable instruments. Measurements were conducted at the head of the tunnel, during blasting operations and during the process of loading and transport of the blasted rock mass. A comparative analysis of actual air loss and losses calculated in accordance with the empirical equations was conducted along the ventilation air duct, as well as the air supply requirements.

Keywords: Rijeka motorway bypass, Air quality, Tunnel excavation

1 INTRODUCTION

1.1 Tunnel Excavation Method

Most excavations of tunnels in karst are challenged with very frequent changes in geological formations and rock mass structure. For this reason, common method of excavation in karst is New Austrian Tunnelling Method or NATM, which provide great flexibility in varying formations (Chapman et.al. 2010)

Almost all tunnels in Croatia are excavated using drill and blast technique, based on NATM method, since it is found to be optimal for excavation conditions in karst (Mustapić 2012). Usual excavation phases of this method include drilling and blasting operations, ventilation, loading and haulage of blasted rock, and application of primary support.

Most profusely sources of dangerous and harmful gases during underground excavations are usage of explosives and diesel equipment for loading and haulage. If ventilation delivers insufficient quantity of fresh air at the working face of a tunnel, concentration of harmful gases can periodically rise above maximum allowable values, or even maintain high values for whole excavation phase.

Air quality measurements in three tunnels of Rijeka Motorway Bypass in Croatia were analysed in this paper, namely Škurinje I, Škurinje II and Trsat (Fig. 1).

1.2 Dangerous And Harmful Gases

Concentration of six gases regularly found during tunnel excavation were measured. They are carbon and nitrogen monoxides and dioxides, sulphur dioxide, acetaldehyde, and methane in addition.

Carbon monoxide is flammable, explosive gas, and extremely toxic. During regular underground operations it is emitted due to detonation of explosives and usage equipment powered by diesel engines. In extraordinary circumstances it occurs during fire and explosive hazards. Toxicity appears with concentrations higher then 35 ppm.

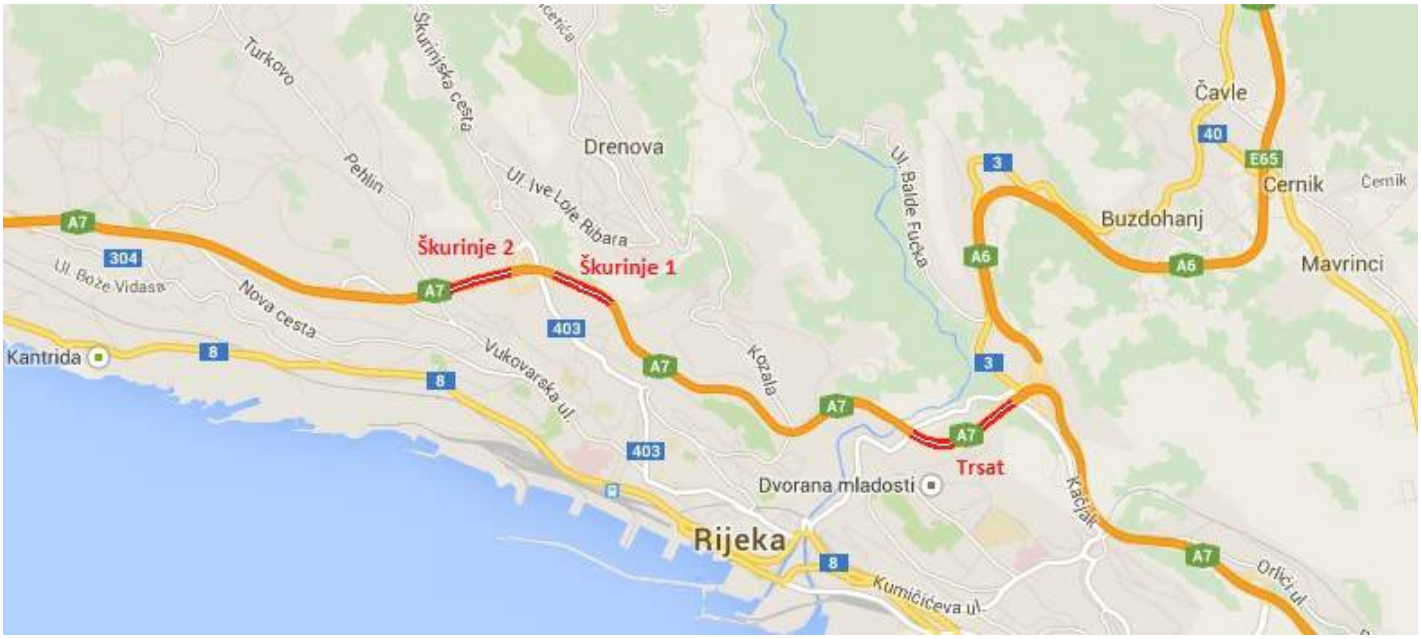

Figure 1. Tunnels locations

Carbon dioxide is normal constituent of air with concentration of 0,039%. It is not considered to be toxic, but it is an asphyxiant gas that can cause suffocation in concentration higher than 7%. Sources of this gas are same as for carbon monoxide.

Nitrogen monoxide is considered immediately harmful in concentration above 100 ppm. In air it rapidly oxidizes to nitrogen dioxide, even more toxic gas. In addition to toxicity, nitrogen oxides are readily soluble in water and thus they dissolve in tissue moisture forming acids, which can cause irritation.

Sulphur dioxide is minor component in diesel exhaust gases, and can be generated by detonation if explosives contain sulphur. It is considered to be immediately harmful in concentrations above 100 ppm.

Acetaldehyde, beside formaldehyde, is one of aldehydes that has highest portion in diesel exhaust gases. It is flammable, explosive, very toxic, and considered immediately harmful in concentrations above 2000 ppm (NOISH 1995).

2 AIR QUALITY LEGISLATION

Croatian legislation on air quality is relatively complex if we account for all application areas. However, there are several regulations of interest for this research, that deal with allowable concentrations of dangerous and harmful gases, and are applicable to the underground excavation of tunnels.

Regulation on technical standards for diesel engines in underground mining operations in non-methane mines (SL 53/90) defines maximum allowable concentrations of gases, or MDK (Tab. 1). MDK is defined as concentration that has no known harmful effects on humans, during every day eight hour work.

Regulation on occupational exposure limits and biological exposure limits for harmful substances (NN 13/09) is newer and has somewhat different approach, as it considers maximum exposure limits instead of maximum concentrations (Tab. 2). Two exposure limits are defined according to this regulation: time weighted average exposure (GVI) - exposure that has not harmful effects during every day eight hour work, and short term exposure (KGVI) - exposure that has no harmful effects during period of 15 minutes, four times daily. Both exposure limits for gases of interest here are presented in Table 2.

Other Regulations (SL 11/97, SL 24/91) deal with marginal requisites on microclimatic parameters, temperature and air quantities and velocities.

Table 1. Maximum allowable concentrations

Gas formula	MDK (ppm)
CO	50
CO_2	5000
NO	25
NO_2	5
SO_2	4
C_2H_4O	10

Table 2. Occupational exposure limits

Gas formula	GVI (ppm)	KGVI (ppm)
CO	30	200
CO_2	5000	-
NO	25	-
NO_2	3	5
SO_2	2	5
C_2H_4O	20	50

Beside maximum allowable concentrations of dangerous and harmful gases, minimum allowed concentration of oxygen at any given time is 19 %.

Required air supply at underground excavation face depends on number of factors. They can include air temperature, moisture and allowable air velocities, but two of them are essential in regular underground work operations: emissions of harmful gases and consumption of oxygen, which are in relation to the number of employees and total power of diesel equipment. It is defined that air flow should be 3-4 m^3/min per employee. In case of usage of diesel equipment air flow should be 4 m^3/min per one kilowatt of total diesel equipment power.

3 AIR QUALITY AND VENTILATION MEASUREMENTS

Concentration of aforementioned harmful gases, methane and oxygen were continuously measured during three excavation phases in sequence: drilling and blasting operations, ventilation phase, and loading and haulage of blasted rock material (Jankovic & Vrkljan 2008a, b, c).

Concentrations were measured using two gas detectors Drager Multiwarn II, which comprise infrared sensor for carbon dioxide, catalytic sensor for methane, and electrochemical sensors for all other mentioned gases.

Total, static and velocity pressures were measured along the ventilation ducts using digital manometer Airflow DM2L, with attached Pitot-Prandtl tube. Measured pressures were used to calculate pressure drop, air flow and velocity, and air loss inside the ventilation duct. In order to accurately determine air supply to the excavation face, air velocity was directly measured at the exit of ventilation duct using digital vane anemometer DA4000.

3.1 Measurement Conditions

Measurements were taken at different distances from excavation face. Distance amounts to 91 m in tunnel Škurinje I, 33 m in tunnel Škurinje II, and 100 m in tunnel Trsat.

In all three tunnels forcing (blowing) ventilation system was applied. It composes of one axial fan of 90 kW power and flexible circular polyester ducts, 1800 mm in diameter. Although mentioned parameters are the same in all three tunnels, fans and ducts have different characteristics summarised in Table 3. Blasting was done using non-electric system (NONEL) in all three tunnels, with plastic explosive charge in main and contour blastholes and gelatinous explosive charge in contour blastholes. Exception is tunnel Škurinje I, where emulsion was used in main blastholes and gelatinous explosive in contour blastholes. Total amount of explosive charges per one blast are shown in Table 4.

Loading and haulage of blasted rock material was carried out using loaders and trucks of different sizes, engine power and number of units, which is also summarised in Table 4.

Table 3. Ventilation system characteristics

Tunnel	Fan make	Nominal airflow (m^3/s)	Nominal pressure (Pa)	Nominal revolution speed (min^{-1})	Duct section length (m)	Overall duct length (m)
Škurinje I	Gia SwedVent	37	1800	1483	20	183
Škurinje II	Ekovent	40	1800	1480	30	127
Trsat	Korfman	33	3700	1480	30	370

Table 4. Explosives and diesel equipment utilized during measurements

Tunnel	Explosive charge	Loading and excavation equipment	Haulage equipment
Škurinje I	166,0 kg	Cat 966H (211 kW) Komatsu PC350 (251 kW)	Volvo A30E (251 kW)
Škurinje II	122,3 kg	Cat 966 G2 (193 kW)	MAN (294 kW) Mixer truck (278 kW)
Trsat	189,6 kg	Komatsu EX350 (192 kW) O&K L45 (177 kW)	Tatra (270 kW) Fiat hitachi (250 kW)

4 AIR QUALITY ANALYSIS

Continuous concentrations of harmful gases were compared to the MDK values according to the Regulation on technical standards for diesel engines in underground mining operations in non-methane mines (SL 53/90), as most authoritative regulation for this objective.

Peak values were noted in order to determine if concentrations rise above maximum allowable. In case they do, time of dilution below maximum allowable concentration was determined.

Typical gas concentrations versus time are presented in Figure 1. It can be seen that concentration of all detected gases raise rapidly after blasting, except oxygen. Methane was measured but was not detected, and thus it is not included in the analysis.

Ventilation system is put into operation immediately after blasting, and during period of 15 to 25 minutes harmful gases are significantly diluted. After that period, concentrations are low enough to proceed with the next tunnel excavation phase, i.e. loading and haulage of blasted rock material.

During loading and haulage phase, concentration of most gases emitted by blasting continue to fall to some extent, due to operating ventilation, but are additionally emitted by diesel equipment. After that, gases are emitted entirely by diesel equipment and remain relatively constant until the end of loading and haulage.

Peak concentration of detected gases and determined time of dilution below allowable concentration according to the Regulation (SL 53/90) are presented in Table 5.

Largest concentration can be observed for carbon dioxide in all there tunnels. Peak values range between 700 and 2800 ppm, but neither of this values is above allowable concentration of 5000 ppm, and thus dilution time is not of significance.

Concentration of carbon monoxide raises above the allowable one, in all three tunnels immediately after blasting. Extremely high concentration was recorded in Škurinje II, where peak concentration amounts to 500 ppm. Compared to most other harmful gases it takes considerable time of dilution, between 8 and 28 minutes.

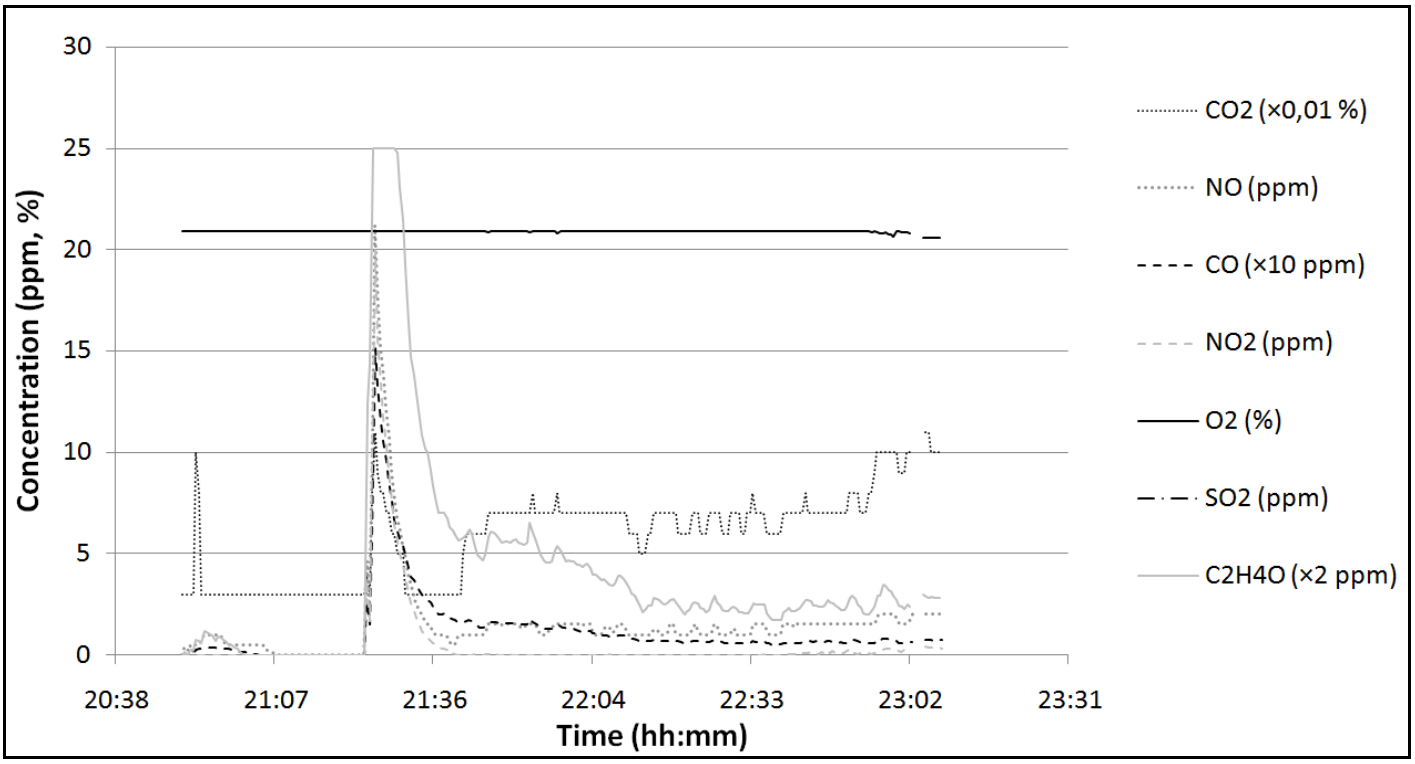

Figure 1. Typical gas concentration diagram

Nitrogen oxide is found to be higher than allowable only in tunnel Škurinje II, but for short period of 4,5 minutes. Concentration of nitrogen dioxide raises above allowable values in all three tunnels, between 3,19 and 20,00 ppm. It requires relatively small time for dilution from 3 to 6 minutes.

Sulphur dioxide was detected in two tunnels, Škurinje II and Trsat. Concentration was very small compared to other gases, with peak values significantly below allowable ones, that is from 0,02 to 0,28 ppm

Concentration of formaldehyde was considerable in all three tunnels, above 46 ppm. This value is roughly five times greater than allowable concentration of 10 ppm.. Accordingly, dilution time for formaldehyde has highest value than for other gases, with range between 19,5 and 37,00 minutes

Table 5. Peak concentrations and dilution time of harmful gases

Gas	Škurinje I	Škurinje II	Trsat
NO	21,18	50	04,95
	-	04:30	-
CO_2	1100,00	2800	700
	-	-	-
CO	151,43	500,00	55,50
	08:50	28:00	20:00
NO_2	20,00	19,15	03,19
	06:00	04:30	03:00
SO_2	00,00	0,28	0,02
	-	-	-
C_2H_4O	50,00	50,00	46,22
	35:30	37:00	19:30

00,00 – Peak concentration values (ppm)
00:00 – Time of dilution below maximum allowable concentration or MDK (mm:ss)

Oxygen concentration differed in three tunnels, but generally varied between 20,60 and 20,90 %, which satisfies minimum criteria of 19 %.

Dilution time of harmful gases mostly depends on concentration of carbon monoxide and formaldehyde, since concentration of these gases exceeds allowable values by multiple times. Actual concentration of formaldehyde in Škurinje I and II was even higher then measured 50 ppm, because this value represents measuring range of the sensor.

All other harmful gases were diluted in relatively short period of up to 6 minutes.

5 VENTILATION PARAMETERS ANALYSIS

Air velocity inside ventilation duct was calculated based on measured dynamic pressure and air density, except at the duct outlet where it was measured directly. In conjunction with duct cross section area, air flow was calculated. Given air flow for all three tunnels, with corresponding distance form tunnel portal is presented in diagrams on Figures 2-4. Total pressure, measured as difference between duct inside and outside in tunnel space, is also shown to present pressure drop as indicator of air duct resistance.

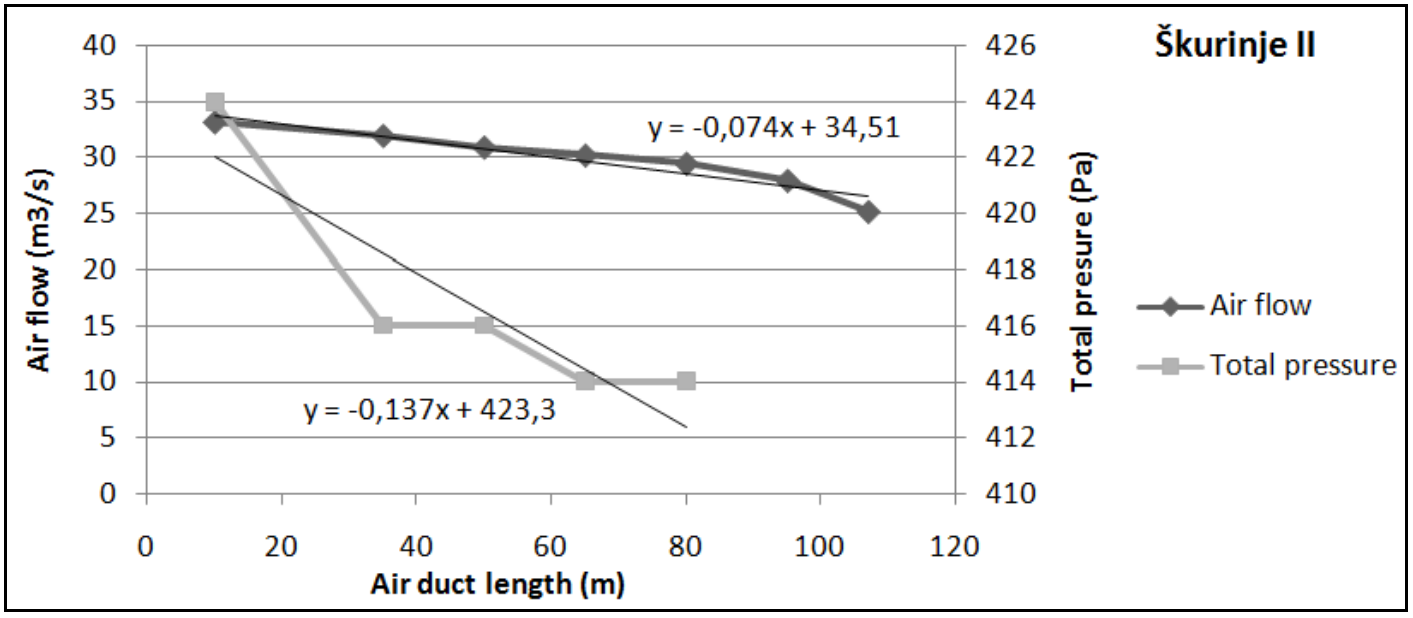

Figure 2. Air flow and pressure drop in ventilation ducts of the Škurinje II tunnel

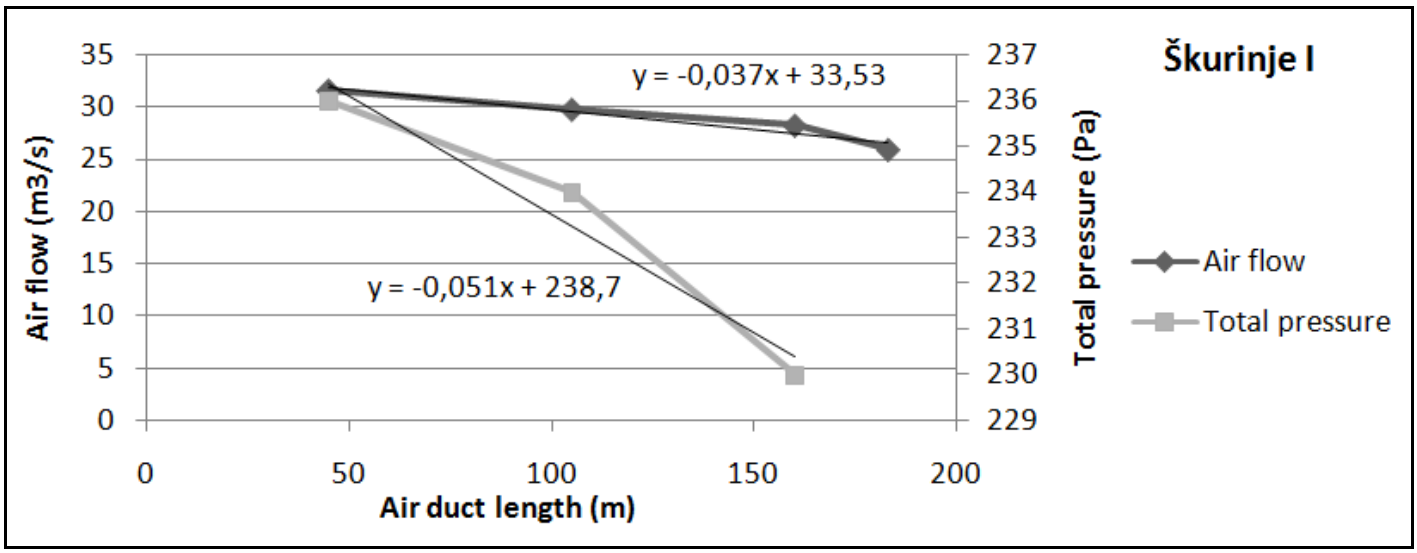

Figure 3. Air flow and pressure drop in ventilation ducts of the Škurinje I tunnel

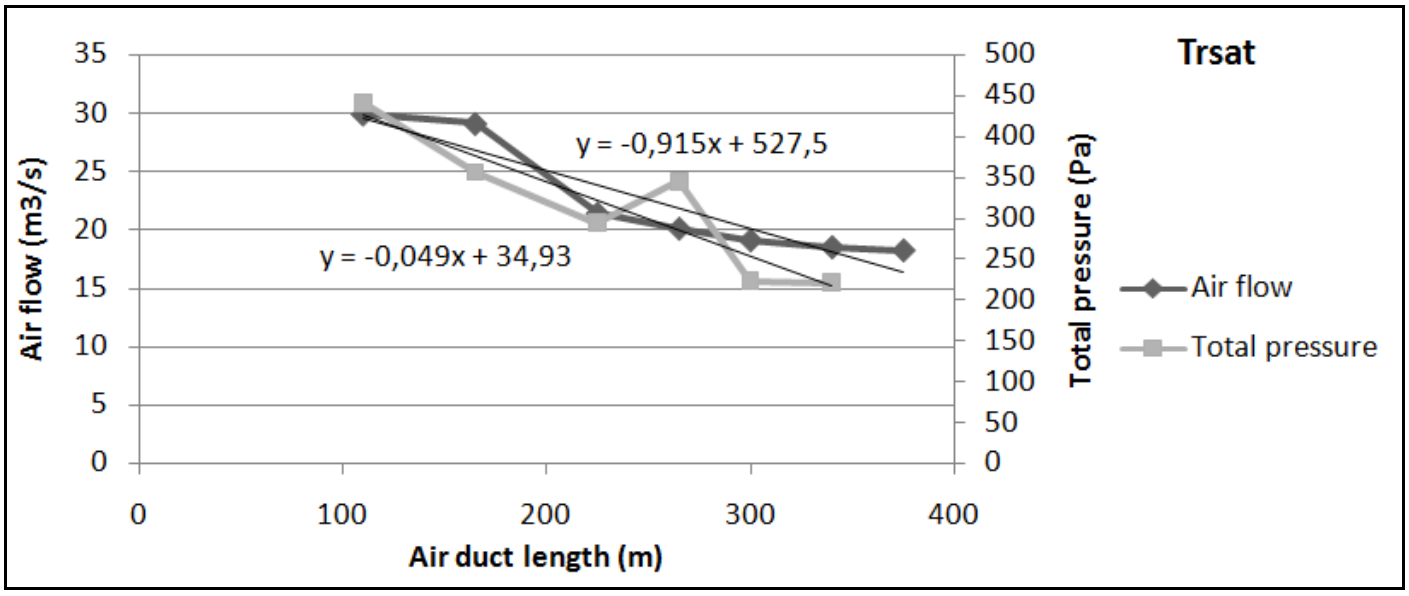

Figure 4. Air flow and pressure drop in ventilation ducts of the Trsat tunnel

Linear regression is applied to the air flow data in order to define mathematical equation of air flow and air loss, in relation to ventilation system length

It can be seen that specific air loss ranges from 0,037 to 0,074 m^3/s per meter of ventilation duct length. If we account for current excavated tunnel length, air loss amounts to 17,6 % for Škurinje I, 24,1 % for Škurinje II, and 38,9 % for Trsat tunnel. Air loss in tunnels Škurinje I and Škurinje II seems to be disproportional, because longer tunnel has lower air loss, but this could be attributed to bad jointing of duct sections or damaged duct. In accordance to its length, Trsat tunnel has largest air loss.

Overall power of diesel equipment utilised simultaneously in a tunnel can vary depending on all operations in progress at one moment. At tunnel excavation face there are usually operating one loader and one truck, due to confined workspace. According to engine powers form Table 4, combination of mentioned equipment results in overall powers from 447 kW to 487 kW, accounting for all three tunnels.

Using the rule for air demand of 4 m^3/s per kW of diesel equipment power, it can be calculated that minimum air demand at excavation face ranges from 30,8 m^3/s to 32,5 m^3/s. Accounting for measured air loss, ventilator air supply should be from 37,4 to 48,7 m^3/s, depending on the tunnel. Data for all three tunnels is presented in Table 6.

Current air flow at the outlet of ventilation duct, that is air supply to the excavation face, is lower than calculated demand in all three tunnels.

Table 6. Air loss and air demand

Tunnel	Diesel power[1] (kW)	Minimum air supply[2] (m^3/s)	Air flow[3] (m^3/s)	100m air loss (%)	Overall air loss (%)	Required air supply (m^3/s)
Škurinje I	462	30,8	26,04	12,77	17,62	37,4
Škurinje II	478	32,5	25,26	24,84	24,09	42,8
Trsat	447	29,8	18,23	14,40	38,87	48,7

[1] one loader + one truck at excavation face
[2] to the excavation face
[3] measured at ventilation duct outlet

Nevertheless, longest time of blasting gases dilution is found to be between 20 and 37 minutes, which is acceptably low, and during loading and haulage phase no gas concentration exceeds maximum allowable values.

5.1 Comparison To Air Loss According To Empirical Equations

In order to determine liability of computational assessment of air losses, results of assessment were compared to measured values. With assumption that ventilation system in good condition losses air only at duct section joints, overall air loss was calculated in accordance with empirical equations (Eq. 1-2) for air loss at ventilation duct joints (Teply 1990):

$$R_c = 0{,}81\frac{\lambda_c \rho}{D^5} l \qquad (1)$$

$$e = \left(8{,}1 \cdot k_{pt} \cdot D \cdot n \cdot \sqrt{R_c} + 1\right)^2 \qquad (2)$$

where:

- R_c duct resistance (kg/m^7)
- λ_c resistance coefficient
- ρ air density (kg/m^3)
- l duct length (m)
- D duct diameter (m)
- e air loss
- k_{pt} joint permeability coefficient
- n number of joints

Resistance and joint permeability coefficients were selected for plastic ducts in forcing ventilation system, and for diameter of 1,8 m. Given values are λ_c=0,02 and k_{pt}=0,000288. All other values were selected according to measurements or ventilation system characteristics. Input data is presented along the results in table 7.

Table 7 Air loss according to empirical equation

Tunnel	Duct length (m)	Number of joints	Air density (kg/m^3)	Duct resistance (kg/m^7)	100m air loss (%)	Overall air loss (%)	Required air supply (m^3/s)
Škurinje I	183	10	1,162	0,1823	4,43	8,1	33,29
Škurinje II	127	5	1,188	0,1293	5,19	6,6	34,65
Trsat	370	13	1,132	0,3600	8,64	32,0	39,04

6 CONCLUSIONS

Longest dilution time of blasting gases is found to be for carbon monoxide (9 to 28 min) and acetaldehyde (19 to 37 min). Dilution of other harmful gases is achieved in very short period, that amounts up 6 min. This excludes carbon and sulphur dioxide, which concentrations do not exceed maximum allowable values at all. Nitrogen oxide had concentration above allowable values only in one tunnel, and for very short period of 4 min.

After dilution of blasting gases, and during loading and haulage, concentration of all gases stays below maximum allowable values and does not rise. This means that air supply to the excavation face is sufficient in all three tunnels.

Calculated minimum air supply, accounting for overall diesel equipment power, is higher than actual air supply to the excavation face. This doesn't represent a problem, due to acceptable dilution time of concentrations below MDK. But as excavation of tunnel advances, there is certain increase in air loss and decrease in air supply, which extends time of dilution and

causes rise of gas concentrations during loading and haulage.

Comparing actual to calculated air loss, it can be seen that empirical equations do not provide reliable results, since calculated air loss is multiple times lower.

Importance of maintaining ventilation ducts and joints can be seen comparing specific air loss in all three tunnels. Škurinje II is shortest of them, but has twice as high air loss air per duct length. Other two tunnels have similar air loss, which is somewhat higher in the longer tunnel.

Assessment of Safe Ground Vibration Level in Sensitive Hilly Slopes Ensuring Human Response

C. Sawmliana, R.K. Singh, P.P. Roy
Blasting Department, CSIR-Central Institute of Mining & Fuel Research (CSIR-CIMFR)

ABSTRACT The paper describes the controlled blasting operations in close proximity of residential houses on hilly slopes at the road construction site of Kaladan Multi-Modal Transit Transport Project of Mizoram state of India. Human response and sensitivity were predominantly considered while fixing the safe level of ground vibration in contrary to the prescribed level suggested by the regulatory agency in India i.e. Directorate General of Mines Safety (DGMS). Experimental blasts were conducted using 32 mm drillhole diameter of 1.5 m (5 ft) depth and 25 mm diameter cartridged explosive with short-delay electric detonators. Ground vibration level of 1.85 mm/s was even found to be very severe and non-acceptable to the inhabitants. To avoid further complaints and inconvenience, controlled blast design parameters were established with limited number of holes and maximum charge per delay in a blasting round so as to confine the ground vibration level within 1 mm/s which was acceptable to the residents.

Keywords: Ground vibration, blasting, Kaladan Multi-Modal Transit Transport Project

1. INTRODUCTION

Ground vibration is one of the most perceptible side-effects of rock blasting which causes human annoyance and structural damage, although damage only occurs at levels many times higher than those that cause annoyance (Pesch and Robertson, 2007). The safe values of ground vibration generated from blasting for different surface structures have been laid down by different countries based on their respective research works. As such, the threshold values of ground vibration prescribed in a particular country may not be applicable in other countries. In India, ground vibration standards have been prescribed by three different organizations viz. Indian Standard Institution (ISI), Directorate General of Mines Safety (DGMS) and Central Mining Research Institute (CMRI). The vibration standard prescribed by ISI (IS: 6922 -1973) under 'Criteria for safety and design of structures subjected to underground blasts' is intended for the safety of normal structures constructed on/in more or less homogeneous soil or rock strata. The term 'underground blasting' had been specified as detonation of explosive in drillholes and boreholes for rock excavation and quarry blasts. Hard rocks refer to granite, basalt, quartzite, marble, crystalline schists, massive slates and other hard massive crystalline rocks whereas soft rock refers to shale, sandstone phyllites, laminated slates, mica schist, weathered hard rocks and other soft rock materials.

The CMRI (presently CSIR-CIMFR) vibration standard prescribed in the year 1993 categorized three different types of structures and formulated the threshold values of ground vibration based on dominant frequency of ground vibration. While framing the safe value of ground vibration level, CMRI vibration standard considered the ages as well as the state of condition of the structures in addition to human perceptions. This has a practical implication that the residents would never allow any blasting activity whenever the level of vibration exceeds some perception level whether it is harmful for structures or not.

The DGMS vibration standard (Technical Circular No. 7 of 1997) grouped the type of structures into two categories viz. (A) Structures not belonging to owner and (B) Structure belonging to owner. Each group is again classified based on the type of

construction, their importance and sensitivities. In such classification, dominant excitation frequency was given due importance.

In India, from practical point of view, it is difficult to follow a particular standard due to different psychological response of human being residing in the vicinity of mining areas and their consequent repercussions. Complaints of structural damages may still be raised even if the level of ground vibration falls below the prescribed threshold level of structural damage. It is normally seen that in many projects, the vibration thresholds are based on human response than on the probability of damages (Jimeno et al., 1995). The authors also experienced the similar incident while working in a road construction project wherein the blast-induced ground vibration levels were forcefully confined within the tolerable limit of the nearby populace in a sensitive hilly area of Mizoram state in India. This paper describes the controlled blasting operations executed at the road construction site of Kaladan Multi-Modal Transit Transport Project, Mizoram wherein the ground vibration level was kept at 1 mm/s as per the acceptable level of nearby inhabitants keeping aside the prescribed limits of the regulating agencies.

2. THRESHOLD VIBRATION LEVELS

The threshold values of ground vibration established by the Indian Standard Institution (ISI, 1973), CMRI (presently CSIR-CIMFR, 1993) and the DGMS vibration standards (1997) are shown in Tables-1, 2 and 3.

Table 1. After Indian Standard Institution (IS: 6922 -1973)

Soil, weathered or soft rock conditions	70 mm/s
Hard rock conditions	100 mm/s

Table 2. CMRI vibration standard (Dhar et al., 1993)

Type of structure	**Threshold value of ppv (mm/s)**	
	≤ 24 Hz	**> 24 Hz**
Domestic houses, dry wall interior, construction structures with plasters, bridge	5	10
Industrial buildings, steel or reinforced concrete structures	12.5	25
Objects of historical importance, sensitive structures, more than 50 years old construction and structures in poor state of condition	2	5

Table 3. DGMS vibration standard (Technical Circular Number 7 of 1997)

Type of structure	Dominant excitation frequency, Hz		
	< 8 Hz	8-25 Hz	> 25 Hz
(A) Buildings/structures not belonging to the owner			
1. Domestic houses or structures (Kuchcha, brick & cement)	5 mm/s	10 mm/s	15 mm/s
2.Industrial buildings	10 mm/s	20 mm/s	25 mm/s
3. Objects of historical importance and sensitive structures	2 mm/s	5 mm/s	10 mm/s
(B) Buildings belonging to owner with limited span of life			
1. Domestic houses/structures	10 mm/s	15 mm/s	25 mm/s
2. Industrial buildings	15 mm/s	25 mm/s	50 mm/s

3. INVESTIGATIONAL SITES AND THE PROBLEMS

The Kaladan Multi-Modal Transit Transport Project was initiated by the Government of India under the Look-East Policy to connect India's land-locked Northeastern states with the southern coast of Myanmar. The project will connect the seaport of Kolkata with Sittwe port in Myanmar; it will then link Sittwe to the land-locked region of Mizoram in northeastern India via inland water transport and road transport (Figure 1). The project included construction of nearly 100 km long highway starting from Lawngtlai Town, NH-54 (in Mizoram) up to Myanmar border. The initial portion of the road alignment passed through the periphery of Lawngtlai town, the capital of Lawngtlai district, Mizoram with a span of about 4 km. Residential houses were located on the hilly slope within 90 to 100 m above the road alignment. In the initial portions viz. at Ch: +400 m and Ch: +2150 m, hard rock formations were encountered during formation cutting which required drilling and blasting operations. The full cutting was required as there was no chance of widening by retaining wall at downhill side due to steep gradient. Hence, blasting operations were carried out for the construction of road in these rocky portions. However, the nearby residents alleged damages to their houses due to ground vibrations and noises generated by the blasting operations. Accordingly, the total blasting operation was stopped following the instruction given by the Deputy Commissioner (DC), Lawngtlai District, Mizoram. Hence, the formation cutting work was delayed in a small segment (about 100 m stretch only) due to the complaints raised by the nearby residents whereas the formation cutting works in other portions of the road were almost completed. In order to restart the blasting operations nearby the residential areas, the controlled blasting study was awarded to the Blasting Department of CSIR-Central Institute of Mining & Fuel Research (CSIR-CIMFR), Dhanbad.

Figure 1. An outline of Kaladan Multi-Modal Transit Transport Project

At Ch: +400 m, the unfinished rocky portion which required drilling and blasting operations for the excavation work was about 100 m length. The required excavated height using drilling and blasting varied from a few meter to 25 m with maximum width of 8.0 m (Plates 1 & 2). The top portion containing soil and softer rock formations had already been excavated using excavator. The rock formation consisted mainly of shale and shaley sandstone of softer formation. Harder sandstone formation of grey colour with thickness varying from 2 to 2.5 m was present in the top portion of the rock strata. The rock strata were dipping against the excavated slope of the highwall, favouring better slope stability. The residential houses were located above the road alignment. The nearest residential house at Ch: +400 m from the required blasting site was 90 m. One hospital was also located at a distance of less than 200 m above the required blasting site.

Plate 1. Far view of the rock formation at Ch: +400 m

Plate 2. Closer view of the rock formation at Ch: +400 m

At Ch: +2150 m, the rock strata mainly consisted of shale with heavily jointed formation. Hard sandstone formation was not found in the required excavated slope. However, the shale strata required drilling and blasting as the excavator deployed at the site could not excavate it. The length of road stretch which required blasting operation was more than 125 m. However, more than 60% had already been excavated. The residential houses were located above the required blasting site and the distance of the nearest house from the blasting site at Ch: +2150 was 89 m.

Plate 3. View of rocky portion that required blasting operation at Ch: +2150 m

4. EXPERIMENTAL BLASTS AND GROUND VIBRATION MONITORING

Before conducting the experimental blasts, an official notice was given by the Deputy Commissioner to the nearby residents of blasting sites regarding the controlled blasting programme. Since the residential houses were located within 100 m from the required blasting sites, it was decided to use 32 mm blasthole diameter, drilled with jack hammer. It was also planned to use short delay electric detonators of 25 milliseconds interval with delay series of zero to 10 numbers. However, due to remoteness of the area and difficulty in acquiring explosive and blasting accessories, only delay series of 0, 2, 5, 6, 7 & 10 numbers were available. The depth of blasthole used in all the experimental blasts was 1.5 m (5 ft). Small diameter (25 mm) cartridged explosive of 125 g weight was used.

Initially, the experimental blasts were conducted with limited number of holes. At Ch: +400 m, the first round of experimental blast was conducted with seven holes in shale strata of softer formation. The total explosive charge was 2.06 kg and maximum charge per delay was 0.624 kg. Blast induced ground vibration was monitored near the foundation as well as on the first floor of adjoining residential houses (Plates 4 & 5). In the next round of experimental blasts, the number of holes was increased in the blasting rounds. In total, eight experimental

blasts were conducted at Ch: +400 m wherein the total number of holes in a blasting round varied from 4 to 17. The explosive charge per hole varied between 0.19 and 0.31 kg. The total charge used in a blasting round varied from 1.15 to 5.31 kg and maximum charge per delay varied from 0.31 to 0.94 kg. The firing pattern of holes for experimental blasts conducted with 17 holes at Ch: +400 m is shown in figure 2. The depth of hole used in all the experimental blasts was 1.5 m (5 ft). In shale strata of softer formation, burden and spacing were 0.8 and 0.8 – 0.9 m respectively. In case of hard sandstone strata, burden and spacing were reduced to 0.7 m and 0.8 m respectively. In order to prevent flyrock, top stemming column was maintained more than 1.0 m in all the blasts.

Plate 4. View of vibration monitoring point near the foundation of an adjoining residential house at Ch: +400 m blasting location

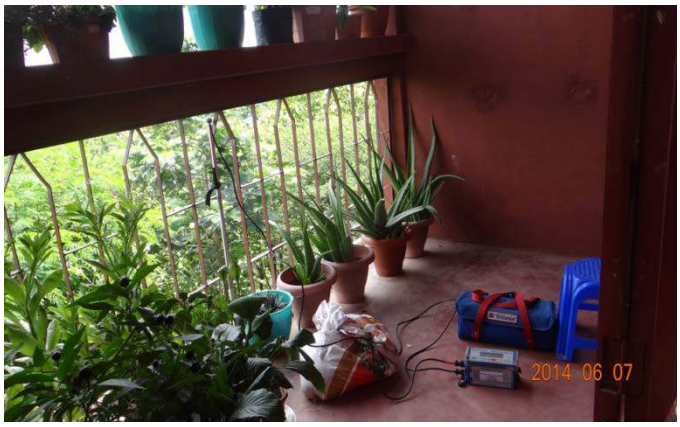

Plate 5. View of vibration monitoring point on the 1st floor of an adjoining residential house at Ch: + 400 m blasting location

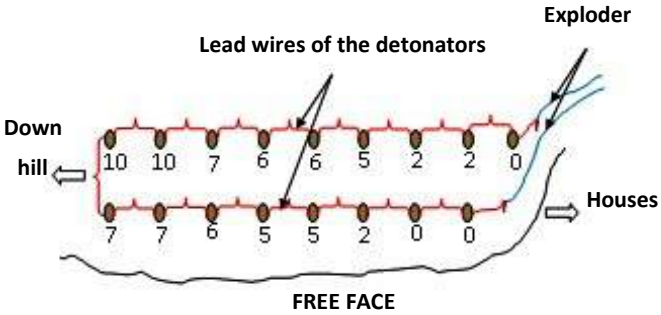

Figure 2. Firing pattern of holes in the experimental blast conducted in hard sandstone with 17 holes at Ch: +400 m (0, 2, 5, 6, 7, 10 are delay series)

At Ch: +2150 m, only shale rocks of softer formation were present. Therefore, burden and spacing were 0.8 m and 0.9 m respectively and the total number of holes varied from 11 to 23. The explosive charge per hole varied between 0.19 and 0.31 kg. The total charge in a blasting round varied from 3.44 to 6.44 kg and maximum charge per delay varied from 0.625 to 1.25 kg. The firing pattern of holes for the experimental blast conducted with 23 holes at Ch: 2250 m is given in figure 3. During the experimental blasts conducted at Ch: +2150 m, one seismograph was always fixed on the first floor of the nearest residential house and another one on the ground surface near the foundation of the house (Plate 6). The distance of vibration monitoring points from the blasting sites varied from 85 to 100 m.

5. GROUND VIBRATION RESULTS AND DISCUSSIONS

The magnitude of ground vibrations recorded during the experimental blasts at Ch: +400 m varied from 0.66 to 1.84 mm/s. The triggering levels of the seismographs were set as 0.50 mm/s. During blasting time, the people resided nearby the blasting sites were requested to stay indoors. Some were asked to sit in chairs while others to stand so that vibration could be felt differently.

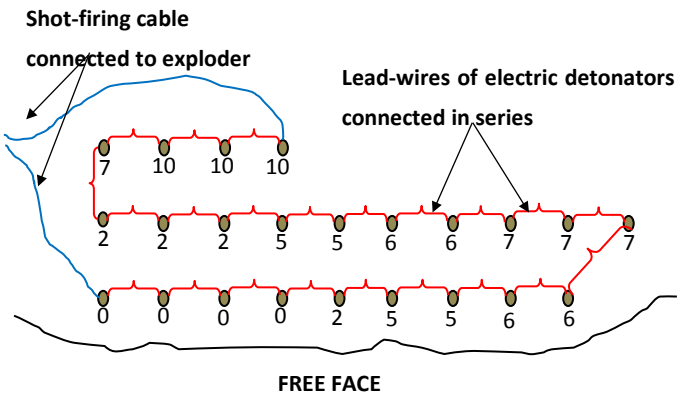

Figure 3. Firing pattern of holes in the experimental blast conducted with 23 holes at Ch: +2150 m (0, 2, 5, 6, 7, 10 are delay series)

Plate 6. View of vibration monitoring point near the house at Ch: +2150 m

When blasting was conducted in shale strata of softer formation using maximum charge per delay of 0.624 kg and total charge of 3.00 kg, ground vibration could not be recorded at adjoining residential houses. It also could not be felt by the people staying inside the house. However, when blasting was conducted in harder formation of sandstone strata, ground vibrations as well as blasting sound were higher than those conducted in shale strata. When the ground vibration value exceeded 1.25 mm/s, the nearby residents could feel the vibration and expressed their annoyance. With the ground vibration level of 1.84 mm/s, they felt frightening and said that the vibration was very severe. It was also leant that those people who were sitting on chairs could feel more vibration than those who were standing.

No vibration data could be recorded during experimental blasts at Ch: +2150 m. The ground vibration could not be felt although number of holes, total charge fired in a round of blast and maximum charge delay were higher in comparison to the experimental blast conducted at Ch: + 400 m. The nearby residents were also satisfied with the experimental blasts as they could not feel any ground vibration. The air overpressure levels recorded from the experimental blasts varied between 104.2 and 115.9 dB (L). Although the blasting sound could be heard and noticed by the nearby residents, no adverse comment was made on the blasting sound. The nearby resident were informed during blasting time and with no ground vibration to feel, they were comfortable with the air overpressure level below 116 dB (L). Maximum care was also taken to reduce the blasting sound by using electric detonators and larger top stemming column.

The Fast Fourier Transform (FFT) analyses of the vibration data showed that the dominant excitation frequency of vibration waves recorded on the ground surface (near the foundation of houses) varied between 8.0 and 15.6 Hz. However, the dominant excitation frequency measured on the first floor of the house varied between 7.25 and 7.38 Hz. Considering such dominant excitation frequency, the safe level of ground vibration for the residential houses as per the DGMS Standard comes to 10 mm/s. However, with the ground vibration level of 1.85 mm/s, the residents felt unsafe and expressed their annoyance to the blasting operation. When explained to them that the measured levels of ground vibration were much lower than the threshold values prescribed by the regulating agency, it was not convincible to them. They had claimed that the cracks had already developed in their houses due to previous blasting operations and any further ground shaking would destabilize their houses.

Plate 7. Final excavated road at Ch: +400 m

Plate 8. Final excavated road at Ch: +2150 m

Therefore, considering the sensitivity and sentiment of the nearby residents, it was decided to reduce the number of holes in a blasting round so that ground vibration level would not cross 1.0 mm/s and further complaints and any untoward incidents could be avoided. The number of holes in a blasting round was restricted to 10 in hard rock and to 15 in softer rock i.e. shale at Ch: +400 m area. Hence, the maximum charge per delay was less than 0.625 kg in case of blasting in hard rock and 0.94 kg in case of blasting in softer rock using the available short delay electric detonators. Since no hard rock strata was present in Ch: +2150 m area and no vibration data could be recorded during the experimental blasts, the total number of holes in a blasting round was restricted to 23. The excavation work using controlled blasting was finally completed without any complaint from the nearby residents. Plates 7 and 8 show the excavated road after the completion of the formation cutting work using controlled blasting.

6. CONCLUSION

When blasting operation is to be conducted nearby sensitive human habitants with hostile attitudes, human response to ground vibration cannot be ignored in deciding the safe level of ground vibration. To avoid any critical situation, it may often require reducing the permissible level of ground vibration to much below the damage threshold level prescribed by the regulatory agencies. Based on the experience stated in the paper, the vibration level of 1.85 mm/s was found to be very severe and detrimental in respect of the perception of the nearby habitants though the damage threshold level of ground vibration was 10 mm/s as per the prescribed standards. Therefore, caring the sentiment of the people and maintaining good relationships are absolutely necessary to accomplish any blasting project in sensitive environment of hilly terrain.

Blastability Characteristics of Ewekoro Limestone Using Rock Mass Classification

B. Adebayo, P.R Adeniyi
Department of Mining Engineering, Federal University of Technology, Akure, Nigeria

S. A. Agbalajobi
Department of Mineral Resources Engineering, Kwara State Polytechnic, Ilorin

ABSTRACT This paper investigates blastability characteristics of Ewekoro limestone using rock strength properties. Rock samples were collected from three different locations at the two faces of the quarry (Ewekoro I, II and III). The rock samples were tested in the Laboratory for uniaxial compressive strength, tensile strength, using 1100 kN compression machine and point load tester respectively. Also, shear strength parameters (angle of friction and cohesion), and the rock mass parameters (tensile strength, global strength index and deformation modulus) of the deposit were determined using Roclab 1.0 from Rocscience where intact uniaxial compressive strength, material constants, disturbance factor of the rock, geological strength index and the intact modulus of the rock were used as input parameters. The results of compressive strength of the rock samples varied from 45.35-97.17 MPa and tensile strength varied from 22.68-48.80 MPa. Ewekoro II has the highest mean compressive strength of 90.0 MPa and mean tensile strength of 48.02 MPa. The friction angles obtained are 24.720, 31.860 and 28.980 for Ewekoro I, II and III respectively. The result of cohesion values are 1.928 MPa for Ewekoro I, 5.566 MPa for Ewekoro II and 2.902MPa for Ewekoro III. Finally, based on the obtained strength properties of the rock, it was discovered that Ewekoro type I has the highest blastability.

Keywords: blastability, rock mass parameters, intact modulus, angle of friction, strength

1 INTRODUCTION

Blastability can be defined as the blasting characteristics of the rock mass subjected to a specified blast design, explosive characteristics and specified legislative constraints depending on the site specifics. In other words, blastability indicates how easy to blast a rock mass under a specified condition. The blastability of rock indicates the ease with which rock mass structure could be loosen to liberate rock blocks as well as create new fractures within the intact material. Therefore any meaningful description of rock mass blastability should be a function of mechanical properties of the intact rock (such as stiffness and strength) and the rock mass structure (size of 'in-situ blocks'). Adebayo and Umeh (2007) concluded that ease of blasting is affected by strength parameters.

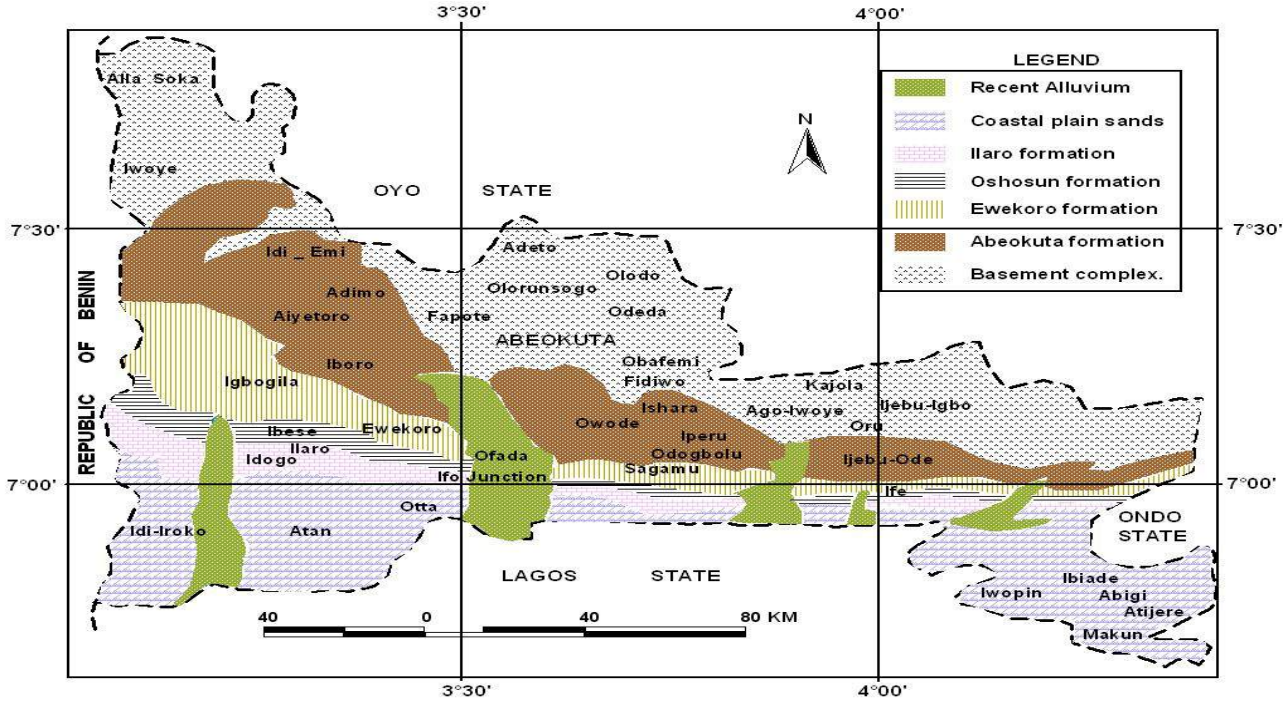
Several approaches have been used for estimating blastability. While some researchers tried to correlate it with the data available from laboratory and field testing of rock parameters, some others have related it with rock and blast design parameters, and yet some others have tried to estimate blastability through approaches based on the drilling rates and/or blast performances in the field. The latest improvements in computer methods have also opened up new vistas to the
researchers to use various artificial intelligence algorithms for determination of blastability. Kaushik and Phalguni (2003) found that a linear relationship exists between the compressive strength of rock (σ_c) and the amplitude of the compressive

stress wave (σ_a) propagated through the rock, which implies that σ_a α σ_c and hence, n α σ_c/σ_t and went further to name (σ_c) /(σ_t) as blasting coefficient. Atkinson *et al.* (1978) proposed that normally rock constant value (0.4 kg/m^3) might vary up to ± 25%. The objectives of the paper therefore are to determine the blastability characteristic and classified the limestone based on the blastability characteristics.

2 MATERIALS AND METHODS

2 1 Description and Location of Study Area

The study area lies within Ogun State, which is bounded in the west by Benin Republic, in the south by Lagos State, in the north by Oyo and Osun States, and in the east by Ondo State. It occupies a total area of 65.8 m^2. Ewekoro is the host to Lafarge Cement Company quarry and lies between longitude 3°05´E to 3°15´E and latitudes 6°40´N to 6°55´N as shown in Figure 1. Ewekoro formation belongs to tertiary-formed Palaeocene and Eocene; and the greater part of the depression is a potential artesian basin where ground water can be sourced. Adegoke *et al.* (1976) outlined the Albran and younger Palaeographic history of Nigeria and summarized the nature and extent of transgressive, regressive phases as well as the nature of the sediment.



Study Area

Figure 1: Geological Map of Ogun State showing the Study Area (After Adegoke *et al.*, 1976)

2.2 Determination of Rock Hardness

The hammer was held vertically above the specimen and the plunger was placed against the specimen and depressed by pushing the plunger against the specimen (Aydin and Basu, 2005). The energy stored in the spring was automatically released and impacts a mass against the plunger. The height of rebound of the mass measured on the scale attached to the instrument and its value is taken as the specimen's hardness.

Ten samples were prepared and tests were performed on each specimen with each test point 15mm apart. The measured test values were arranged in descending order and the lower 50% were discarded. The test was performed using ISRM suggested method. The upper 50% was averaged and the rock hardness value was calculated using Equation 1.

$$H = S_aC \quad (1)$$

Where
S_a = Mean Schmidt Hammer's reading
C = Correction factor

Type N Schmidt Hammer test is mostly use for concretes while ISRM (1981) recommends the use of type L for rocks. Therefore the average values of type N obtained were converted to type L reading using Equation 2. The results are shown in Table 5.For conversion of Type N Schmidt Hammer Values to Type L Schmidt Hammer Values which is applicable to rock is expressed in Equation 2

$$R_N = 1.0646R_L + 6.3573 \quad (2)$$

2.3 Determination of Tensile Strength

Point Load Tester Model A125 was used for these tests. The machine is capable of performing the same test on three different shapes of specimen i.e. cylindrical, block and irregular shapes. The cylindrical shape can be used in two different ways – diametral and axial**.** The load frame can accommodate test samples size of up to 101.6mm in diameter and the machine has a load capacity of 55kN. The prepared specimen was loaded into the test machine and the platens were closed to make contact with the specimen along the core diameter. The point of contact of the platens was not less than half of the specimen diameter from nearest free and after longest axis has been measured as suggested by ISRM 1981. The loading diameter (D) was measured from the scale pointer and recorded. The loading rate was then increased steadily at a constant rate of 0.5 – 1.0 MPa in such a way that failure occurred within five minutes. The failure load (P) was recorded and the uncorrected tensile strength as a measure of Point Load Strength Index σ_T was calculated from Equation 3.

$$\sigma_T = \frac{P}{D^2} \quad (3)$$

P = Failure load, kN

D = Specimen diameter, m
This procedure was repeated for the replicated samples tested and the uncorrected test result is presented in Tables 9.

2.4 Determination of Uniaxial Compressive Strength

1100 kN Compressive Machine Model WF55632 with DIGICON 2 metering device capable of measuring up to ± 5% tolerance was used for this study. The machine is incorporated with DIGICON 2 metering device and has a load capacity of 1000kN. The test specimens were right circular cylinders with a slenderness ratio of 3 at a diameter of 54mm. The samples were tested at a natural water content of 0.21%. The test specimen was loaded into the machine between the upper and lower platens. A spherical seat was placed on the top end of the specimen so as to ensure that the applied load was axially and evenly distributed. The loading platen and the spherical seat were then aligned accurately to the centre of the platens. The load was applied at a constant stress rate of 0.5 – 1.0 MPa/sec such that failure occurred within 5 – 10 minutes of loading. At failure the peak stress is regarded as the maximum stress the specimen could carry when a unidirectional stress is applied in an axial direction to the end of the specimen. No end capping materials were used. This procedure was repeated for the other specimens. The compressive strength, (σ_c) was calculated from Equation 4

$$\sigma_c = \frac{P}{A} = \frac{4P}{\pi D^2} \quad (4)$$

σ_c= Uniaxial Compressive Strength, MPa
P = Peak load at failure, kN
A = Cross-sectional area of specimen, m^2

2.4.1 Density

The objective of the test is to measure the dry density of rock samples of irregular form from the three Ewekoro deposits. The Saturation and Buoyancy technique for

irregular rock sample was adopted and the procedures follow the standard suggested by ISRM (1981) and conform to ASTM (1994). The saturated volume of the sample was calculated using Equation 5.

Saturated volume of samples = V_2-V_1 (5)

Where V_1 (ml) is the initial water level and V_2 (ml) is the final water level in the cylinder after the immersion of the irregular rock sample.
The dry density of the rock samples was calculated using Equation 6. Where M (g) is the oven dried mass at a temperature of 105^0C.

Dry density of the rock samples = $\frac{M}{V2-V1}$ (6)

2.4.2 Point Load Index

The Point Load Index (IS) Values were estimated from the uniaxial compressive strength (UCS) values using Equation 7 established purely for carbonate rocks.

$$I_s = 0.047UCS - 0.328 \quad (7)$$

The IS (like the UCS) was also used for the strength classification and characterization of the intact rocks. It was further used with the Fracture Spacing Index (I_f) and the Geological Strength Index (GSI) for the assessment of the most economic excavation method which is shown with the aid of appropriate charts.

2.5 Determination of Rock Mass Strength Parameters

The rock mass strength parameters were estimated from RocLab 1.0 software. The required input data were loaded and the strength parameters were displayed.

3 RESULTS AND DISCUSSION

The result of rebounds hardness values for limestone is presented in Table 1. The rebounds hardness value varied from 29.8327 for Ewekoro type I to 40.4327 for Ewekoro type II.

Table 1. Conversion of Type N Schmidt Hammer (Rebounds Hardness Values) to Type L Values

Samples	N Values	L Values
Ewekoro I	36.2	29.8327
Ewekoro II	46.8	40.4327
Ewekoro III	39.4	33.0327

Table 2 shows the summary of uniaxial compressive and point load strength index and their classification according to ISRM (1985) standard. All the rock types tested are of ‘‘Very High Strength class” to “High Strength Class’’. Ewekoro type II deposit has the highest value which is in agreement with its high density and hardness values.

Table 2. Summary of Rock Strength Parameters and their Classification

Samples	UCS (MPa)	Is (MPa)	Rock Class
Ewekoro I	47.91	1.92	High Strength
Ewekoro II	96.00	4.18	Very High Strength
Ewekoro III	58.70	2.43	High to Very High Strength

Table 3 presents the tensile strength of the limestone. The results revealed that the value of tensile strength varied from Ewekoro I varied from 23.24 – 25.95 MPa, 47.50 – 48.80 MPa, 28.20 – 31.63 for Ewekoro I, II and III respectively.

Table 3. Tensile Strength of Ewekoro Limestone

S/N	Ewekoro I (MPa)	Ewekoro II (MPa)	Ewekoro III (MPa)
1	23.75	47.50	28.20
2	23.87	47.71	28.66
3	23.58	48.10	29.55
4	22.68	48.10	29.55
5	24.84	47.65	28.56
6	25.95	48.09	30.03
7	23.92	48.80	31.63
8	23.36	48.55	31.01
9	23.24	47.92	28.40
10	24.37	47.80	28.43

Table 4 presents the estimated rock parameters obtained from RocLab software global strength of the limestone varied from 6.021 MPa for Ewekoro I to 20. 026 MPa for Ewekoro II.

Table 4. Estimated Rock Mass Parameters for Ewekoro Limestone

	Hoek–Brown Classification			Mohr-Coulomb Fit	Rock Mass Parameters (MPa)				
	M_b	S	a	C′ (MPa)	ØDeg	Sigt	Sigc	Sigcm	E_{rm}
Ewekoro I	0.821	0.0029	0.502	1.928	24.72	0.171	2.563	6.021	1963.12
Ewekoro II	2.012	0.0155	0.501	5.566	31.86	0.740	11.908	20.026	3240.00
Ewekoro III	1.408	0.0067	0.501	2.902	28.98	0.281	4.786	9.851	2569.68

Where:
GSI = Geological Strength Index
mi ,mb, s, and a = Material Constants
C′ = Cohesion (MPa)
Ø = Friction Angle
Sigt = Tensile Strength (MPa)
Sigc = Uniaxial Compressive Strength (MPa)
Sigcm = Global Strength (MPa)
Erm= Deformation Modulus

Table 5 is a summary of the density result. The Table shows that Ewekoro II has the highest density values while Ewekoro I has the least value.

Table 5. Summary of Density for Ewekoro Limestone

Test No	Ewekoro I (t/m^3)	Ewekoro II (t/m^3)	Ewekoro III (t/m^3)
1	2.40	2.69	2.51
2	2.41	2.68	2.49
3	2.40	2.76	2.54
4	2.37	2.72	2.49
5	2.43	2.67	2.47
Average Value	2.40	2.67	2.47

4 BLASTABILITY CLASSIFICATION OF EWEKORO LIMESTONE

Considering the uniaxial compressive strength and the tensile strength of the samples obtained from three different locations on the deposit, the Ewekoro I is easy to blast having a UCS of 47.91 MPa and tensile strength value of 2.40 MPa, Ewekoro II falls under moderate class as

shown in Table 6. Ewekoro III has easy blastability property as presented in Table.

Table 6. Rockmass Parameters and Blastability for Ewekoro Limestone

FACTORS AFFECTING BLASTABILITY	DEPICTING PARAMETERS	NUMERICAL VALUE		
		Ewekoro I	Ewekoro II	Ewekoro III
1. Strength	(i) Uniaxial Compressive Strength (MPa)	47.91	96.00	58.70
	(ii) Point Load Strength Index (MPa)	1.92	4.18	2.43
2.Rock Resistance to Fracture	Density ρ (t/m^3)	2.40	2.67	2.47
3. Resistance to Dynamic Loading	Schmidt Hardness Value	36.20	46.80	39.20
4. Discontinuity Plane's Strength	(i) Cohesion C (MPa)	1.928	5.566	2.902
	(ii) Friction Angle Ø	24.72	31.86	28.98
Blastability Class		High	Low	Moderate

5 CONCLUSION

The various factors that control the rock fragment size were considered and the rock strength parameters of the Ewekoro limestone were studied. Results show that based on the rock strength parameters the first location (Ewekoro I) has the highest blastability having uniaxial compressive strength of 47.91MPa, point load strength index of 1.92 MPa, friction angle of 24.72° and cohesion of 1.98. Ewekoro III comes next with uniaxial compressive strength of 58.70 MPa, point load strength index of 2.43 MPa, friction angle of 28.98°, and 2.902 cohesion values while Ewekoro II at the second location has the lowest blastability going by its strength parameters values of 96.0 MPa for uniaxial compressive strength, 4.18 MPa point load strength index, 31.86° friction angle and 5.566 cohesion value.

Charge Distribution Pattern For Different Zones In Tunnel Blasting Operations: Case Study Of The Alborz Tunnel

M. Mohammadi
General Mechanic Contracting Co., the Alborz tunnel site, Alborz, Iran

M. F. Hossaini
Faculty of Mining Engineering, Engineering University College, University of Tehran, Tehran, Iran

S. A. Taleghan, R. Bolghonabadi, N. Hajiantilaki
General Mechanic Contracting Co., the Alborz tunnel site, Alborz, Iran

ABSTRACT The most suitable type of explosive for each blasting zone amongst available explosives in the Alborz Tunnel is investigated in this paper applying concept of impedance for rock types of Tuff and anhydrite which have been tested to determine their seismic properties. For hole diameter of 57 mm, the best choice of explosive for cut and lifter holes is ANFO and for contour holes it is emulsion explosive with diameter of 27 mm. The results were the same in case of drilling holes with diameter of 45 mm. Also the results show that the coupling factor has more important role than impedance factor on the amount of transmitted energy in this particular case.

Keywords: Charge distribution, Blasting, Alborz Tunnel

1 INTRODUCTION

Tunneling as an important activity in the field of underground construction is done due to road or rail transportation, water supply and sewer, mountain caverns for industrial, recreational and storage purposes [1]. In spite of its destructive characteristic, drilling and blasting method is the most satisfactory way for excavation of rock because this method of excavation needs low capital investment and has the characteristics of high progress rate for underground excavation works [2].

Lack of adequate free surfaces toward which breakage can occur effectively, characterizes the blasts done for tunnel excavation. Creation of an opening by means of a cut and then stoping to enlarge the opening is the principle behind tunnel blasting. The different zones in tunnel blasting are shown in figure 1 [3]. Stoping holes can be compared to bench blasting though it requires powder factors four to ten times higher. Contour holes establish the final shape of the tunnel and are spaced closely [4]. While the cut and cut spreader holes due to its role in creation of free face to the other sections are of great importance, the contour holes also are important because of its impact on the final shape of the tunnel. Lifter holes also due to operating in contrast with direction of the gravity are noticeable and need maximum possible energy transmission from explosives to rock. The present paper tries to choose the most optimum charge for these sections employing the concept of impedance. It should be noted that the cut and cut spreader holes need to have most possible amount of charge to be able to create the second free face for the other holes while the contour holes need to have least possible amount of charge due to its impact on the final shape of the tunnel.

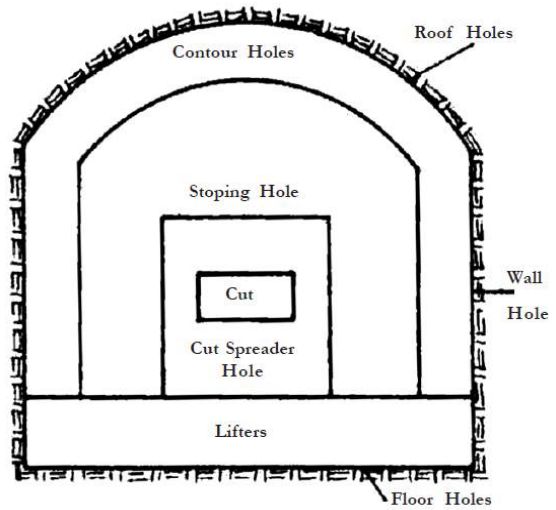

Figure 1. Zones in tunnel blasting [3]

2 CASE STUDY

The Albroz Tunnel with a length of 6400 m is one of the largest tunnels which are going to be excavated along Tehran-Shomal freeway in north of Iran. Drilling and blasting method is employed to excavate the 65 m2 face of tunnel heading where compacted clay is used as stemming material and hole diameter is 57 mm. the available explosives are emulsion explosive with diameter of 27 mm and 35 mm and ANFO. The rock type is Tuff and Anhydrite which have been tested to determine their seismic properties. Figures 2 and 3 show the location of the Alborz Tunnel and an example of blasting patterns used in this tunnel respectively.

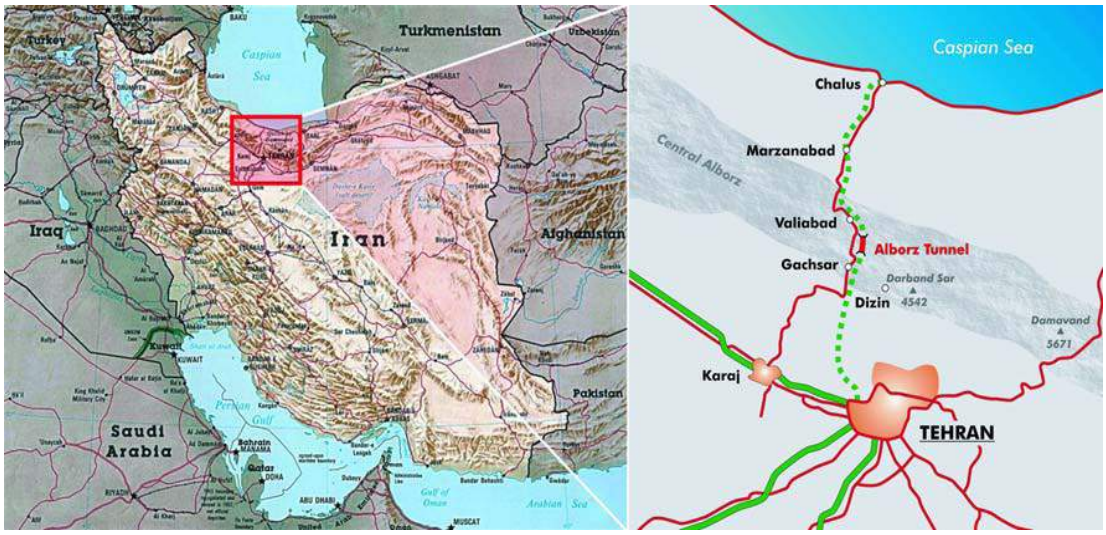

Figure 2. Location of the Alborz Tunnel [5]

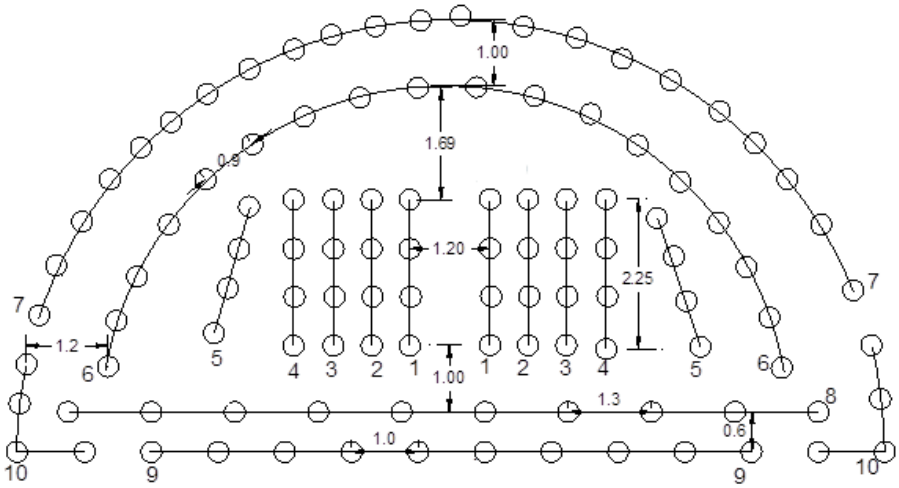

Figure 3. An example of blasting patterns used in the Alborz tunnel

3 CONCEPT OF IMPEDANCE

Energy transmission to rock mass as a result of blasting is affected by two factors [6]:

- Quality of rock mass and explosives (impedance factor)
- Coupling of charge and rock mass in holes (coupling factor)

Impedance is a factor that controls the amount of energy transmitted to rock mass from the explosives during blasting operations. The impedance of rock and explosives can be calculated from equations 1 and 2 respectively [6].

$$I_r = D_r.V \quad (1)$$

$$I_e = D_e.V_e \quad (2)$$

Where I_r and I_e are impedance of rock and explosives in kg/m^{2}sec, D_r and D_e are densities of rock and explosives in kg/m^3 respectively, v_e is velocity of detonation of explosives in m/sec and V is velocity of elastic waves in rock in m/sec.

When the impedances of the mediums are equal, a large part of the energy will be transmitted and the rest will be reflected while if the impedance of one medium is much more than the other, as for example between rock and air, almost all of energy will be reflected as a tensile wave which can be especially important in rock breakage. This is valid for the wave pressure as well as for the transmitted energy [3].

Energy transmission coefficient or impedance factor (η_1) can be calculated from the equation 3 [6].

$$\eta_1 = 1 - \frac{(I_r - I_e)^2}{(I_r + I_e)^2} \quad (3)$$

Coupling factor (η_2) can be computed using equation 4 [6].

$$\eta_2 = \frac{1}{e^{\phi_h/\phi_c} - (e-1)} \quad (4)$$

Where φ_c and φ_h are charge and hole diameter respectively.

If the total energy of explosives is shown as E_e, the energy transmitted to rock in a blasting round (E_t) can be calculated from equation 5 [6].

$$E_t = \eta_1.\eta_2.E_e \quad (5)$$

In this paper, using the aforementioned concepts, the most suitable charge for cut, contour and lifter holes will be selected bearing in mind that the cut and lifter holes need maximum transmittable energy while the contour holes should have the least possible transmission of energy from which the final shape of the tunnel could be established with minimum percent of overbreak and underbreak.

4 SELECTION OF CHARGE FOR DIFFERENT ZONES

The available explosives in the Alborz Tunnel are emulsion explosive with diameter of 27 and 35 mm along with ANFO which are referred as explosive type a, b and c respectively from this point forward. The diameter of drill holes is 57 mm and there is two rock types namely Tuff and Anhydrite. The wave velocity test on rock specimens was carried out with OYO Sonic viewer–SX version 1.20E testing equipment. The results of the test along with rock densities and computed impedance for each type are shown in table 1.

Table 1. Wave test results along with rock densities and calculated impedance of rock types.

Rock type	Density (kg/m^3)	P-wave velocity (m/sec)	Impedance (kg/m^{2}sec)
Tuff	2660	5467	$14.54*10^6$
Anhydrite	2830	6462	$18.29*10^6$

The properties of explosives along with calculated values of impedance are shown in table 2.

Table 2. properties of available explosives along with calculated impedance of explosives.

Explosive type	Density (kg/m^3)	Velocity of detonation (m/sec)	Impedance (kg/m^2sec)
a	1400	6000	$8.4*10^6$
b	1500	5000	$7.5*10^6$
c	900	4500	$4.05*10^6$

As the energy content of emulsion explosive is 80 to 104 percent of ANFO[7] the calculations of transmitted energy are done based on energy content of ANFO, where the energy content of explosives a and b is regarded as 90 and 95 percent of ANFO respectively. For example the total amount of transmitted energy to Tuff in case of using explosive a will be as follows:

$$\eta_1 = 1 - \frac{(14.54 * 10^6 - 8.4 * 10^6)^2}{(14.54 * 10^6 + 8.4 * 10^6)^2} = 0.93$$

$$\eta_2 = \frac{1}{e^{57/27} - (e-1)} = 0.15$$

$$E_t = 0.9*0.93*0.15*E_{ANFO} = 0.13E_{ANFO}$$

Therefore, the transmitted energy to Tuff in case of using Explosive a will be 13 percent of energy content of ANFO. The rest of the calculations of transmitted energy in case of using each explosive type in each rock type are given in table 3. It should be noted that the diameter of charge in case of using ANFO is regarded as 54 mm as it is charged with compressed air. As it is obvious, the amount of transmitted energy in both rock types is the highest in case of using explosive c or ANFO and it is the lowest in case of using explosive a or emulsion explosive with diameter of 27mm. Therefore in both rock masses, using ANFO in cut and cut spreader sections in order to attain maximum possible fragmentation and emulsion explosive with diameter of 27 in contour holes to establish the final shape of the tunnel with minimum possible percent of overbreak is recommended.

Though the impedance of explosives a and b is nearer to impedance of both rock types, the amount of transmitted energy is higher in case of using explosive c and that's because of the impact of coupling factor which is more higher in explosive c. regarding the concept of energy transmission and the fact that lifter holes operate in contrast with the direction of gravity, the best choice of explosive for this section would be explosive c (ANFO) but the fact that these holes have water inside, forces the selection of other explosives due to negative impact of water on ANFO. Therefore the second best choice, namely explosive b (emulsion explosive with diameter of 35 mm) was used in lifter holes showing that the effect of ground condition can be of crucial importance.

Table 3. Energy transmission to each rock type in case of using different explosives for holes with diameter of 57mm.

Rock type	Explosive a	Explosive b	Explosive c
Tuff	$0.13E_{ANFO}$	$0.25E_{ANFO}$	$0.59E_{ANFO}$
Anhydrite	$0.12E_{ANFO}$	$0.23E_{ANFO}$	$0.51E_{ANFO}$

5 EFFECT OF DIAMETER OF HOLES

In this section the effect of diameter of holes on energy transmission is investigated. The available bits in the Alborz Tunnel allow drilling of 45 mm holes in addition to 57 mm. Therefore, the amount of energy transmission is calculated for 45 mm holes. The results are given in table 4. In this case, the diameter of charge in case of using explosive c (ANFO) is regarded as 42.75 mm which is 95 percent of diameter of hole like the previous section.

Table 4. Energy transmission to each rock type in case of using different explosives for holes with diameter of 45mm

Rock type	Explosive a	Explosive b	Explosive c
Tuff	$0.23E_{ANFO}$	$0.45E_{ANFO}$	$0.59E_{ANFO}$
Anhydrite	$0.22E_{ANFO}$	$0.41E_{ANFO}$	$0.52E_{ANFO}$

In this case, the results are the same as the previous section. Comparing tables 3 and 4 in both rock types for explosives a and b, the values of transmitted energy have increased noticeably. This is due to increase of coupling factor because of decrease in diameter of holes. In case of using explosive type c (ANFO) the values of transmitted energy have remained the same as previous section which was due to constancy of coupling factor in this case. Therefore the importance of coupling factor can be concluded in this particular case where the efficiency of blasting operations can be affected by this factor.

6 CONCLUSIONS

In this research, employing concept of impedance, the most suitable charge for each section of tunnel blasting was selected. The obtained results are as followings:

- The amount of transmitted energy in both rock types is the highest in case of using explosive c or ANFO and the lowest in case of using explosive a or emulsion explosive with diameter of 27mm.
- In both rock types, using ANFO in cut and cut spreader sections in order to attain maximum possible fragmentation is recommended.
- In both rock types, using emulsion explosive with diameter of 27 mm in order to establish the final shape of the tunnel with minimum possible overbreak is recommended.
- Though the impedance of explosives a and b is nearer than the impedance of explosive c to impedance of both rock types, the amount of transmitted energy is higher in case of using explosive c and that's because of the impact of coupling factor which is more higher in case of using explosive c.
- The best choice of explosive for lifter holes is explosive c (ANFO) but the fact that these holes have water inside, forces the selection of other explosives due to negative impact of water on ANFO. Therefore the second best choice, namely explosive b (emulsion explosive with diameter of 35 mm) was used in lifter holes showing that the effect of ground condition can be of crucial importance.
- Decreasing the diameter of holes from 57 mm to 45 mm has no effect on changing the explosive type for each section but the amount of transmitted energy in both rock types has noticeably increased in case of using explosive types a and b. this is because of the increase in coupling factor due to decrease in hole diameter. The coupling factor in case of using explosive c has been remained constant due to which the amount of transmitted energy has not changed.
- The coupling factor has more effect than the impedance factor in the amount of transmitted energy in this particular case.

Improving Drilling and Blasting Programs At Al-Jazi Limestone Quarry-Lafarge-Jordan

M. Amaireh
Tafila technical university, Natural Resources and Chemical Engineering Department/ Mining Engineering Tafila Jordan

ABSTRACT A 60 meters thickness outcropped medium-hard limestone is being extracted for the use in Alrashadiyah cement plant-Lafarge-Jordan. Several benches each of 10 m. high have been designed for this purpose. Thin layers of clay and shale interact with limestone beds. The company has to drill and blast the limestone beds for subsequent operations.

In this modest study, we are going to shed light on quarry drilling and blasting practices of the company, analyzing the important factors affecting the operation, and give suggestions about improving the overall efficiency of the whole operation.

1 INTRODUCTION

1.1 Drill Performance

In evaluating drill performance, four parameters are measured or estimated most frequently:

1-process energy and power consumption
2-penetration rate
3-bit wear (life)
4-cost (ownership + operating = overall)

Energy and power affect operating cost, but they are more important as determinates of penetration rate. Both penetration rate and bit wear are major criteria of importance, with wear critical in deep holes and hard rock. Cost is the ultimate measure of performance; a drill can have excellent performance, but if it is not cost effective, then an alternative system should be sought. It is well to understand, however, that a goal of mining is the minimization of all rock breakage costs and that drilling does not stand alone. Overall breakage costs include costs for blasting and also for crushing and grinding if mineral processing occurs.

1.2 Blast Performance

It has been observed in many case studies that power consumption of loading machineries and crushers operating on the site and of primary crusher operating on the plant depends on the ratio of desired fragmentation obtained from the blast. On the other side, a lower ratio of fragmentation decreases the primary blasting costs.

Poor fragmentation results lead to:

1-increased secondary blasting
2-increasing loading cycle time.
3-increased difficulty in transport
4-increased energy consumption at crushing or milling
5-low crusher or mill performances

On the other hand, when operating on fragmentation results in order to reduce secondary blast or other kind of secondary fragmentation before crushing, primary blast costs and drilling costs increase, making the efficiency of the mine site workings decrease.

When secondary blasting is avoided or reduced to its minimum in order to increase mine site working efficiency, the amount of cost related to the reduction of dimension of blocks is transferred to crushing or milling, reducing its efficiency and increasing its costs.

Loading, hauling and crushing costs decreased with increasing rock fragmentation while drilling and blasting

costs increased with increasing rock fragmentation.

2 COMPANY PRACTICE

2.1 Limestone Properties

The study area (Aljazi limestone quarry) consists of a successive benches of limestone beds as shown in Figure 1.

Figure 1. Pit benches

Figure 2. Bench layers

Figure 2. shows us the interacting layers of clay, marl, and shale.

2.1.1 Weight characteristics

Limestone has the following weight characteristics:
1-Bank weight (2610 kg/m^3)
2-Swell percent (69%)
3-Swell factor (0.59)
4-Loose weight (1540 kg/m^3)
5-Specific gravity (2.65 g/cc)

2.1.2 Limestone physical properties

Limestone physical properties are:
1-Hardness 3 to 4 on Mohr's Scale.
2-Compressive Strength1800-2100 Kg/cm^2.
3-Water Absorption Less than 1%.
4-Porosity Quite low.
5-Weather Impact Resistant.

2.1.3 Limestone chemical properties

Limestone chemical properties are:
1-Lime CaO (38-42)%
2-Silica SiO_2 (20-25)%
3-Alumina Al_2O_3 (2-4)%
4-Other oxides (1.5-2.5)%

2.2 Drilling Equipments and Tools

The company uses the following drilling equipments and tools:

2.2.1 DI 300 Titon DTH drill rig

1-Model Titon 300,Figure 3.
2-Hole Range (89-127) mm
3-Drill Pipe Diameter (76-89)mm
4-Drill Tube Length (4000)mm
5-Compressor (14 m3/min/17 bar)
6-Weight (40749) kg

Figure 3. Drill Rig

2.2.2 DTH hammer

1-Model (Mission 40).Figure 4.
2-Bit Range (115-152)mm, (4.5-6.0) inch.
3-Outside Diameter (98)mm, (3.86) inch.
4-Hammer Length (914)mm, (36) inch.

2.2.3 DTH drill bits

1-Model (Mission 40 Bits).Figure 5.
2-Bit Diameter (115-121)mm, (4.50-4.75) inch.

Figure 4. Hammer

Figure 5. Bit

2.3 Blasting Materials

The company experience the following blasting materials

2.3.1 ANFO prill

A dry blasting agent blend of Ammonium Nitrate and Fuel. ANFO PRILL is an efficient, economical and easy to use explosive. It comes in (25 kg) plastic bags of specific gravity (0.85), it's local price (JD 671 /tonne).

2.3.2 Watergel explosives

Slurry explosives are energy efficient, waterproof, that can be used for mining, quarry and construction blasting. Detonator sensitive PETRABOOST (cap-sensitive), packaged in carton packs (20±1 kg) of 4 polyethylene cartridges of 125mm diameter, 7 pieces of 83mm diameter, and 10 pieces of 70mm diameters. Specific gravity (1.1). Price (JD 1.7/kg). all cartridges are (50 cm) length.

2.3.3 Electric detonators

Electric detonators: designed to provide precise control that is necessary consistent blasting results in variety of blasting applications. Price (JD 2.72/detonator).

2.4 Company Blasting Design

The company blasting design is based on the following assumptions:

1. average bench height = 10.0 m
2. burden distance = 3.5 m
3. spacing distance = 3.5 m
4. subdrilling = 0.6 m
5. stemming depth = (hole depth)/3
6. bit diameter = 114.3 mm
7. main explosive:
   a. ANFO
   b. sp.gr.(0.8)
   c. loading density (7 kg/m)
   d. price (JD 671/tonne)
8. initiating explosive:
   a. Petra Boost
   b. sp.gr. (1.1)
   c. loading density (8% of ANFO)
   d. price (JD 1.7/kg)
9. detonator:
   a. electric delay detonator
   b. price (JD 2.72/piece)

2.5 Company Calculations

According to the company records, we can summarize it's drilling and blasting practice as follows:

Table 1. Blasting design parameters

Blasting design parameters	Shot No. 1 (20 holes)	Shot No. 2 (15 holes)	Shot No. 3 (20 holes)
Burden, m	3.5	3.5	3.5
Spacing, m	3.5	3.5	3.5
Planned hole depth, m	10	11	8
Avg. actual hole depth, m	6.9	11	6.9
Avg. stemming depth, m	2.3	3.7	2.3
Avg. powder column length, m	4.6	7.3	4.6

Table 2. Explosives consumption

Explosive consumption	Shot No. 1 (20 holes)	Shot No. 2 (15 holes)	Shot No. 3 (20 holes)
ANFO/shot (kg)	641.67	770.00	640.73
Boost/shot (kg)	64.17	61.60	51.26
Total (ANFO+ Boost) /shot (kg)	705.84	831.60	691.99

Table 3. Powder factor calculations

Powder factor calculations	Shot No. 1 (20 holes)	Shot No. 2 (15 holes)	Shot No. 3 (20 holes)
Total rock volume blasted / shot, m^3	1690	2021	1690
Total (ANFO + Boost) / shot (kg)	705.84	831.60	691.99
Average powder factor (Kg/m^3)	0.40	0.41	0.41

Table 4. Explosives cost calculations

Explosive cost calculations	Shot No.		
	1 20 holes	2 15 holes	3 20 holes
Total ANFO/shot (kg)	641.67	770.00	640.73
Total Boost/shot (kg)	64.17	61.60	51.26
ANFO cost @ JD0.671/kg	430.56	516.67	429.93
Boost cost @ JD1.70/kg	109.09	104.72	87.14
Detonator price JD2.72 / piece	54.40	40.80	54.40
Total explosive cost per shot (JD)	594.05	662.19	571.47

Table 5. Rock cost calculations

Rock blasted cost	Shot No.		
	1 20 holes	2 15 holes	3 20 holes
Total rock volume blasted per shot, m^3	1690	2021	1690
Total explosive cost per shot (JD)	594.05	662.19	571.47
Blasted rock cost JD/m^3	0.35	0.33	0.34

We could say that (according to the company practice), the average cost of unit volume of limestone rock produced by blasting in Aljazi limestone quarry is (JD0.34/m^3).

3 STUDY PRACTICE

3.1 Blast Design Parameters

The more important parameter in the blast design is how to choose the burden distance, because nearly all the other parameters depend on it. But to achieve a good shot we should have a stiffness ratio of at least (3). The average bench height (L) is 10 meters which is approximately (33 ft).

$$SR(Stiffness\ Ratio)=\frac{L}{B}\Rightarrow B=\frac{L}{SR}=\frac{33}{3}=11\ ft=3.35\,m$$

This value of burden distance should be the field distance or the corrected distance. The correction comes from the rock conditions such as deposition and structure. The conditions of limestone rock in the quarry are as follows:

1-deposition (bedding dipping into face), we should adopt a (0.95) value for K_d

2-structure (heavily cracked, frequent weak joints, weakly cemented layers), we should adopt a (1.30) value for K_s .

So, the calculated value of burden can be predicted as follows:

$$B_{corrected}=B\times K_d\times K_s$$

$$\Rightarrow 11=B\times 0.95\times 1.3$$

$$\Rightarrow B=\frac{11}{0.95\times 1.3}=8.9\ ft$$

The general formula for calculating the burden distance is:

$$B(ft)=\left(\frac{2SG_e}{SG_r}+1.5\right)D_e(in),$$

so we can use it to find the suitable exp*losive diameter as folows*

$$\Rightarrow 8.9=\left(\frac{2\times 0.8}{2.65}+1.5\right)\times D_e$$

$$\Rightarrow D_e=\frac{8.9}{\left(\frac{2\times 0.8}{2.65}+1.5\right)}=4.24\approx 4.25\,inch\,(108mm)$$

As ANFO is the main explosive, and it takes the shape of the hole; the suitable bit diameter will be (4.25 inch.).

We can now predict the blast design parameters assuming the burden distance(11ft).

Stemming depth

$$T=0.7\times B=0.7\times 11=7.7\approx 8\ ft\,(2.5\,m)$$

subdrilling depth

$$J=0.3\times B=0.3\times 11=3.3\approx 3\ ft\,(1.0\,m)$$

spacing; delayed initiation: 1 < SR < 4

$$\Rightarrow S\ \frac{L+7B}{8}=\frac{10+7(3.35)}{8}=4.2\,m$$

Spacing in the field should be within plus or minus 15% of the calculated value.

$$4.2-(15\%\times 4.2)\langle\ S\ \langle\ 4.2+(15\%\times 4.2)$$

$$\Rightarrow 3.6\,m\langle S\langle 4.8\,m$$

so, values of S should be within this range.

Blasthole depth (*H*)= bench height + subdrilling=33+3=36 ft (11 m)

Powder column (*PC*) = blasthole depth – stemming=36-8=28 ft (8.5 m)

We could summarize our work as follows:

Table 6. Suggested blast design parameters

Suggested blast design parameters	
Burden, (m)	3.5
subdrilling, (m)	1.0
Stemming, (m)	2.5
Spacing, (m)	4.5
Bench height, (m)	10
Hole depth, (m)	11
Powder column, (m)	8.5

3.2 Explosive Loading

1. loading density of ANFO at (0.8) specific gravity and (4.25) inch diameter is (4.94lb/ft) (7.36kg/m).
2. loading density of Boost at (1.1) specific gravity and (3.25) inch diameter is (3.98lb/ft) (5.93 kg/m).
3. loading density of boost as a percentage of ANFO varies according to several factors, such as
   a. rock structure, which is here heavily cracked, frequent weak joints, weakly cemented layers.
   b. blasthole diameter, 4.25 inch. is considered medium size hole.
   c. powder column length, 8.5 m is not considered a deep hole.

Loading density of Boost could reach (10% of ANFO) in the tough conditions, but in our case we may use (5% of ANFO), which may be suitable.

A powder column of 8.5m may need one full length cartridge of PETRA Boost of 83 mm diameter and 50cm length, which is equal to (2.9 kg). So, the remaining 8 meters of the column powder could be filled with ANFO.

3.3 Explosive Calculations

So, the explosives calculations could be as follows:

$$\begin{aligned}&Amount\ of\ ANFO\ /\ hole\\&= loading\ density \times column\ powder\ length\ of\ ANFO\\&= 7.36 \times 8.0 = 58.9\ kg\ /\ hole\end{aligned}$$

$$\begin{aligned}&Cost\ of\ ANFO\ /\ hole\\&= 58.9\ kg\ /\ hole \times JD\ 0.671/\ kg\\&= JD\ 39.52\ /\ hole\end{aligned}$$

$$\begin{aligned}&Amount\ of\ Boost\ /\ hole\\&= 5\% \times amount\ of\ ANFO\ /\ hole\\&= 0.05 \times 58.9 = 2.9\ kg\ /\ hole\end{aligned}$$

$$\begin{aligned}&Cost\ of\ Boost\ /\ hole\\&= 2.9\ kg\ /\ hole \times JD\ 1.7\ /\ kg\\&= JD\ 4.93\ /\ hole\end{aligned}$$

$$\begin{aligned}&Total\ \cos t\ of\ \exp losives\ /\ hole\\&= 39.52 + 4.93 + 2.72\\&= JD\ 47.17\ /\ hole\end{aligned}$$

$$\begin{aligned}&Total\ amount\ of\ \exp losives\ /\ hole\\&= 58.9 + 2.9\\&= 61.8\ kg\ /\ hole\end{aligned}$$

$$\begin{aligned}&Amount\ of\ rock\ blasted\ (m^3\ /\ hole)\\&= Pattern\ Area\ (m^2) \times Bench\ Height\ (m)\\&We\ may\ choose\ a\ pattern\ of\ (3.5\,m \times 4.5\,m)\\&Amount\ of\ rock\ blasted = 3.5 \times 4.5 \times 10\\&= 157.5\,m^3\ /\ hole)\end{aligned}$$

$$\begin{aligned}&Powder\ Factor\ (PF)\\&= \frac{Amount\ of\ Explosives\ /\ hole}{Amount\ of\ Rock\ Blasted\ /\ hole}\\&= \frac{61.8\,kg\ /\ hole}{157.5\,m^3\ /\ hole} = 0.39\,kg\ /\ m^3\end{aligned}$$

$$\begin{aligned}&Total\ Cost\ /\ Rock\ Blasted\\&= \frac{Total\ \cos t\ of\ Explosives\ /\ hole}{Amount\ of\ Rock\ Blasted\ /\ hole}\\&= \frac{JD\ 47.17\ /\ hole}{157.5\,m^3\ /\ hole} = JD\ 0.30\ /\ m^3\end{aligned}$$

Summarizing our work a follows:

Table 7. Explosives cost.

Item.	Cost (JD)
ANFO cost JD/hole	39.52
Boost cost JD/hole	4.93
Detonator cost JD/piece	2.72
Total explosives cost JD/hole	47.17
Rock blasted / hole m^3	157.5
Rock blasted cost JD/m^3	0.30

4 CONCLUSIONS

According to the company practice of drilling and blasting operations in Aljazi limestone quarry, and our detailed study of the case mentioned, we can conclude the following matters:

First: by comparing the blast design parameters for both we arrive at these results:

Table 8. Comparison of blast design parameters.

Blast design parameters	Company practice	Study practice
Bench height, (m)	10	10
Burden, (m)	3.5	3.5
Spacing, (m)	3.5	4.5
Subdrilling, (m)	0.6	1.0
Stemming, (m)	2.3	2.5
Actual hole depth, (m)	6.9	11
Powder column, (m)	4.6	8.5

Second: by comparing the explosives calculations for both we arrive at these results:

Table 9. Comparison of explosives cost.

Explosive calculations comparisons		Company practice	Study practice
Amount of explosives /hole (kg / hole)	ANFO	32.1	58.9
	Boost	3.2	2.9
Cost of explosives / hole (JD / hole)	ANFO	21.53	39.52
	Boost	5.45	4.93
Cost of detonator / hole (JD/piece)		2.72	2.72
Total cost of explosives / hole (JD/hole)		29.7	47.17

Third: by comparing the rock blasted cost calculations for both we arrive at these results:

Table 10. Comparison of blasted rock calculations.

Item.	Company practice	Study practice
Total rock volume blasted / hole, m^3	84.5	157.5
Total explosive cost / hole JD	29.7	47.17
Blasted rock cost JD/m^3	0.35	0.30

It can be seen that the blasted rock cost (JD / m^3) calculated by the study team is better than the one practiced by the company.

So, we could suggest the followings:

1. Try to use (4.25) inch. bit instead of (4.5) inch.
2. You may expand the spacing distance from (3.5)m to (4.5)m because of the rock conditions.
3. Use (5%) instead of (8%) as a percentage of ANFO quantity for calculating the suitable amount of Boost.

ABSTRACT This paper presents the results of a numerical study that has been performed to investigate the factors affecting the maximum bending moment induced in a jointed tunnel lining. The effects of joint number and orientation have been studied in detail. Observations of the results demonstrate that increasing joint number reduces the maximum bending moment induced in the lining. However, the effects of joint number and orientation on the maximum bending moment induced in the tunnel lining become insignificant once the critical joint number has been exceeded. In addition, the sensitivity of the joint number to various ground conditions, tunnel depths and lining flexibility are also highlighted. From the parametric studies, a simple design methodology is proposed to facilitate the determination of maximum bending moment induced in a jointed tunnel lining without incorporating joints in the analysis.

Keywords: Jointed tunnel, bending, lining

1 INTRODUCTION

The design of the precast segmental lining is based upon the proposed tunnel alignment and the expected geological condition at the tunnel level. The geometrical arrangement of the segment type might vary along the tunnel route, dependent on the tunnel boring machine steering alignment. This in turn affects the orientation of joints within each segmental ring. Furthermore, the possible mode of joint orientation is governed by the joint number. The combination of these two factors might influence the stresses induced in the tunnel lining. Subsequently, both the cost and planning purposes might be affected. Hence, it is the main purpose of the present research to investigate the various factors affecting the maximum bending moment induced in a jointed tunnel lining. These factors include joint number and orientation for a given range of ground condition, tunnel depth and lining flexibility. Based on the results obtained, a simple design methodology to determine the maximum bending moment induce in the jointed lining without incorporating joints in the analysis are prepared and presented.

2 FINITE ELEMENT MODELLING

Figure 1 illustrates the most favourable and critical orientation of joints adopted in this numerical investigation. The study was performed using a two-dimensional finite element method program, PLAXIS. Typical lining parameters of Singapore Mass Rapid Transit (MRT) Tunnel were adopted in the modelling and were summarized in Table 1. The main analysis focused on tunnel of 6m in diameter (D) with a depth-to-diameter ratio (H/D) of 2. The ground is considered elastic with properties as suggested by Copsey and Doran (1987) for the Bukit Timah Residual Soil, as shown in Table 2. These properties have been varied during the parametric studies. The modelling procedures involved a full-face excavation of a tunnel with segmental lining supporting the tunnel immediately after the excavation. The lining segments were modelled by applying a number of joints within the lining with their orientations shown in Figure 1. A

reference joint is defined as a joint that is located closest to the tunnel crown, in clockwise direction from the tunnel crown. The location of the reference joint was measured by an angle "Θ". An angle $\Theta = 0^o$ represents a reference joint being positioned at the tunnel crown, while an angle $\Theta = 45^o$ represents a reference joint located at the tunnel shoulder.

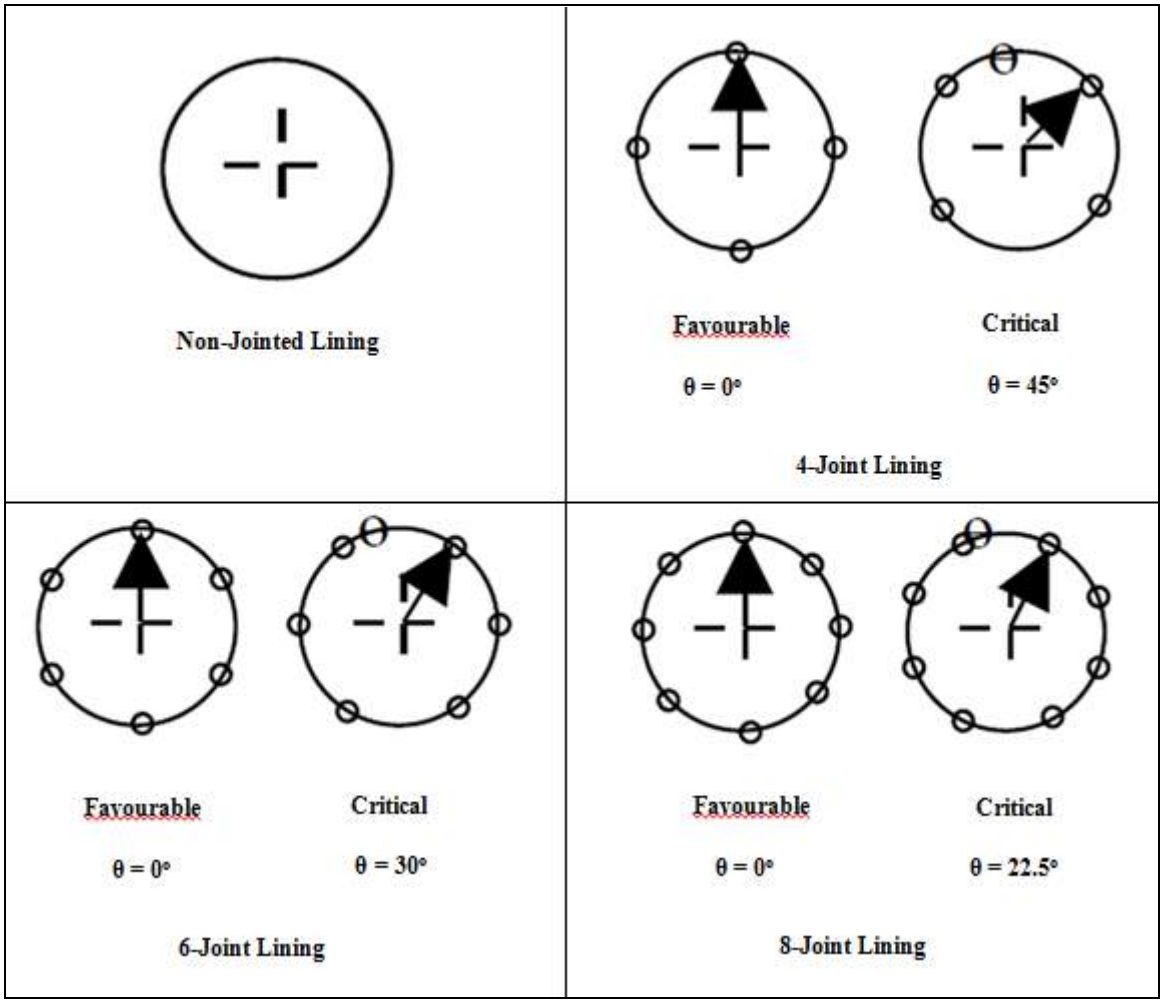

Figure 1. Illustrations of Jointed Tunnel Lining

Table 1. Properties of Elastic Tunnel Lining

Parameter	Symbol	Value	Unit
Young's modulus	E_1	32000	MN/m^2
Poisson's ratio	υ_1	0.2	-
Lining thickness	t	0.275	m

Table 2. Properties of Bukit Timah Residual Soil (after Copsey and Doran, 1987)

Parameter	Symbol	Value	Unit
Unit weight	γ_S	18	kN/m^3
Young's modulus	E_S	8250	kN/m^2
Poisson's ratio	υ_S	0.495	-
Coefficient of earth pressure at rest	K_0	0.5	-

3 PARAMETRIC STUDIES

A series of parametric studies was conducted to investigate the effects of joint number and orientation on the maximum bending moment induced in the tunnel lining. Furthermore, additional analyses focused on 6-joint, 8-joint and non-jointed tunnel lining were also being performed for a given range of coefficient of earth pressure at rest, tunnel depth and lining flexibility. Both 6-joint and 8-joint were chosen to represent the typically joint numbers encountered in segmental tunnel ring.

3.1 Effect of Number and Orientation of Joints

The influence of number and orientation of joints on the maximum bending moment induced in the tunnel lining was studied. The results of the largest and lowest maximum bending moment, correspond to the most critical and favourable joint orientation for each joint number, are plotted in Figure 2a.

Figure 2(a) shows that increasing joint number reduces the maximum bending moment induced in the lining. This is attributed to the fact that the span of the beam is shorter with more number of joints, in turn, induced lower bending moment in the lining. The maximum bending moment induced in the lining becomes negligible small when the joint number exceeds 8-joint. In addition, it should be noted that the most favourable orientation of 4-joint induced much lower maximum bending moment as compared to 5-joint and 6-joint. This indicates that the joint orientation significantly influence the maximum bending moment induced in the lining. However, the maximum bending moment for cases involved a minimum of 8-joint is about similar in magnitude, regardless of the joint orientations. This could be explained by the fact that for tunnel ring with greater segment number, the span of each beam becomes shorter. Hence, the average loading acting on each beam becomes almost similar in magnitude, despite joint orientations. As a result, the variation of maximum bending moment with joint orientations becomes insignificant for cases involved greater joint number. In addition, a comparative study was carried out for 4-joint, 6-joint and 8-joint tunnel lining and the results are presented in Figure 2(b). The 4-joint lining was adopted as a reference case in the investigation as it shows the most significant variation of maximum bending moment with joint orientation, as indicated in Figure 2(a). Both 6-joint and 8-joint lining were chosen as they represent the typical joint numbers encountered in most segmental tunnel ring. The results in Figure 2(b) show that the maximum bending moment induced in the jointed lining is the lowest for reference joint at $\Theta = 0^o$, i.e. when the reference joint is located at tunnel crown. However, the maximum bending moment induced in the lining is the largest when the reference joint is located in between the angle of $\Theta = 0^o$ and the largest possible Θ value for each case of joint number. For instance, the largest maximum bending moment for 4-joint, 6-joint and 8-joint tunnel lining occurred at $\Theta = 45^o$, 30^o and 22.5^o respectively, as illustrated in Figures 1 and 2(b). These observations are of practically important in the design of segmental tunnel ring due to the fact that the location of the reference joint for each segmental tunnel ring varies along the tunnel alignment. Hence, the stresses induced in each segmental tunnel ring of different joint orientation are different, for the same ground condition and tunnel depth.

3.2 Effect of Coefficient of Earth Pressure at Rest

The effect of K_o-value was studied in this section. The K_o-value of 0.5 and 1.0 were adopted to represent normally consolidated ground while K_o-value of 2.0 for overconsolidated ground. The results of the study are presented in Figure 3 (a . as shown in Figure 3(a), the largest maximum bending moment occurred when $K_o = 2.0$ and the lowest was observed for $K_o = 1.0$ (approximately zero moment), with $K_o = 0.5$ in between.

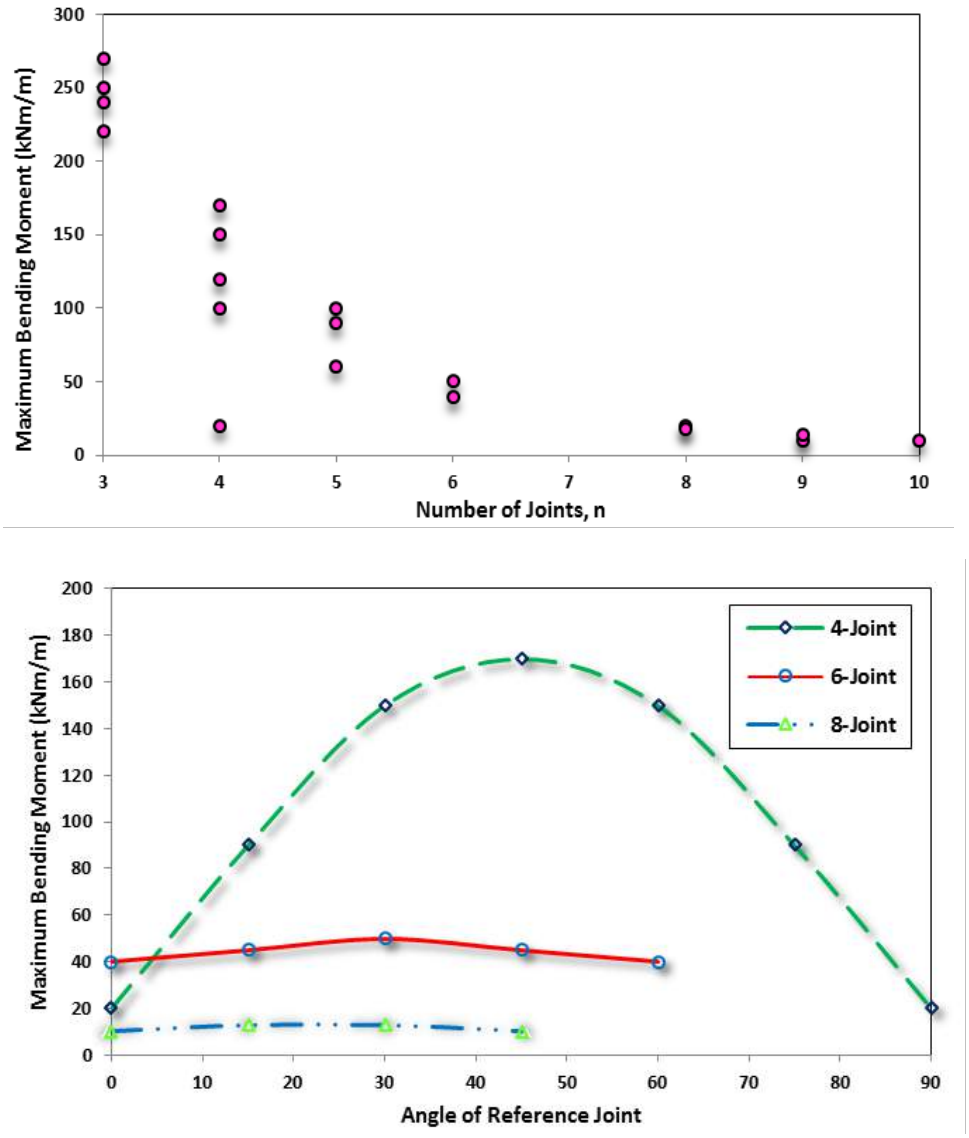

Figure 2. Variation of Maximum Bending Moment with (a) Number; and (b) Orientation of Joints

As expected, this is attributed to the larger difference between the vertical and horizontal loading acting on the lining for K_o = 2.0, as compared to K_o = 0.5 and 1.0. For the given range of K_o-value, the maximum bending moment induced in the lining with a maximum of 3-joint is greater than nonjointed lining. However, a lower maximum bending moment was observed for lining with a minimum of 5-joint, as compared to the non-jointed lining. In addition, it should be noted that the maximum bending moment induced in the 4-joint lining is about similar in magnitude as the non-jointed lining, for the given range of K_o-value. These observations are in line with the statement made by Muir Wood (1975) that the effect of joints would only influence the rigidity of the lining if the number of lining segments is greater than 4.

3.3 Effect of Tunnel Depth

The influence of tunnel depth on the maximum bending moment induced in the jointed tunnel lining was studied. Analyses were performed for a range of depth-to-diameter ratios, i.e. H/D ranging from about 1.0 to 3.5, for shallow and deep tunnel case. Results of the variation of maximum bending moment with depth of burial are presented in Figure 3(b.(Figure 3(b) shows the maximum bending moment induced in the lining increases with tunnel depth. This is due to the increase in the overburden pressure acting on the lining as the depth

increases. At shallower depth of burial, e.g. H/D of about 1.0, the maximum bending moment induced in both 6-joint and 8-joint lining is about similar. However, the difference becomes increasingly significant at greater tunnel depth. This indicates the influence of joint number is much more significant for deep tunnel case as compared to shallow tunnel. In addition, it should be noted that the maximum bending moment induced in the non-jointed lining at shallower depth of burial is significantly larger than cases involved 6 and 8-joint. Furthermore, a relatively steeper slope shown in Figure 3(b) for non-jointed lining as compared to 6-joint and 8-joint indicates that the incremental maximum bending moment with depth of burial for non-jointed lining is much more significant than jointed lining.

3.4 Effect of Lining Flexibility

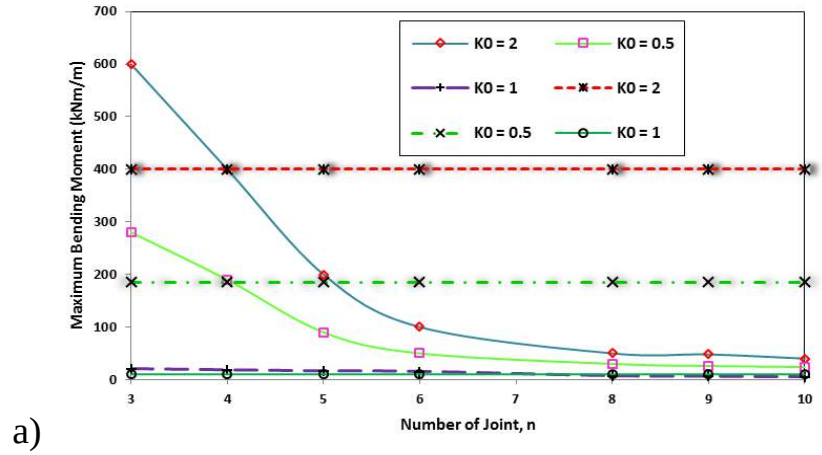
The influence of lining flexibility on the maximum bending moment induced in the jointed tunnel lining was examined based on the flexibility ratio, F, defined by Peck (1972) in Equation 1. Increasing lining flexibility increases flexibility ratio. Hence, the lining behaves more flexible. However, it should be pointed out that the flexibility ratio proposed by Peck (1972) assumed a continuous tunnel lining and therefore does not take into consideration of joint factor. Figure 3(c) shows that for jointed tunnel with stiff lining, the maximum bending moment induced in the lining is significantly influenced by the number of joints. For instance, increasing joint number from 6 to 8-joint for very stiff lining case with flexibility ratio of about 0.05 reduces nearly 70% of the maximum bending moment in the lining. However, the influence of joint number becomes gradually insignificant with increasing lining flexibility, particularly for cases involved lining with flexibility ratio of greater than 15. It is important to emphasize that similar lining thickness was adopted for both jointed and nonjointed tunnel lining, for a given flexibility ratio defined by Peck (1972). The results shown in Figure 3c) indicate that increasing joint number for jointed lining is tantamount to increasing lining flexibility which in turn, flexibility ratio of non-jointed lining. This is attributed to the fact that the maximum bending moment induced in both jointed and non-jointed lining show a similar descending trend with increasing joint number and lining flexibility respectively. In addition, observations of the results also reveal that the application of flexibility ratio proposed by Peck (1972) in the interpretation of lining flexibility for cases involved jointed lining might not be as efficient as for continuous lining. For the same lining thickness, the lining flexibility of jointed lining is higher than the non-jointed lining, resulted from the joint effect. Thus, the necessity of considering a new effective second moment of inertia to replace the existing second moment of inertia, as defined in Equation 1, is established to facilitate the determination of effective flexibility ratio for jointed lining. Furthermore, this finding also opens up the possibility of estimating the maximum bending moment induced in the jointed lining without incorporating joints in the analysis and subsequently, simplifying the design procedures of the jointed lining. The detail illustrations are presented in the following section.

$$F = (E_s/(1+\upsilon_s))/(6E_lI_l/(1-\upsilon_1^2)R^3) \quad (1)$$

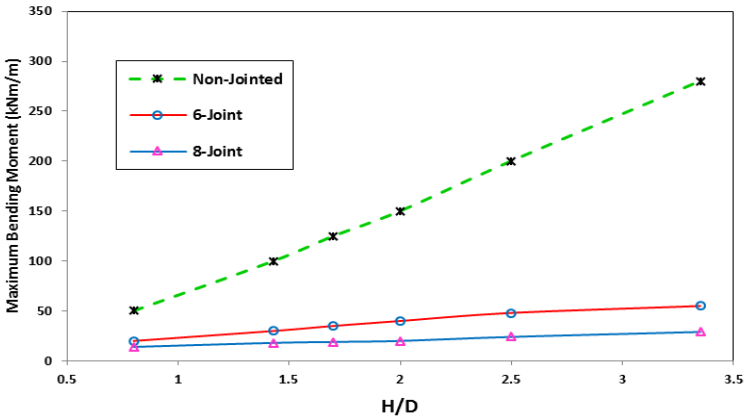
where I_l is the second moment of inertia for continuous tunnel lining; and R is the tunnel radius.

4 SIMPLIFIED DESIGN METHODOLOGY

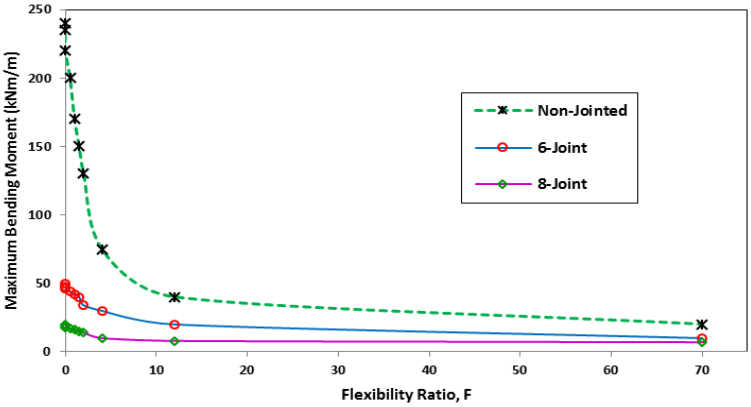
From the parametric studies, a simplified design methodology was proposed to facilitate the determination of maximum bending moment induced in a jointed tunnel lining without incorporating joints in the analysis. The design chart shown in Figure 4 gives the maximum and minimum effective second moment of inertia for the non-jointed lining that is of equivalent to the jointed lining. It can be noted from the design chart that increasing number of joints reduces the effective second moment of inertia, I_e, of the lining which in turn, equivalent to a reduction in the lining thickness of the nonjointed lining.



a)



b)



c)

Figure 3. Variation of Maximum Bending Moment (most critical joint orientation) with (a) K_o-Value (b) Tunnel Depth; and (c) Flexibility Ratio (as defined in Equation 1)

The design chart, together with Equations 2 and 3, facilitate the determination of both $I_{e,max}$ and $I_{e,min}$. The $I_{e,max}$ correspond to the effective second moment of inertia for the most critical orientation of joints while $I_{e,min}$ represents the effective second moment of inertia for the most favourable orientation of joints. The substitution of I_l in Equation 1 with $I_{e,max}$ and Ie,min enables the effective flexibility ratios of the non-jointed lining to be computed, which correspond to the most critical and favourable orientation of joints for the jointed lining. These effective flexibility ratios allow the moment coefficients, and subsequently maximum bending moments induced in the jointed lining to be estimated from Figure 5 and Equation 4 respectively. The design of the jointed tunnel lining could therefore be carried out based on the relatively lower

maximum bending moment estimated using this approach, as compared to the conventional design methodology assuming continuous tunnel lining, for cost and planning purposes.

$$I_{e,min}/I = 429/n^{4.} \quad (2)$$

$$I_{e,max}/I = 159.2/n^{4.3} \quad (3)$$

$$M_p = M_{max}/\gamma HR^2 \quad (4)$$

Where M_p is the moment coefficient; M_{max} is the maximum bending moment; and n is the joint number.

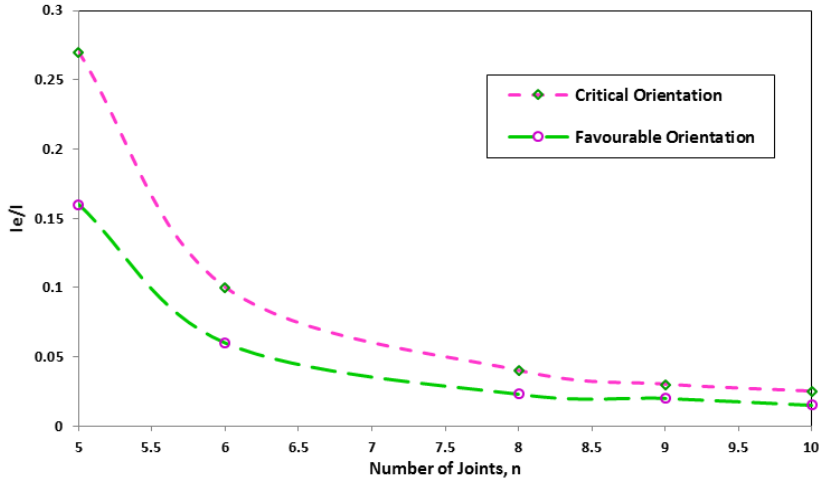


Figure 4. Variation of I_e/I with Number of Joints

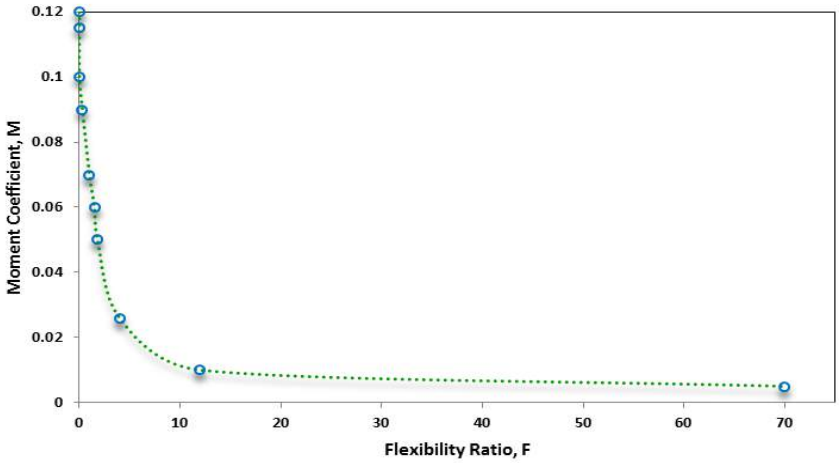

Figure 5. Variation of Moment Coefficient with Flexibility Ratio

5 CONCLUSIONS

A numerical study to investigate the factors affecting the maximum bending moment induced in a jointed tunnel lining has been performed. The influence of number and orientation of joints, ground condition, tunnel depth and lining flexibility have been studied in detail. The finite element method program PLAXIS was adopted in the investigation. Observations of the results demonstrate that the number and orientation of joints have significant influence on the maximum bending moment induced in the jointed lining, for a given range of ground condition, tunnel depth and lining flexibility. The lowest maximum bending moment (most favourable joint orientation) induced in the lining when the reference joint is located at tunnel crown ($\Theta = 0^o$). However, the largest maximum bending moment (most critical joint orientation) induced in the

lining when the reference joint is located at an angle between $\Theta = 0^o$ and the largest possible Θ value for each case of joint number. For segmental tunnel ring of less than 4-joint, with the most critical joint orientation, the maximum bending moment induced in the lining is greater than the non-jointed case. However, the opposite trend was observed for segmental tunnel ring of more than 4-joint. The maximum bending moment induced in 4-joint segmental tunnel ring is about similar to non-jointed case. For cases of K_o-value of lesser or greater than unity, the influence of joint number on the maximum bending moment induced in the lining is significant. The largest maximum bending moment induced in the lining for K_o = 2.0, as compared to K_o = 0.5. The influence of joints on the maximum bending moment induced in the lining increases with tunnel depth. However, the maximum bending moment for the non-jointed lining increases more significantly with tunnel depth as compared to jointed lining. The influence of joint number on the maximum bending moment induced in the lining is significant for stiff lining case of small flexibility ratio. A simplified design methodology has been proposed to facilitate the determination of the maximum bending moment induced in a jointed tunnel lining without incorporating joints in the analysis. The results of the parametric studies, together with the proposed design methodology are believed to be useful for the preliminary design of jointed tunnel lining.

Evaluation of Blast Induced Ground Vibrations at Ozarslan Quarry

Özarslan Taşocağında Patlatma Kaynaklı Yer Sarsıntılarının Değerlendirilmesi

M.C. Ozyurt, U. Kalayci, A. Karadogan, U. Ozer
Istanbul University, Mining Engineering Department, Istanbul, Turkey

ÖZET Bu çalışmada, Kırklareli ili Vize yöresinde bulunan Özarslan Taşocağında yapılan patlatma kaynaklı titreşim ve yersarsıntıları incelenmiştir. Çalışma kapsamında, 13 atıma ait 48 olay, titreşim ölçer cihazlar ile kaydedilmiştir.

Elde edilen veriler, dört bantlı filtrelemeye tabi tutularak gerçek titreşim ve frekans verilerinin elde edilmesi amaçlanmıştır. Kaydedilen maksimum parçaçacık hızı ile ölçekli mesafe arasındaki ilişki statik analiz ve anlamlılık testi ile değerlendirilmiştir. Değerlendirme sonucunda söz konusu ilişkinin anlamlı olduğu ortaya konmuştur.

Anahtar kelimeler: Yer sarsıntısı, titreşim analizi

ABSTRACT This paper presents blast induced vibration analysis on blasting at Ozarslan Quarry located in Vize district in Kırklareli province in Turkey. During the study, 13 shots were monitored at different times and 48 events were recorded by vibration monitors.

A four layered band filter applied to vibration data in order to obtain actual vibration signal and frequency data. The recorded peak particle velocities and scaled distances were subjected to statictical analysis and variance analysis. After the evaluation, site specific attenuation formula is obtained and found as significant.

Keywords: Ground vibration, vibration analysis

1 INTRODUCTION

After the detonation of explosive, the immediate vicinity of the blast hole that may extent as the diameter of the blast hole is called as shock zone. In this zone, the rock behaves mechanically as viscous solid and the rock is crushed or extensively cracked. The domain immediately outside the shock zone is called as the transition zone. In this zone, the rock behaves as non-linear elastic solid and new fractures are initiated and propagated in the radially compressive stress field. The outside of transition zone is called as seismic zone. In seismic zone the rock behaves linearly elastic (Brady and Brown 1985).

For damage levels which occurs in seismic zone, the carried energy level of vibrations is not only responsible (Kalaycı, 2011). The following parameters are using for determination of the energy level of vibrations; particle displacement (mm), particle velocity (mm/sec), particle acceleration (mm/sec2), wave frequency (Hz).

Features and characteristics of ground vibration are effected by blasting design and parameters; especially the amount of explosives detonated at the same time, firing sequence (time delay) and the direction of the firing, in the close fields of shot point. However, far from shot point, ground and rock mass characteristics, which carries the seismic waves, effects the vibration feature and specialty. Besides, land coefficients and the frequency of vibrations are important and decisive factors for damage mechanism (Karadoğan, 2008; Özer et all, 2011).

Blast induced damage criteria developed by various researchers, until today have been applied with varying degrees of success. Frequency is one of the basic damage criteria according to many researchers. Frequency based damage approaches; Rockwell's (1934) energy formula based on frequency and amplitude; Crandell's (1949) energy ratio approach which based on acceleration and frequency; the chart of Langefors and Kıhlström (1973); Medearis's (1976) damage estimation based on particle velocity and dominant frequency; United States Bureau of Mine's (1980) Criteria Based on particle velocity, frequency, construction and building type; German DIN 4150 standards (1984), which based on particle velocity, frequency and structural characteristics; Indian CMRI standards (1987), which based on particle velocity, frequency and structural characteristics; United States Office of Surface Mining's (OSM), peak particle velocity limit, scaled distance and frequency based approach (Karadogan, 2008).

Frequency and particle velocity components are the most effective parameters on blast induced damage. Several methods are using for determining of the rock mass frequency by seismic waves. These methods are zero crossing frequency and Fourier frequency methods. Zero crossing frequency, calculates the event waveform's frequency at the largest peak by using 1/period formula. The zero crossing calculation is limited because it assumes a single predominant frequency at the peak, typically represented by sinusoidal waveforms. In practice the peak may be the result of two or more major frequency components representing compound waveforms (Kalaycı et al, 2014).

The most trustable method to determine the frequency is the Fourier transform method which is the mathematical tool that deconstruct the waveform into its sinusoidal components. Thus, it transforms the time based function to frequency based function. The Fourier algorithm is used for digital filtering to extract the cosine and sine parts of the fundamental frequency component. These components are functions of time and have the same frequency as the fundamental harmonic of the signal (Kalaycı et al, 2014).

2 TEST SITE DECSCRIPTIONS

The research program was carried out in order to eliminate environmental problems and to optimize blasting conditions during the blasting excavations at Ozarslan Const. and Mining Industry.and Trade's Quarry located in Vize district in Kırklareli provincein Turkey. The location of this site is shown in Figure 1.

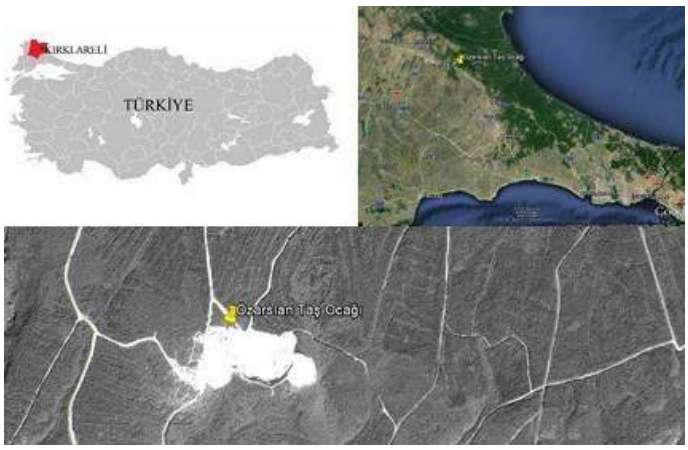

Figure 1. The Location of Ozarslan Quarry

2.1 Geology

Kırklareli Limestone (The Sogucak Formation), the most common shallow marine unite in Thrace, consists mainly of limestones deposited in a variety of depositional settings ranging from reef to back-reef and to fore-reef environments The unit in most cases directly overlies the metamorphic rocks and upper Palaeozoic siliciclastics in the nothern and eastern part of Thrace.

The Soğucak Formation is either overlain by continental beds of the Pınarhisar Formation or by deep marine (partly shallow marine as in Karaburun) beds of the Ceylan Formation, which is widely distributed in the southern part of Thrace. The Pınarhisar Formation comprises continental sandstones/conglomerates and Congeria-rich limestones considered to be Oligocene in age based on fish remains, ostracods and molluscs (Less et all, 2011).

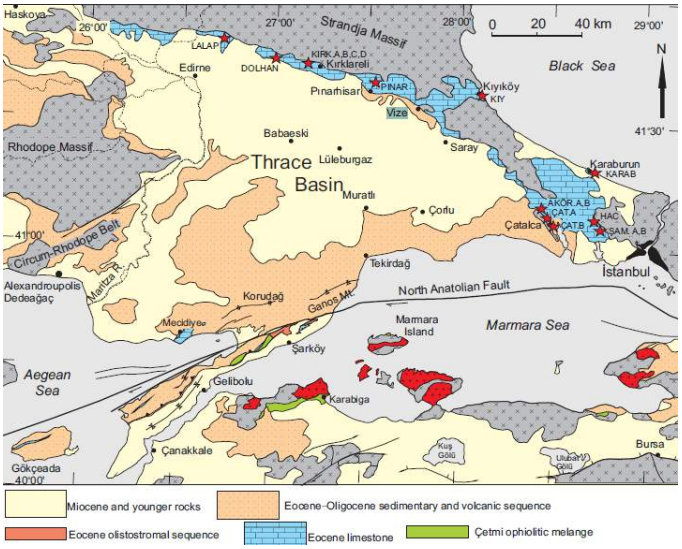

Figure 2. Tectonic map of the Th race and Marmara region with the location of stratigraphic sections and samples (red stars) (Less et all, 2011)

Figure 3. The Kirklareli formation's reef environment

2.2 Physico-Mechanical Parameters of Rock

According to recent studies in Ozarslan Quarry, the physico-mechanical parameters of rock are presented in Table 1.

Table 1. Physico-Mechanical Parameters of Rock (Ozer, et all, 2013).

PARAMETERS	VALUE
Density	2,34 g/cm^3
Ultrasonic Sound Transmission	5147 m/sn
Toughness Strength	1,26 Mpa.m^1/2
Uniaxial Compressive Strength	93,94 MPa
Uniaxial Tensile Strength	5,3 MPa

According to the physico-mechanical parameters of rock, it was understood that the blasting operations were inevitable for excavation in Ozarslan Quarry.

3 TEST PROCEDURE

In this study, the blast design and procedures were observed. During this observation, no changes were made to the blasting patterns that are systematically applied by company engineers.

During the field study, 13 shots were monitored, and 48 events were recorded by 9 vibration monitors (four of them are 4 channels, 5 of them are 8 channels). Most of these monitors were located along and both sides of the Fault that cuts the field in the direction of N-S. The coordinates of monitor stations and shot points were determined by GPS and blasting patterns were recorded for each shot.

After the measurements, the obtained data were analyzed by taking Particle velocities, frequencies, distances, charge amounts, the fault plane and rock unit changes along the fault plane into consideration. At the analysis stage, scaled distance were estimated by the SD equation which extensively suggested in literature

$$(SD = R / W^{0.5})$$

Where, SD, scaled distance; R, distance; W, maximum charge per delay.

After the measurements, the obtained data were analyzed by taking Particle velocities, frequencies, distances, charge amounts, the fault plane and rock unit changes along the fault plane into consideration.

To calculate the frequency values, Fast Fourier Transform algorithm is used via Matlab program. The fast Fourier transform (FFT) is a discrete Fourier transform algorithm which reduces the number of computations (Matlab, 2014).

The functions Y = fft(x) implement the transform and inverse transform pair given for vectors of length N by

$$X(k) = \sum_{j=1}^{N} x(j)\omega_N^{(j-1)(k-1)}$$

$$x(j) = (1/N)\sum_{k=1}^{N} X(k)\omega_N^{-(j-1)(k-1)}$$

Where $\omega_N = e^{(-2\pi i)/N}$ is an Nth rooth of unity.

5 EVALUATION OF THE RESULTS

During the Ozarslan Quarry blasting operations, vibration monitors were used for investigation of frequency and particle velocity levels around the fault plane. The stations of vibration monitors were located in boundaries of field, and also along and both sides of the fault plane. 48 events were recorded for 13 shots.

To estimate particle velocity, the relationship between particle velocty and scaled distance, derived by considering charge per delay and distance between shot location and vibration monitors' stations is investigated. The relationship between particle velocity and scaled distance is shown in Figure 4.

As a result of the regression analysis by considering distance between shot location and vibration monitors' stations, charge per delay and peak particle velocity, the formula that contains the constants of the study area,

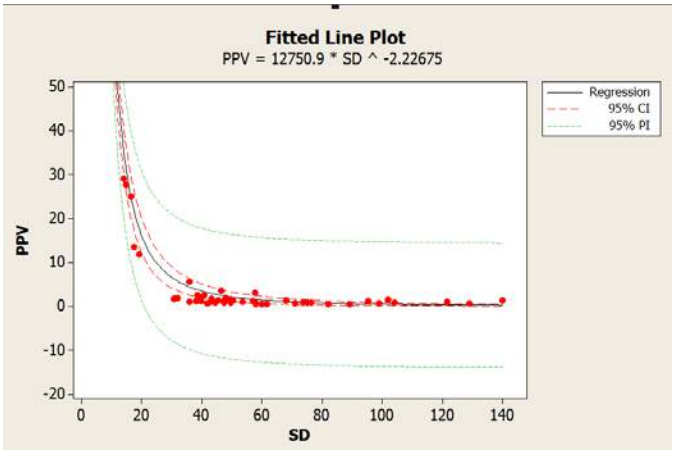

Figure 4. The Relationship Between Particle Velocity And Scaled Distance

recommended for use in blasting operations to estimate particle velocity. The formula is given in Equation 1.

$$PPV = 12750 \times SD^{-2,227} \quad (r=0,866) \qquad (1)$$

To validate that if SD variation is affected the PPV values, hypothesis test is performed. Hypotheses are as follows; H_0 (Null) hypothesis: PPV values are not affected by SD variation; H_1 hypothesis: PPV values are affected by SD variation.

All hypothesis tests use a P-value to weigh the strength of the evidence. The p-value is a number between 0 and 1 and interpreted in the following way:

•A small p-value (typically ≤ 0.05) indicates strong evidence against the null hypothesis, null hypothesis should be rejected.

•A large p-value (> 0.05) indicates weak evidence against the null hypothesis. That means unsuccessful to reject the null hypothesis.

•P-values very close to the designated limit (0.05) must considered to be marginal (Rumsey, 2011).

Analysis of variance results (Anova) is given in Table 5.

Table 5. Analysis of variance results

Source	Sum of Squares	Degree of Freedom	Mean Squares	P Value
Regression	7976.90	99	79.7786	0.002
Residual	0.97	1	0.9661	
Uncorrected Total	7977.86	100		

Due to the P value lower than 0.05, null hypothesis is rejected. In other words, in this data set the peak particle values are affected by variation of scaled distance values at %5 significance level.

The noises prevent the existence of dominant frequency in vibration analysis. For this reason, 4-band filter has been applied to vibration datas. Band filter coefficients and flow chart are given in Figure 5.

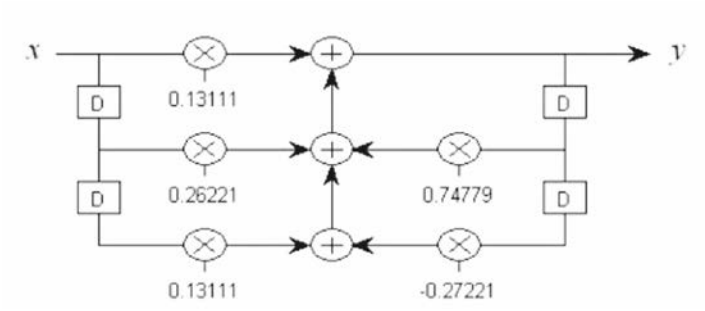

Figure 5. Band Filter Coefficients And Flow Chart

Filtered L component of vibration caused by Shot No. 5 is shown in Figure 6. This process is performed to each shots' all vibration components.

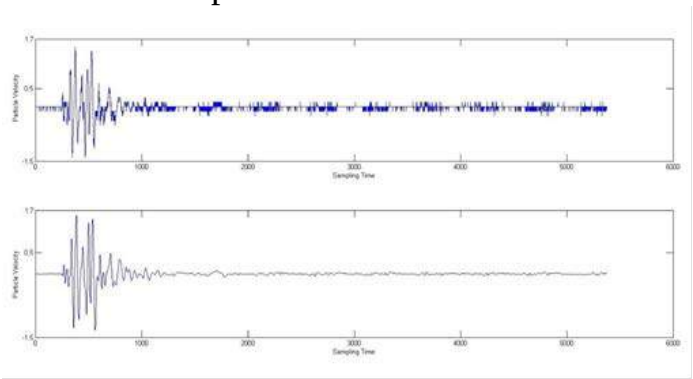

Figure 6. Filtered L Component of Vibration Caused by Shot No. 5

When the change in frequency values recorded are closely examined, 3 different frequency groups are spotted.

The frequency range spectrum, which calculated with Fourier Transform method and its filtered view, also given for each region in Figure 7.

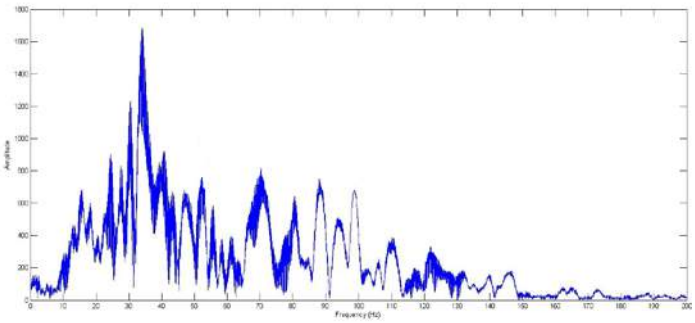

Figure 7. Frequency Oscillation Of Region I

As a result of filtering process, frequencies that given maximum amplitude, are about 30 Hz.

6 EVALUATION OF THE RESULTS

During the study, 48 events for 13 shots were recorded. As result of investigation of these events, some suggestions were presented.

It was understood that the blasting operations were inevitable for excavation in Ozarslan Quarry, the physico-mechanical parameters of rock.

In order to monitored vibration and air shock caused by blasting, vibration monitor devices were placed around the quarry. The recorded peak particle velocities and scaled distances were subjected to statictical analysis. The results are written below.

Filtering process outputs a dominant frequency. As a result of this, filtering process must be done. The noise affects the measured data. Therefore, it shouldn't be used in calculations.

The variance analysis on the measured data is performed, relationship and significance of datas are tested. As result of the test, the relationship between PPV and SD is proved to be significant.

As a result of filtering process, frequencies that given maximum amplitude, are about 30 hz.

Vibrations propagation equation for Ozarslan Quarry is found in the %95 confidence interval, by nonlinear analysis.

Before analyzing the frequency data, 4 layered band filter is applied to vibration data to prevent noises. While analyzing the frequency data both zero crossing and Fourier transform methods were used. According to results, Fourier transform method was decided because of reliability and utilization extensity.

ABSTRACT In this study, plaster stemming application at a basalt quarry was investigated. For comparison of two stemming method, test blasts were carried out in the same quarry bench. For unit volume rock, plaster stemming provided lower cost than drill cuttings stemming. Because, burden and spacing distances were increased at plaster stemming round. Although length of charge column was increased, the cost of unit volume rock was lower for plaster stemming round. Rock piles fragmentation of plaster stemming round and drill cuttings stemming round were similar.

Keywords: Plaster stemming, blasting, stemming, fragmentation, vibration

ÖZET Bu çalışmada, bir bazalt ocağında alçı sıkılama uygulaması incelenmiştir. İki sıkılama yönteminin karşılaştırılması için aynı basamakta test atımları yapılmıştır. Birim hacimdeki kayaç için, alçı sıkılama daha düşük maliyet sağlamıştır. Çünkü, alçı sıkılama atımında, dilim kalınlığı ve delikler arası mesafe artırılmıştır. Bunun yanında, sarj kolonu boyu artmasına rağmen, birim hacim kaya maliyeti, alçı sıkılama yönteminde daha düşük olmuştur. Her iki atımın parça boyut dağılımı birbirine yakın gerçekleşmiştir.

Anahtar Kelimeler: Alçı sıkılama, patlatma, sıkılama, parçalanma boyutu, titreşim

1 INTRODUCTION

The stemming of blast hole collars in surface mines with an inert material redirects blasting energy to the rock more efficiently, thus the energy is utilized more effectively in breaking rock. In this procedure, high efficiency of blockage is important since the blast gases should not be allowed to escape due to loose stemming material. More efficient stemming with better confinement therefore increases the generation of fines. In addition, better rock breakage can be obtained. On the other hand, scatter distance is increased; giving rise to a looser muck pile that can be more easily loaded and transported (Ozkahraman, 2006).

Drill cuttings are the most common stemming material used in open pits and quarries, since they are most readily available at blast sites and are cheap. However, dry drill cuttings eject very easily from blast holes without offering much resistance to the explosion of blast energy is wasted and lost to the atmosphere (Cevizci, 2013).

Apart from the work of Cevizci (2012), there is no previous work found in the literature citing the usage of this material. Blasting tests were carried out in quarries using both the suggested new stemming method and classical stemming material, and

performance measurements carried out by image analysis of fragmented rock piles.

The new method employs a plaster prepared as a thick paste, which hardens in less than 25–30 minutes after application. The hardened plaster creates a very strong plug, therefore the stemming column length can be reduced and the explosive column length increased. This increased explosive column results in better rock breakage than similar holes stemmed with dry drill cuttings. Also, this increased utilization of hole length reduces specific drilling costs due to increased burden and spacing distances. Blast hole drilling constitutes a major cost in blasting operations. Another advantage of the new method is better fragmentation, with more induced cracking in the rock mass.

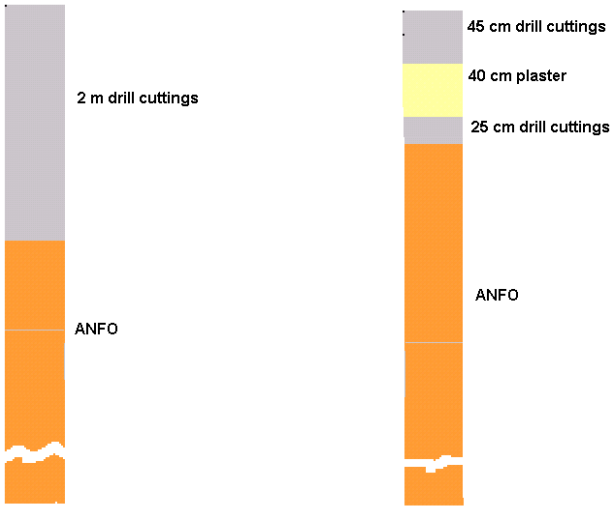
In one series of blast tests, blasting costs per unit volume of rock were reduced to 16 % by increasing burden and spacing distances (Cevizci 2012). Also, better fragmentation was obtained by using the plaster stemming method. Blast trials showed that plaster stemming produced finer material. In the same blast tests, +30 cm size fragments reduced to 5.4 % of the total, compared to 37.7 % in the conventional method of drill cuttings stemming. With this method of stemming, vibration and air shock values increased slightly due to more blast energy being available for rock breakage, but these increased values were small and under the permitted limit for blast damage criteria (Cevizci 2012)

2 METHOD

The study was carried out at Asagi Caglayan basalt quarry of Bazalt Company. The quarry is located at south-west of Eskisehir city. Both fast-setting moulding plaster and drill cuttings were used as stemming material at different lengths in similar blast holes on the same quarry bench. A thick milky moulding plaster was prepared by mixing ten units of plaster powder and seven units of water in a barrel, and charged into the blast holes as shown in Figure 1. This wet paste hardens in 25–30 minutes. The design of the stemming, using the tests at Asagi Caglayan basalt quarry is shown in Figure 2.

Figure 1. Application of plaster paste to hole collar

Wet plaster should not be placed in contact with ANFO, which is water-sensitive, thus 25 cm of drill cuttings were placed between the explosive and the plaster paste. Plaster column length was 40 cm. The top 45 cm of the drill hole should not be filled with plaster, since this section of the hole collar is deformed and cracked during drilling.



(a)Drill cuttings St.(b) Stemming with plaster

Figure 2. Blast hole stemming at Asagi Caglayan Basalt quarry

No benefit is expected from filling this section with plaster, and therefore it was filled with dry drill cuttings after the plaster had hardened instead of leaving it empty. This had the advantage of protecting the hole from loose stones dropping in.

3 BLAST TRIALS AND RESULTS AT ASAGI CAGLAYAN BASALT QUARRY

Two blast rounds fifteen meters apart were carried out with the plaster stemming and with the classic conventional drill cuttings stemming, each consisting of one row of six holes. First round was carried out by using plaster stemming. Second round was carried out by drill cuttings stemming. Both two rounds all 89 mm diameter holes were drilled with Gemsa drillers. Compared to blasting with drill cuttings stemming, burden and spacing distances were approximately 15 % farther at plaster stemming method (Table 1). Nobelex TG dynamites were used as primer at the bottom of holes. Only one primer initiated with Nonel cap in each hole which was considered enough for detonation. The firing was started with detonation cord. At the surface 25 ms and at hole bottom 500 ms Nonel millisecond caps were used. Bench height was approximately 10 m.

Drill cutting stemming method is generally used globally in open pits and quarries. Therefore, the stemming blast holes with drill cutting procedure was a standard procedure and details of this procedure is not given in the paper instead the new and more efficient plaster stemming method is more emphasized. For comparison of two stemming procedure, test blasts were carried out in the same location. Therefore, the rock structure and strength were similar. In both rounds ANFO, with one primer containing of 500 g dynamite was used. A quick hardening moulding plaster was used for plaster stemming.

3.1 The Evaluation Of Blast Trials

The blasting results of two stemming methods were compared. Muck pile fragmentation was evaluated using Split Desktop image-analysis software and verified standard ‘‘compare photo’’ method. The rock piles from the blasting tests at Asagi Caglayan Basalt quarry are shown in Figure 3 and Figure 4. The cumulative percentage of retained size at the Asagi Caglayan Basalt quarry blasting tests is given in Table 2.

Figure 3. Rock pile from blast round with drill cuttings stemming at Asagi Caglayan Basalt quarry

The first round was carried out using drill cuttings stemming with six holes. The length of the stemming was 2 m. The second round was carried out by plaster stemming with six holes. The length of the stemming was 1.1 m. Each blast hole was filled with 46.2 kg ANFO initiated with one primer with 0.5 kg in weight in the case of the drill cuttings stemming method. For the plaster stemming method, the quantity of ANFO was 51 kg per blast hole. The total length of ANFO column in the plaster stemming method was 90 cm greater than for the conventional method of drill cuttings stemming.

Table 1. Summary of properties of materials at blast sites, blast patterns and measurements of blast tests

Blast Tests	Dip direction/ angle of dip /angle of blast direction relative to dip direction of discontinuity	Block size index (cm)	RQD (%)	Stem. Leng. (m)	Bench Height (m)	Aver. Burd. (m)	Aver. Spac. (m)	+ 70 cm Size Fraction (%)	Delay (surface/ Bott.) (ms)	Spec. charge (kg/ m^3)	Specific drilling (m/m^3)
Aşağı Çağlayan (drill cut. stem.)	30/65/0	44	60	2	10	2	2.1	55	25/ 500	1.14	0.29
Aşağı Çağlayan (Plaster stem.)	30/65/0	44	60	1,1	10	2.35	2.5	50	25/ 500	0.95	0.22

Figure 4. Rock pile from blast round with plaster stemming at Asagi Caglayan Basalt quarry

Table 2. Comparison of cumulative percentage of retained size (oversize) from blast trials with plaster stemming and drill cuttings stemming

Fragment size (cm)	Asagi Caglayan Basalt quarry	
	Drill cuttings stemming (%)	Plaster stemming (%)
200	11.0	3.4
150	21.4	11.0
100	39.5	30.1
70	55.2	49.5
50	67.7	65.4
40	74.4	73.8
30	81.4	82.1
20	88.3	89.8
15	91.7	93.3
10	94.9	96.3
5	97.8	98.7

The blasted area was 29.2 m^2 for the plaster stemming trial, and blasted volume was 292 m^3 in situ. The specific charge was found to be 0.95 kg/m^3 and the specific drilling was 0.22 m/m^3. The blasted area was 22.1 m^2 for the drill cuttings stemming blast trial and yielding the blasted volume was 221 m^3 in situ. The specific charge was 1.14 kg/m^3 and the specific drilling was 0.29 m/m^3.

The total length of holes for the plaster stemming trial at Asagi Caglayan Basalt quarry was 20.8 m less than for the drill cuttings stemming round. This resulted in 24 % less drilling per unit volume rock. The cost saving for drilling calculated was $208 (20.8mx10$/m). At this site, specific drilling and specific charge decreased because a larger burden and spacing were applied with the plaster stemming method. In order to fragment the same volume of rock as for the plaster stemming round, an additional hole length of 20.8 m should be drilled for the drill cuttings stemming round. The profit per unit volume was $0.94 and total profit by using plaster stemming was $ 277.4 (Table 3).Therefore, the plaster stemming trial was found to be more economic, as well as giving similar fragmentation.

4 ENVIRONMENTAL EFFECTS AT ASAGI CAGLAYAN BASALT QUARRY

With this method of stemming, vibration and air shock values increased slightly due to more blast energy being available for rock breakage, but these increased values were small and under the permitted limit for blast damage criteria (Cevizci, 2012).

Because of too close measuring distance (22 m), all values were over the permitted level (Figure 5 and 6). But if measuring distance is enough, there will be no problem (Cevizci, 2012).

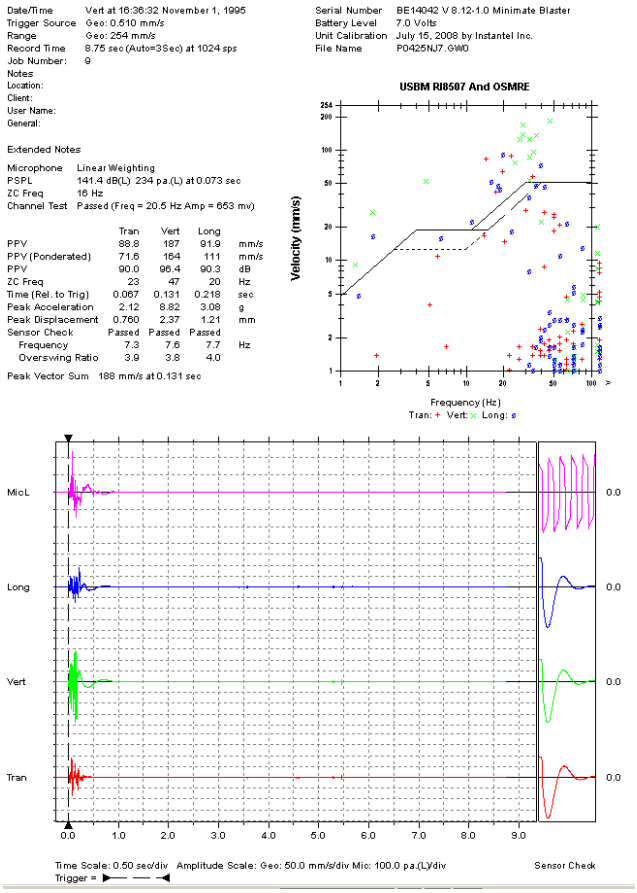


Figure 5. Measured vibration and noise levels in the dill cuttings stemming test

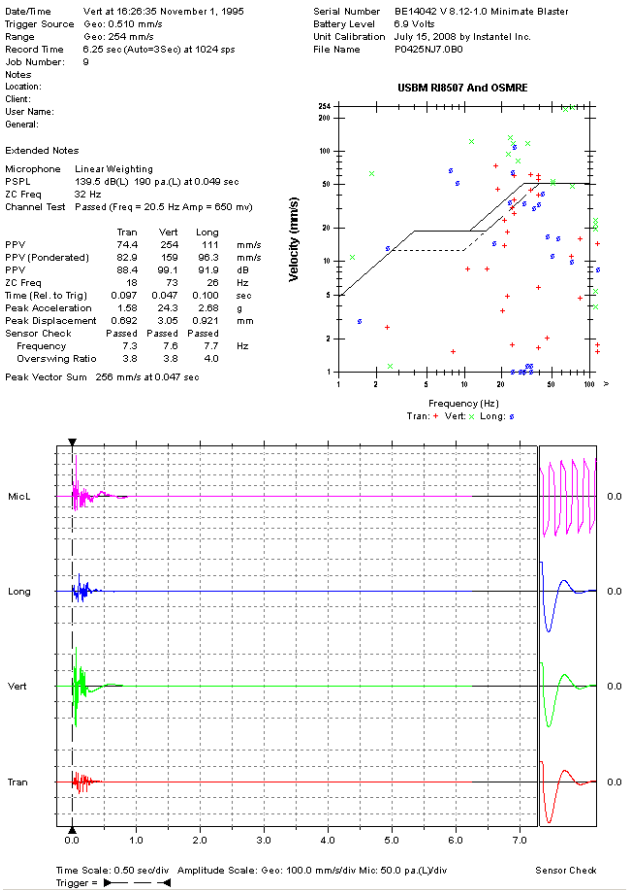

Figure 6. Measured vibration and noise levels in the plaster stemming test

Table 3. Comparison of blasting cost of plaster stemming versus drill cuttings stemming

Cost item	Asagi Caglayan Bas. quarry	
	Plaster stemming ($)	Drill cuttings stemming ($)
ANFO	302.9	274.8
Nonel caps	32	32
Initiating el. cap	0.5	0.5
Dynamite	51	51
Plaster and labor	20	-
Drilling cost	648	648
Total Cost	1054.44	1006.3
Fragmented rock(m^3)	292	221
Unit cost ($/$m^3$)	3.61	4.55
Specificc.(kg/m^3)	0.95	1.14
Specificdrill.(m/m^3)	0.22	0.29

4 CONCLUSION

In the method presented in this study, the inefficiency of the drill cuttings method of stemming is overcome by using plaster stemming. With the old method of stemming, loosely placed drill cuttings do not effectively confine the high-pressure stress produced by blasting. The study clearly shows how gases escaping from the drill hole, without efficient confinement, waste blasting energy. With the plaster stemming method, the pressure of the explosive is used successfully due to the more efficient confinement of the blast because better fragmentation was obtained.

Stemming heights were 0.9 m greater in the old drill cuttings stemming method than with the plaster stemming method. These long stemming columns caused problems in blasting, since the upper collar region was not broken properly, creating large boulders (Cevizci & Ozkahraman, 2012). This region, called the hard cap rock region, is not effectively broken with the classic drill cuttings stemming method. Generally, as the stemming column increases in length, more boulders are produced, which are dangerous and costly to move.

Additionally, the new method offers a more profitable solution. The cost of drilling for one meter of hole length is almost $10.8.

With plaster stemming, more of the hole length is better utilized by increasing the loaded length of the hole, resulting in better breakage at the hole collar. The increased length of loading in the hard cap rock region improves the cap rock breakage, thus reducing the creation of oversized boulders and increasing both efficiency and profit. It was observed that a plaster stemming column 0.40 m in length provided a more robust sealing than 2 m of drill cuttings used in the classical method.

ABSTRACT Predicting rate of penetration (ROP) of tunnel boring machine (TBM) ground conditions has been a crucial issue in the mechanized tunneling. TBM penetration rate and machine performance in a given project is a function of various rock mass properties such as RMR or GSI rock mass classification, orientation of joints or plane of weakness relative to tunnel axis, intact rock properties including rock strength, as well as machine specification including net thrust or cutterload. Influence of these parameters on machine performance was investigated along the Alborz service tunnel constructed by an open or gripper type TBM. Statistical analysis was performed on the data collected from the site to seek relationship between above noted parameters and the penetration rate (PR) of TBM. The results showed that each of the three different parameters has strongly affected the penetration rate of TBM. Multi variable regression analysis was performed to examine the combined effects of these parameters on the observed penetration rate of TBM. A site specific empirical formula is introduced to predict TBM rate of penetration based on the rock, rock mass, and machine operating parameters with reasonably good coefficient of correlation.

Keywords: TBM penetration rate, rate of penetration, rock mass properties, TBM operational parameters

1 INTRODUCTION

Over the years, a number of rock mass classification systems have been introduced in mining and civil engineering for different purposes including rock mass characterization, stability analysis, and support design. In fact, when Terzaghi (1946) introduced his rock load idea, followed by Lauffer's (1958) stand-up time concept and Deere's (1963) RQD index, these empirical design approaches were directed towards the selection of rock support system for conventional tunnel construction by drill and blast. Even the subsequent "modern" rock mass classifications, proposed in the 1970s, by Wickham at al. (1972), Bieniawski (1973) and Barton et al. (1974) were predominantly directed to drill and blast tunnels and not based on TBM bored tunnels. These models were developed based on special weighting system for each rating factor for use in ground support design and not geared towards measuring or quantifying the influence of rock mass features on TBM performance. This is perhaps the main reason for suggested modifications by the proposers of the two main rock mass classification systems, namely Q and RMR in recent years when introducing Q_{TBM} and RME (Barton, 2000; Bieniawski et. al.,

2006) to overcome shortcoming of these systems in predicting TBM field performance in various rock mass conditions.

Due to the simplicity and worldwide acceptance of the classification systems in general engineering practices, they have been long utilized in TBM performance prediction. However, as was illustrated by Khademi Hamidi et al. (2010), use of such rating based classification systems in their present scheme has many practical limitations. There has also been some attempts to modify the RMR classification system for use in performance prediction of hard rock TBM. This study will focus on modification and use of GSI classification system (Hoek and Brown, 1997) in predicting TBM penetration rate.

2 PROJECT DESCRIPTION AND GEOLOGY OF THE STUDY AREA

Alborz service tunnel is the longest tunnel (6.5 km) along Tehran-Shomal Freeway, situated in the high elevation portions of Alborz Mountain Range in Iran, connecting the capital city of Tehran to the Caspian Sea in the North. This service tunnel with diameter of 5.20 m was excavated by an open gripper TBM in advance of two main tunnel tubes to be excavated by conventional methods. The purpose of the service tunnel is site investigation, drainage of the rock mass, providing access for main tunnel excavations and for service, ventilation and drainage during operation of the complete tunnel system which will be used as road tunnel. Site investigation for the service tunnel included geological surface mapping, geophysical investigation along the alignment from the surface and some index laboratory tests on rock samples. The results of geotechnical site investigations show that the main lithological units through in which the tunnel will be driven consist of sandstone, tuff, gypsum, shale, and limestone layers (Figure. 1).

3 FACTORS INFLUENCING TBM RATE OF PENETRATION

Predicting rate of penetration of TBM (ROP) is one of the most important issues to estimate the advance rate of TBM. Performance of a TBM in a given project depends on many factors including rock material, rock mass parameters, machine characteristics, and operational parameters. Some of the factors influencing the TBM performance are discussed in following sections.

3.1 Intact Rock Characteristics

Some of the rock characteristics and properties that influence TBM performance are:

- Intact rock strength (e.g. uniaxial compressive strength “UCS”, Brazilian tensile strength “BTS”, Point load index “Is (50)”),
- Toughness (as represented by Punch penetration index, Fracture toughness index),
- Hardness and drillability (Siever’s J-value, Total & Taber hardness index, Schmidt hammer hardness),
- Brittleness (Swedish brittleness number “S20”, brittleness indices; $B_1 = \sigma_c / \sigma_t$ and $B_2 = [(\sigma_c - \sigma_t) / (\sigma_c + \sigma_t)]$), where σ_c and σ_t are uniaxial compressive and tensile strength of intact rock, respectively,
- Abrasiveness (often measured by Cerchar Abrasivity Index, Abrasion Value “AV”),
- Poisson ratio “ν”, modulus of Elasticity “E”, Internal friction angle “φ”, Porosity, Grain size etc.

3.2 Rock Mass Properties

Rock mass properties are defined as rock structure (or block size) and joint conditions. They could be listed as:

- GSI rock mass classification system indicates combined effect of jointing and weathering as rock mass properties,
- RMR rock mass rating classification system, based on intact rock strength, RQD, discontinuity spacing, joint

conditions ground water conditions, and adjustment for joint orientation.

- NGI or Q rock mass classification system, Q = (RQD/Jn).(Jr/Ja).(Jw/SRF) that is based on RQD, joint number, joint roughness, joint surface alteration, groundwater, and stress conditions.
- RMi classification system, RMi = σci * JP. where Jp is related to volumetric joint count (Jv) through the block volume (Vb), the mean block diameter (L), spacing of joints within a set (S) and the joint conditions rating (jC).

3.3 Ground Conditions

There are other rock mass properties that may not be accounted for in the rock mass classifications but can impact TBM performance such as:

- Joint orientation relative to the tunnel axis
- Stress condition (i.e. SRF that represents stress reduction factor in Q system), in-situ stress conditions (σv and σh),
- Ground water conditions that is included in some classifications and not the others

3.4 Machine Specification and Operational Parameters

The main machine specifications that are pertinent to rate of penetration can be summarized as follows:

- Disc cutter Geometry (e.g. diameter, tip width, angle of tip), maximum allowable velocity
- Cutters spacing and number of on the cutter head
- Applied cutter load
- Machine thrust (representing cutter load),
- Cutterhead rotational speed (RPM),
- Cutterhead torque,
- Cutterhead power,

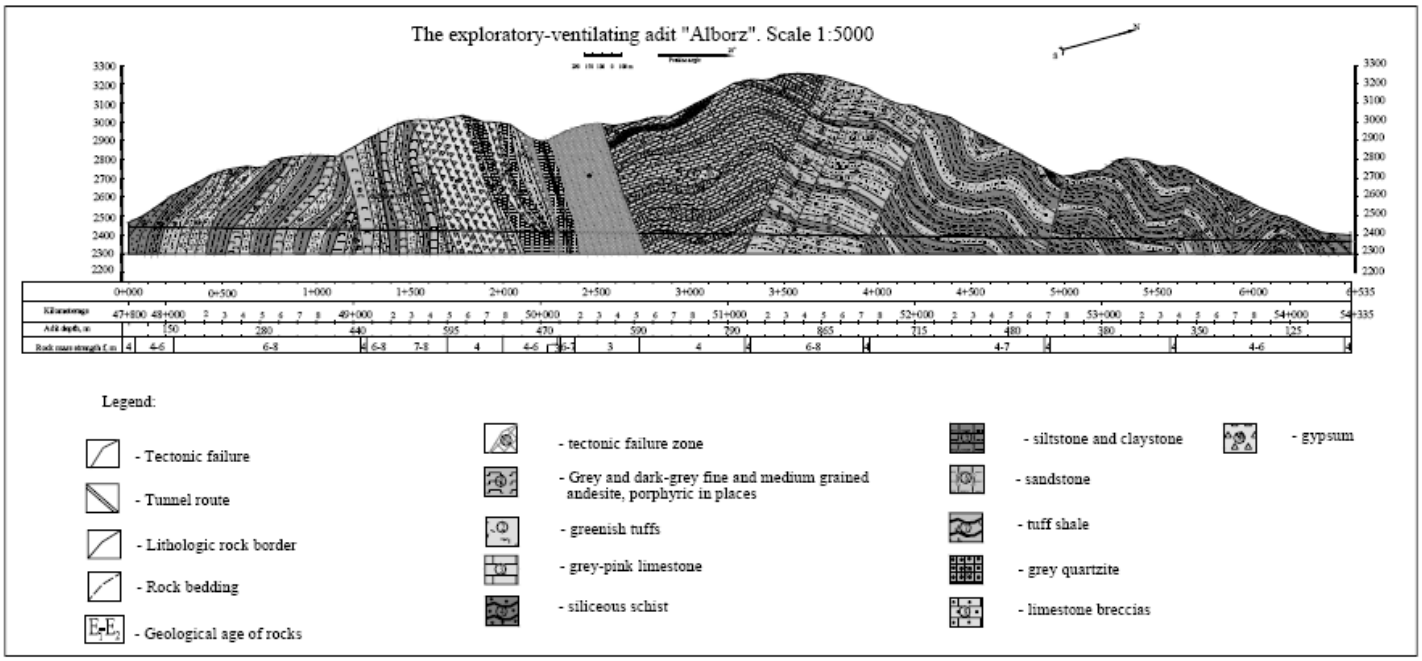

Figure 1. Longitudinal geological profile of the Alborz tunnel

One should keep in mind that developing a predictive model which can take into consideration all these parameters together has been always a problem. This is why over three decades after its inception, no single universal model has been proposed for TBM performance prediction. In this study, an attempt is made to consider some of these parameters for predicting TBM penetration rate. Among the rock material characteristics, UCS was selected for developing a model due to simplicity and commonality of the test for representing intact rock strength properties. Also, cutter load was selected as the machine parameter in the model.

As mentioned by Shahriar et al. (2010), rock mass properties can be extracted from

part of the Q, RMR, RMi and GSI classification systems. In this study GSI rock mass classification was selected to reflect the rock mass properties for TBM tunneling.

Three distinct parameters were taken into account for constructing the model as discussed before and they are:

- F_{GSI} = GSI, representing rock mass properties
- $F_f = (F_N.K_a.K_d)/UCS$, to reflect intact rock properties and machine specifications, and
- F_α = log ArcSin (Sin α_f * Sin ($\alpha_t - \alpha_s$)), joint orientation.

F_{GSI} is the fabric index of GSI system. F_N is cutter load, K_a and K_d are the correction factors for cutter spacing and diameter in NTNU TBM prognosis model (Bruland, 1998), and α is the angle between tunnel axis with planes of discontinuities.

4 PROPOSED SITE SPECIFIC MODEL FOR PREDICTING TBM PERFORMANCE

In order to develop a model for predicting TBM performance 33 data sets were compiled from 34 tunnel sections along the 6.5 km of bored Alborz service tunnel. The database consists of 34 records including input parameters of the GSI classification system, uniaxial compressive strength of rock material (UCS), the angle between tunnel axis and the joint sets (alpha), the TBM thrust and the measured TBM rate of penetration (ROP). In this study, the modified thrust per cutter normalized by UCS was used to reflect intact rock strength and cutter load. Descriptive statistical distribution of variables in the database and input parameters for development of the model are summarized in Table 1.

Table 1. Descriptive statistics of input parameters in the TBM field performance database

Variables	N	Min.	Max.	Mean	Variance
GSI	33	36	55	46.5	22.5
$(F_N.K_a.K_d)/UCS$ (Ton/MPa)	33	2.02	5.95	2.81	0.754
F_{alpha}(degree)	33	8.00	83.0	39.41	39.381
ROP (m/h)	33	2.85	5.30	3.93	0.535

The proposed TBM performance prediction model has been developed by performing multiple linear regression analysis on the data sets from Alborz Service tunnel project. Relationship between independent variables and actual measured ROP are illustrated in Figures 2 to 4.

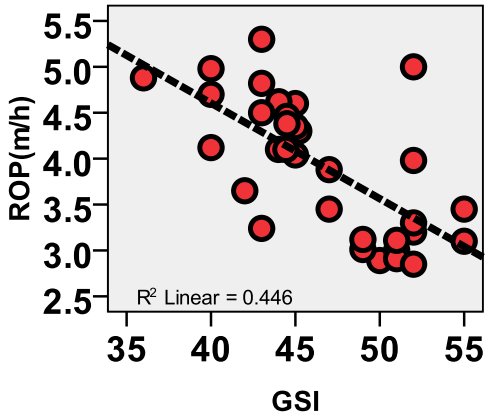

Figure 2. Relation between measured ROP and GSI

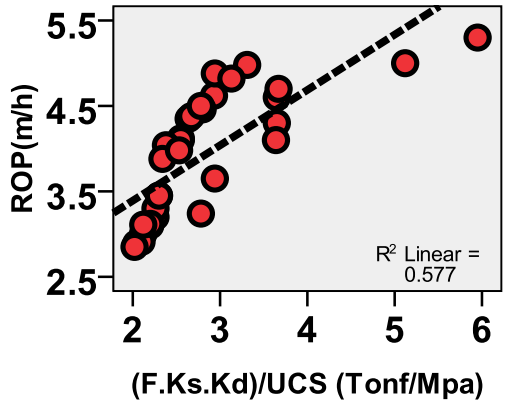

Figure 3. Relation between measurd ROP and F_{fmod}

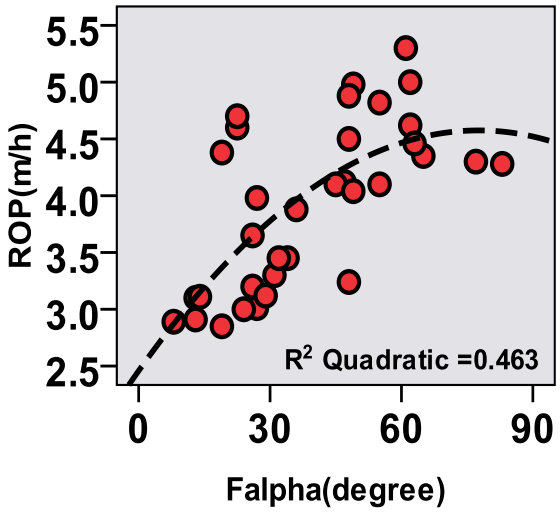

Figure 4. Relation between measured ROP and F_α

The figures also contain the correlation factors (R^2) which denote the degree of correlation between the two parameters. For the given data set, Fig.3 (relating ROP with UCS and cutterload) shows the highest R^2 value, (0.58). The R^2 value decreases for relationship between ROP and F_{alpha} (R^2 = 0.46) or GSI (R^2 = 0.45). The results indicate that the modified thrust per cutter normalized by the uniaxial compressive strength of rock material and F_{alpha} is the most significant variable controlling the rate of penetration of TBM.

As shown in the Fig. 2, increasing GSI will result in decreased ROP, since decreased the number of joint sets leads to stronger rock mass and more difficult boring process, thus decreasing penetration rate. Similarly, the increase in GSI due to better joint condition leads to lower boreability. Uniaxial compressive strength of intact rock (UCS) has a crucial influence on penetration rate in such a way that penetration rate will decrease with increased UCS as expected. The effect of TBM thrust on ROP has been also studied by many researchers. In this study, cutter thrust, modified by two parameters including K_a and K_d representing machine specification, is normalized by UCS and used in the statistical analysis. The normalized value of UCS by cutter load is expected to show improved result due to incorporation of the effect of machine thrust in the model using this composite index. As illustrated in Fig. 3, with the increase in F_f ($F.K_d.K_a/UCS$) that could be by higher cutter load or lower rock strength, penetration rate will increase. The angle α, represent-ting orientation of discontinuities relative to the axis of the tunnel, have been measured in the field by measuring strike and dip of the joints mapped at the face. The α in degrees, can be calculated using the equation suggested by Bruland (1998):

$$\alpha = \text{ArcSin}\,(\text{Sin}\,\alpha_f * \text{Sin}\,(\alpha_t - \alpha_s)) \qquad (1)$$

Where, α_f and α_s are dip and strike of planes of discontinuities in rock mass, and α_t is the direction of the tunnel axis in degrees.

The relationship between ROP and α angle illustrated in Fig. 4, is consistent with findings of the field studies by Bruland (1998), Yagiz (2008) and Khademi Hamidi at al. (2010).

In order to develop a linear equation, all the parameters for setting up the model including objective and independent variables should have a reasonable normal distribution. For checking the validity of the proposed model by statistical analysis, is necessary to check for any type of co-linearity between the parameters used in the regression model. Co-linearity occurs when two or more independent variables are highly correlated. The *variance inflation factor* (VIF) analysis performed on independent variables shows that there is no inter-correlation between independent parameters. Hence, the TBM performance model based on three independent variables of GSI, F_f, and Fα with good correlation coefficient with ROP can be considered valid for prediction of performance of the given machine of the same diameter in similar geologies.

A model has been developed by using standard statistical analysis software package (SPSS). The model has P factor of less than 0.05 which is an indicator of validity of the model based on the statistical analysis of input data. This model with high correlation coefficient is recommended as the main model for performance estimation of open type TBM of the same size and

general specification as Alborz tunnel TBM. The proposed multiple linear regression model is as follow:

$$ROP = 4.304 - 0.057*GSI – 0.435*F.k_a.k_d/UCS + 0.693*\log \alpha \quad (2)$$

A comparison between the measured and estimated ROP of the model is illustrated in Fig. 5. As seen in the Fig. 5, the predicted data shows strong correlation with the measured values of TBM ROP in database with a good correlation coefficient of nearly 79%.

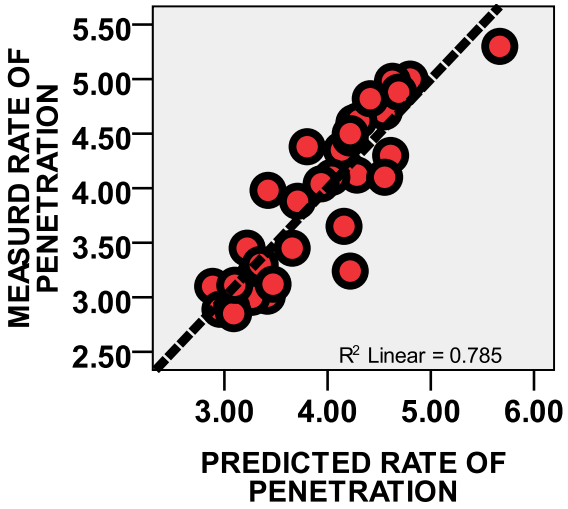

Figure 5. Comparison between measured and predicted ROP in Alborz Service Tunnel

5 CONCLUSIONS

A site specific model for estimation of rate of penetration of hard rock TBM is proposed by using multiple regression analysis on field data collected from 6.5 km of Alborz service tunnel. The model is based on use of GSI for rock mass classification, cutter load, UCS, and the angle between the dominant joints and tunnel axis (alpha). Multi-variable linear regression was employed to develop a correlation between the measured ROP and three input parameters with correlation coefficient of about $R^2 = 0.79$. The proposed model showed meaningful correlations with the observed ROP. The statistical significance and validity of the obtained models was checked by using standard statistical tests, which proved that the obtained relationship is reliable for the given database of TBM field performance and can be considered for estimation of ROP for a machine with similar specifications in similar geological units.

Availability Analysis of Drum Shearer Machine; a Case Study

S. H. Hoseinie, B. Ghodrati

Division of Operation & Maintenance Engineering, Lulea University of Technology, Lulea, Sweden

A. Hosseini

Tabas Parvadeh Coal Company, Iran Minerals Production & Supply Co., Tabas, Iran

ABSTRACT Drum shearer plays an important role in the face production in longwall coal mines. Therefore, monitoring of this machine can lead the whole extraction operation to high level of productivity and safety. Availability is one of the most important measures for evaluation of the mining machineries. High availability of equipment can be helpful in satisfying the desired production goals. In this article the availability of drum shearer in an Iranian coal mine has been studied. For this purpose, the failure and maintenance data for a period of two years have been used. After data sorting and analysis, the inherent availability, achieved and operational availability of this machine have been calculated. The results show that the studied shearer machine performs in high level of availability. Nevertheless, the logistics delay time and administrative delays with the share of 25% of whole downtimes are so important influencing factors which should be controlled and planned to minimize it.

1 INTRODUCTION

Nowadays, all of the elements of modern, high production longwall systems are provided in an integrated manner for maximum productivity gains and lowest cost per ton.

A longwall production chain consists of several subsystems and machines which their operational conditions affect the total availability, and reliability performance of the production face. Due to continuance production system in longwall mines especially face-to-surface ore hauling system, availability of each machinery is very critical for system continuity and production.

Shearer is the most critical part of longwall production process. That's why high-performance longwall operations demand shearers that deliver the highest productivity, availability and reliability (Caterpillar, 2011).

High reliability and maintainability of the shearer lead operation to high availability. High availability itself ensures the maximum return on investment for longwall operation.

Reliability of the longwall systems have been studied by several researchers so far, nevertheless, few studies have been done on availability of these systems (Furuly et al., 2014, Hoseinie et al., 2014). In this article, operational and downtime hours of drum

shearer in an Iranian coal mine in have been analyzed and a comprehensive availability analysis has been done on this machine. It has been tried to answer the following questions:

1) What is the mean time between failures and mean time to restore of whole drum shearer machine
2) How much are the availability related parameters of shearer
3) How much are the inherent availability, achieved and operational availability of studied machine

2 AVAILABILITY ANALYSIS

2.1 Background and Definitions

Availability is the probability that a system or component is performing its required function at a given point/over a stated of time period when operated and maintained in a prescribed manner (Ebeling, 2009). In other words, availability is the ability of an item to be in a state to perform a required function under given conditions at a given instant of time or over a given time interval, assuming that the required external resources are provided (IEC, 1990, CEN, 2010).

Like reliability, availability is a probability. Consider a system (device) which can be in one of two states, namely 'up (on)' and 'down (off)'. By 'up' it is meant that the system is still functioning and by 'down' it is meant that that the system is not functioning. In the latter case the system is being repaired or replaced, depend on whether it is repairable or not (Barabady, 2005). Availability depends on the combined aspects of reliability, maintainability and maintenance supportability (IEC, 1990, CEN, 2010).

System reliability and availability analysis is a mature field and there is abundance of analysis techniques including methods such as reliability block diagrams, fault tree analysis, failure mode and effects analysis, Markov processes and Bayesian analysis (Høyland and Rausand, 1994, Närman et al., 2014). There are three common measures that widely are used in practice and can be found in both standards and books (Ebeling, 2009, Stenström, 2014); inherent availability, achieved and operational availability. The mathematical definitions and detailed components of these measures are presented in following.

2.2 Availability Measures

2.2.1 Inherent availability

Inherent availability is the steady state availability when considering only the corrective downtime of the system (Ebeling, 2009). It is defined as the expected level of availability for the performance of corrective maintenance only. Inherent availability is determined purely by the design of the equipment. It assumes that spare parts and manpower are 100 percent available with no delays. It excludes logistics time, waiting or administrative downtime, and preventive maintenance downtime. It includes corrective maintenance downtime. Inherent availability is generally derived from analysis of an engineering design. Inherent availability fulfills the need to distinguish expected performance between planned shutdowns (Katukoori, 2006). Inherent availability is expressed as Equation (1).

$$A_i = \underset{t\to\infty}{Lim} A(t) = \frac{MTBF}{MTBF + MTTR} \quad (1)$$

Inherent availability is based solely on the failure distribution and repair-time distribution. It can therefore be viewed as an equipment design parameter, and reliability-maintainability trade-off can be based on this interpretation (Ebeling, 1997).

2.2.2 Achieved availability

The probability that an item will operate satisfactorily at a given point in time when used under stated conditions in an ideal support environment (i.e., that personnel, tools, spares, etc. are instantaneously available) (Katukoori, 2006, Ebeling, 2009). Achieved availability is defined as the achieved level of availability for the

performance of corrective and preventive maintenance. It is determined by the hard design of the equipment and the facility. It excludes logistics time and waiting or administrative downtime. It includes active preventive and corrective maintenance downtime. Achieved availability also assumes that spare parts and manpower are 100% available with no delays.

This measure is very similar to inherent availability with the exception that preventive maintenance downtimes are also included. It can be computed by looking at the MTBM and $\overline{M}$ by using Equation (2).

$$A_a = \frac{MTBM}{MTBM + \overline{M}} \tag{2}$$

Where, MTBM and $\overline{M}$ are calculated by Equation (3) and (4) (Ebeling, 2009).

$$MTBM = \frac{t_d}{m(t_d) + t_d / T_{pm}} \tag{3}$$

$$\overline{M} = \frac{m(t_d)MTTR + (t_d / T_{pm})MPMT}{m(t_d) + t_d / T_{pm}} \tag{4}$$

2.2.3 Operational availability

Operational availability is a measure of the average availability over a period of time and it includes all experienced sources of downtime, such as administrative downtime, logistic downtime, etc. It is the probability that an item will operate satisfactorily at a given point in time when used in an actual or realistic operating and support environment (Ebeling, 2009). It includes logistics time, ready time, and waiting or administrative downtime, and both preventive and corrective maintenance downtime. Finally, the operational availability is the availability that the customer actually experiences and is expressed as Equation (5) (Ebeling, 2009).

$$A_o = \frac{MTBM}{MTBM + \overline{M}'} \tag{5}$$

Where, $\overline{M'}$ is determined by replacing the MTTR with MTR= MTTR + SDT + MDT as shown in Equation (6) (Ebeling, 2009).

$$\overline{M}' = \frac{m(t_d)(\mathrm{MTTR} + \mathrm{SDT} + \mathrm{MDT}) + (t_d / T_{pm})MPMT}{m(t_d) + t_d / T_{pm}} \tag{6}$$

Above definition includes all supply and maintenance delays as a part of the unscheduled downtime.

The calculation of A_o can vary somewhat depending on the definitions of uptime and downtime. The inclusion of certain ‘‘operational states’’ can be legitimately expressed as either uptime or downtime; and as long as the definition is clear there can be various ‘‘correct’’ interpretations (methodology).

3 CASE STUDY

The case study of this research was done in an Iranian coal mine. The annual production of the mine is 1.5 million ton raw coal and it is planned to be in operation for 30 years lifetime. The most suitable seam for mining has 1.8m thicknesses and is extracted by retreat longwall method using a double-drum shearer machine. The length of studied longwall face is 215m and panel length is 1200m.

3.1 Data collection and classification

In this paper, for availability analysis of the drum shearer, failure, maintenance, operation and workshop data from archived records along with direct observations collected from October 2007 to October 2009 was used.

According to available data, the first panel in studied mine has been extracted during the 960 working shifts. Each shift is seven hours and one hour is considered for shift changing and employees transfer (totally equal to 8 hours).

It total, 139 failures have been happened during the data collection period and

machine has done 2606 hours cutting operation. The histogram of TBFs and TRs of the recorded failures are presented in Figure 1 and Figure 2 respectively.

The Figure 1 shows that TBFs of drum shearer machine vary from few minutes to more than 100 hours. However, more than 90% of the failures have been happened in a period less than 50 hours.

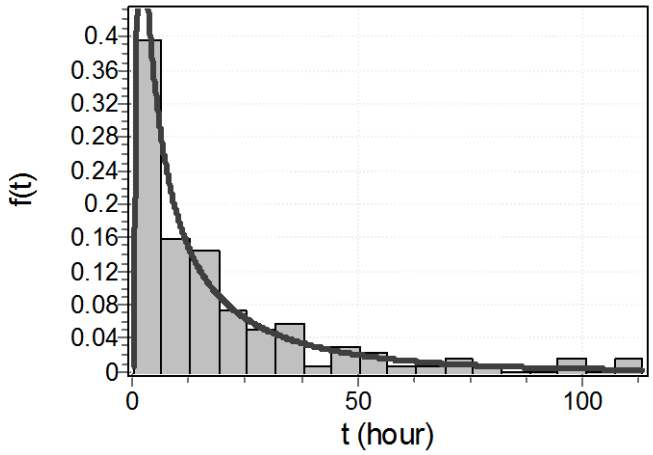

Figure 1. Probability density function of TBFs

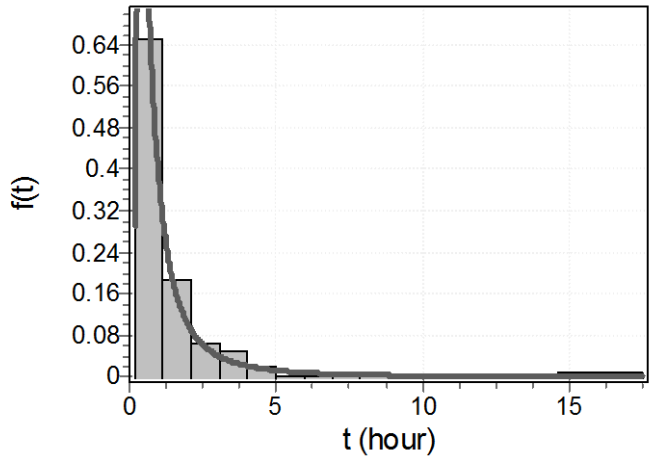

Figure 2. Probability density function of TRs

The Figure 2 shows that the drum shearer has had a wide range of time to restore. However, more than 65% of failures has been maintained in less than one hour.

The calculations show that MTR for studied drum shearer is 1.47 hour (88.5 minutes) which includes the maintenance operation, support and logistic, testing and re-running the machine.

3.2 Calculation of input parameters

Using the collected data, and considering the current preventive maintenance and service plan in mine, the input parameters for calculating the availability measures have been calculated and presented in Table 1.

Table 1. Calculated input parameters based on collected data

Parameter	Value
MTBF	18.42 hour
MTTR	1.1 hour (66 minute)
t_d	2606 hours
T_{pm}	80 hours
$m(t_d)$	139
MPMT	0.83 hours (50 minute)
SDT + MDT	0.37 hour (23 minute)

3.3 Calculation of Availability Measures

3.3.1 Inherent availability

As it was discussed before, the inherent availability is the simplest availability measure which is calculated by Equation (1). Regarding the available data in Table 1, inherent availability of studied drum shearer is 94.3%. It means that in ideal condition without any delay in maintenance support and logistics, machine will be available in 94.3% of its active lifetime.

3.3.2 Achieved availability

Regarding the Equation (2) to (4), for calculating the achieved availability, MTBM and $\overline{M}$ most be calculated. Using the presented parameters in Table 1, MTBM is equal to 13.95 hours and also $\overline{M}$ =1.05 hour. Therefore, achieved reliability for the current operation and maintenance plan in studied mine is equal to 93%.

3.3.3 Operational availability

As it was discussed, the operational availability is the measure that customer actually experiences and it directly affects the mine production rate. Therefore, its proper calculation is critical and very important. In this measure, MDT and SDT are included in calculations. Based on the field data, the detailed information on these

delay times was missed. However, the time to restore and its mean value were clearly available. Thus, the difference between the TR and TTR was assumed as a delay times in total (SDT+MDT) which is equal to 23 minutes in average. Thus, MTR (=MTTR+SDT+MDT) is equal to 1.47 hour.

Regarding the Equations (6) and the calculated input parameters, $\overline{M'}$ is equal to 1.35 hour. Therefore, using Equation (5), the operational availability is 91.2%.

3.1 Discussion

According to the achieved results from data analysis and availability modeling, the values of three availability measures are presented in Figure 3.

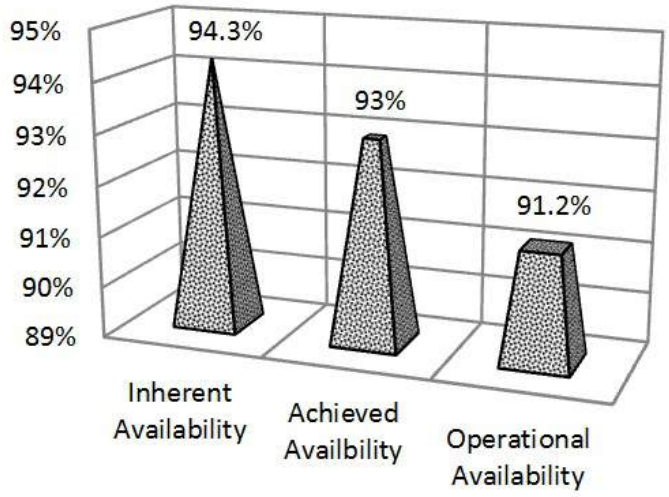

Figure 3. Calculated availability measures for studied shearer machine

As shown in Figure 3, inherent availability of studied drum shearer is the highest value among the three measures. The less value of achieved availability in comparison with the inherent one reveals that in this mine, preventive maintenance reduces the machine availability due to more stoppages. However, 1.3% is really negligible difference in availability, nevertheless, the positive effects of preventive maintenance in reliability of this machine is very impressive (Hoseinie et al, 2012).

The comparison between the achieved and operational availability shows that the maintenance and support delays are responsible for 2.8% in availability of the whole machine. 2.8% reduction in availability is not so much change in operation condition but the important point is that the 25% of TR is belongs to delays. It means that by improving the maintenance logistic is value of reduction is removable.

4 CONCLUSION

In this article, availability of drum shearer machine was analyzed using three common measures; inherent, achieved and operational availability. The results show that, TBFs and TR of this machine in very variable and changes from few minutes to several hours.

The calculations reveal that in total, the studied drum shearer performs in a very good level of availability. However, the logistics and support delays during the maintenance operation reduces the availability from 94.3% in inherent level to 91.2% in operational level, it is more or less acceptable. Because, in longwall mining in which the whole operation is located in underground, the operation logistics is very complicated and costly. In this view, machine and operation are in a very good condition.

As calculation show, the current preventive maintenance plan with intervals of 80 hours sounds good view point of machine availability. Because, it doesn't reduce the machine's availability in considerable level.

Determination of Optimum Drum Shearer for Tabas Mine Using Decision Making Process

E. Bakhtavar
Urmia University of Technology, Urmia, Iran

ABSTRACT Mechanization and the proper decision in relation to choice the most appropriate shearer machine for longwall mines lead to maximum productivity with minimum energy consumption. In this paper, a mechanized shearer loader system has been selected among four alternatives for Tabas Parvadeh1 coal mine by integrating the results from an analytical procedure and a multi-criteria decision making system. During the decision making process, the analytical procedure was initially used to find effective criteria. Then most important criteria were considered on the basis of the mechanical properties of coal seam and the important characteristics of shearer loader, especially from technical viewpoints. Finally, a two drums shearer system was selected to be applicable in Tabas Parvadeh1 mine. The results of using the MCDM system are completely in accordance with the results of the analytical procedure.

Keywords: Tabas Mine, drum shearer, VICOR, decision making

1 INTRODUCTION

Generally, mechanized coal extraction can provides better production, productivity and safety (Singh, 1999). Performance of the mechanical machines (such as road headers, continuous miners, and shearers) is one of the most important factors affecting the production rates in coal mining engineering projects.

In order to obtain the maximum possible productivity and minimum energy consumption in coaling selection of the most suitable shearer loader is of at most important together with the most fitness picks and a good arrangement on cutter head. Selection of the most appropriate shearer directly depends on physical and mechanical characteristics of a coal seam which directly control mechanical characteristics of shearer machine.

There is a study of detailed investigation for the Iranian coal seams (Shahriar et al., 2009). The study represents some simple field and laboratory tests carried out to visualize the nature and variation extent of mechanical properties across C1 coal seam in Parvade1 mine.

.

A research in form of an analytical procedure was presented by Bakhtavar and Shahriar (2013) in order to select a shearer loader machine to be most appropriate for coal extraction in Tabas Parvadeh1 longwall mine. In this research, the mechanical properties of C1 coal seam were focused during designing and selecting the components of a shearer such as pick, drum, and vanes. The laboratory and in-situ tests were also reviewed and their suitability to aid machine design and selection was discussed.

In the present study, with considering the results obtained from the analytical procedure by Bakhtavar and Shahriar (2013) and using VIKOR decision making system the most appropriate shearer loader machine has been selected for Parvadeh1 longwall mine located in east of Iran. In this case, the most crucial mechanical properties of C1 coal seam together with the critical physical characteristics of shearer loader system have been focused during the decision process

2 TABAS PARVADEH1 COAL REGION

The main coal horizons in Tabas Parvadeh1 region (located in east of Iran as shown in Figure 1) are seams B1, B2, and C1 that occurred within 50 m of strata. Other seams C2, D and possibly E will affect mining principally because of their methane content. Parvadeh1 coalfield is a basin between two major North-South trending fault systems, the Kalmard Fault and the Hidden Fault to the West and the Nayband Fault to the East. The covered rocks are mostly mudstone with prominent coarsening up siltstone and sandstone sequences. The seam thickness of C1 varies from approximately 2.2 m in the northeast to 1.5 m in the South West.

Figure 1. Location of Tabas Parvadeh1 coal field

There is a very general indication of an increase in sulphur content from the North to the South in this seam. In the initial mining area sulphur content varies from 1.75 to 2.0% (IRITEC, 2003).

According to Russian classification of coal seams, the C1 coal seam of Tabas Parvadeh1 is taken in the class of Low Volatile Coking Coal or Low Volatile Bituminous Coal, and due to National Coal Board (NCB) classification, its class is 301, additionally based on American Society for Testing Materials (ASTM) classification, it is taken place in class1 of Bituminous Coals (Shahriar et al., 2009).

The detailed engineering of the mine infrastructure ensures that it is adequate so that the longwall can operate based upon the information provided by the supplier in the tender and appended to the order (IRITEC, 2003).

3 MOST APPROPRIATE SHEARER

3.1 A Summary on the Results of the Analytical Procedure

The results obtained from the analytical procedure adopted by Bakhtavar and Shahriar (2013) have been used together with the results of a MCDM system in order to find the most appropriate shearer loader for mechanization of Tabas Parvadeh1 coal faces.

The mechanical characteristics of C1 coal seam in Tabas Parvadeh1 mine which resulted from a number of in-situ and

laboratory tests are summarized in Table 1 (Bakhtavar and Shahriar, 2013). As given in Table 1, the compressive strength of C1 coal seam is low and also there are three joint sets in Tabas Parvadeh1 longwall mine. The data given in Table 1 are essential for the suitable judgments by experts during the decision process, especially using MCDM systems.

Four alternatives of shearers were considered for selection during the analytical procedure (research by Bakhtavar and Shahriar (2013)) as given in Table 2. Besides, the most important technical characteristics of the shearer alternatives resulted during the analytical procedure are summarized in Table 2. According to the results obtained during the analytical procedure, especially with emphasis on the required shearer cutting power of 886.4 KW (nearly 93%), among the four shearer alternatives, "double ended ranging drum shearer (DERDS)" model EL600 is most appropriate for selection.

Table 1. Mechanical characteristics of C1 coal seam (Bakhtavar and Shahriar, 2013)

Parameter	Meaning (Unit)	Value
σ_c	Uniaxial compressive strength (MPa)	6.66
σ_t	Tensile strength (MPa)	0.39
δ	Shear strength (MPa)	0.53

Table 2. Shearer characteristics made by DBT Company (Bakhtavar and Shahriar, 2013)

Electra Range	EL3000	EL2000	EL1000	EL600
Seam range (m)	2.2-6.0	1.5-3.5	1.8-5.0	1-3.5
Typical machine length (m)	14.6	12.2	11.8	11.9
Typical installed power (KW)	1940	1940	1380	869
Available cutting power (KW)	2×850; 2×650	2×500	2×600	2×450; 2×375; 2×285
Cutting drum diameter (m)	1.9-3.0	1.2-2.2	1.4-2.5	1.1-2.2
Machine weight (tons)	100	55	75	50

3.2 VIKOR for Decision Making on the Most Appropriate Shearer

VIKOR (Vlse Kriterijumska Optimizacija I Kompromisno Resenje in Serbian) was introduced as a compromise ranking method which categorized in Multi-Criteria Decision Making (MCDM) system. VIKOR system focuses on ranking and selecting from a set of alternatives, and it also can find compromise solutions for a problem with conflicting criteria (Opricovic and Tzeng, 2004 and 2007). This system is capable to optimize aggregation of different criteria scores of various alternatives simultaneously.

In this research, decision is made for selection of the most appropriate shearer among the four alternatives considered in the analytical research. In this case, the main characteristics of shearer loaders those influenced by the coal seam physical and mechanical properties are emphasized. They are assigned as technical criteria. It is notable that the authors assumed that the capital investments of the shearers are not critical and the most important limitations are technical considerations in Tabas Parvadeh1 mine. It means that no economical criteria are considered during the selection process. The technical criteria which considered for the decision process are as given in Table 2.

All criteria scores and weights during the shearer selection process can majorly assign from the ideas of related experts using questionnaires. Significance of the criteria for the shearer decision process was specified according to the judgments of a number of experts by the means of a scoring range 0-100.

In first step, decision matrix should be organized as the following:

$$A=\begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1J} \\ a_{21} & a_{22} & \cdots & a_{2J} \\ \vdots & \vdots & \ddots & \vdots \\ a_{I1} & a_{I2} & \cdots & a_{IJ} \end{bmatrix} \quad (1)$$

$$N=\begin{bmatrix} n_{11} & n_{12} & \cdots & n_{1J} \\ n_{21} & n_{22} & \cdots & n_{2J} \\ \vdots & \vdots & \ddots & \vdots \\ n_{I1} & n_{I2} & \cdots & n_{IJ} \end{bmatrix} \quad (2)$$

where,

A: Decision matrix

I: Number of alternatives *i*

J: Number of criteria *j*

a_{ij}: Performance score of alternative *i* with respect to criterion *j*

The decision matrix of the shearer selection problem according is given in Table 3. The matrix includes the weights and performance scores based on Equation 1.

Then the scores are normalized using Equations 2 to 4.

$$n_{ij}=\frac{a_{ij}}{\sqrt{\sum_{i=1}^{I}(a_{ij})^2}};\ j=(1,2,...,J) \quad (3)$$

$$n_{ij}=\frac{\frac{1}{a_{ij}}}{\sqrt{\sum_{i=1}^{I}(\frac{1}{a_{ij}})^2}};\ j=(1,2,...,J) \quad (4)$$

Table 3. Decision matrix during the shearer selection

Criteria	Shearer alternatives				Mean scores	Weight
	EL3000	EL2000	EL1000	EL600		
Seam thickness range (m)	2.2-6.0	1.5-3.5	1.8-5.0	1-3.5	78	0.22
Typical machine length (m)	14.6	12.2	11.8	11.9	31	0.09
Typical installed power (KW)	1940	1940	1380	869	89	0.25
Available cutting power (KW)	2×850; 2×650	2×500	2×600	2×450; 2×375; 2×285	37	0.11
Cutting drum diameter (m)	1.9-3.0	1.2-2.2	1.4-2.5	1.1-2.2	56	0.16
Machine weight (tons)	100	55	75	50	61	0.17

Table 4 shows the normalized decision matrix (*N*) based on Equation 2. The normalized values (n_{ij}) can be calculated for benefit and cost related criteria using Equations 3 and 4, respectively.

In this step, the ideal (Z*) and non-ideal (Z−) solutions are determined through Equations 5 and 6. For the shearer selection process the results from the ideal and non-ideal solutions are given in Table 5.

$$Z^*=\left\{\max_i n_{ij} \mid j=1,2,...,J\right\}=\left\{n_1^*,n_2^*,...,n_J^*\right\} \quad (5)$$

$$Z^-=\left\{\min_i n_{ij} \mid j=1,2,...,J\right\}=\left\{n_1^-,n_2^-,...,n_J^-\right\} \quad (6)$$

Table 4. Normalized decision matrix during the shearer selection

Criteria	Shearer alternatives				Weight
	EL3000	EL2000	EL1000	EL600	
Seam thickness range	0.09	0.55	0.37	0.74	0.22
Typical machine length	0.21	0.42	0.63	0.63	0.09
Typical installed power	0.11	0.11	0.21	0.96	0.25
Available cutting power	0.26	0.52	0.26	0.77	0.11
Cutting drum diameter	0.1	0.59	0.4	0.69	0.16
Machine weight	0.11	0.63	0.21	0.74	0.17

Table 5. Ideal and non-ideal solutions

Criteria	Ideal solution	Non-ideal solution	Weight
Seam thickness range	0.74	0.09	0.22
Typical machine length	0.63	0.21	0.09
Typical installed power	0.96	0.11	0.25
Available cutting power	0.77	0.26	0.11
Cutting drum diameter	0.69	0.1	0.16
Machine weight	0.74	0.11	0.17

Equation 7 is given to find a consensual set of criteria weights according to the mean scores of the experts.

$$W_j = \prod_{k=1}^{K} (W_j^k)^{W_k} \tag{7}$$

where,

W_j: Weight of the jth criterion

W_j^k: Weight of the jth criterion according to expert k's judgment

W_k: Normalized weight by expert k

K: Number of experts

In the last step, after calculating utility and regret measures through Equations 8 and 9 VIKOR index should be calculated.

$$U_i = \sum_{j=1}^{J} \frac{W_j (n_j^* - n_{ij})}{(n_j^* - n_j^-)} \tag{8}$$

$$R_i = \max_j \left[\frac{W_j (n_j^* - n_{ij})}{(n_j^* - n_j^-)} \right] \tag{9}$$

where,

U_i: Utility measure

R_i: Regret measure

Q value as VIKOR index should be calculated using Equation 10. The shearer alternatives are sorted by the values U_i, R_i, *and* Q_i.

$$Q_i = \nu \left[\frac{U_i - \min_i U_i}{\max_i U_i - \min_i U_i} \right] + (1-\nu) \left[\frac{R_i - \min_i R_i}{\max_i R_i - \min_i R_i} \right] \tag{10}$$

Where,

ν: Weight of the maximum group utility (or weight of the strategy of "the majority of criteria") which is usually set to 0.5 (Tong et al., 2007)

Table 6 shows the results including all utility and regret measures and VIKOR index for the shearer alternatives.

The alternative which includes minimum VIKOR index is determined as the best compromise solution. Therefore, the shearer loader model EL 600 is the best choice among four alternatives considered in this research from the technical point of view according to the results summarized in Table 6.

Table 6. VIKOR index for the shearer selection

Parameters	Shearer alternatives			
	EL3000	EL2000	EL1000	EL600
Utility measure	1	0.47	0.68	0
Regret measure	0.25	0.25	0.22	0
VIKOR index	1	0.73	0.78	0

3.3 Final Results and Discussion

According to the analytical procedure, characteristics of the four shearer alternatives were considered to be adjusted to the mechanical properties of the coal seam located in Tabas Parvadeh1 longwall mine. In this case, the physical parameters of shearer such as pick, drum and vanes were designed and consequently the most useful kind of drag pick was selected among point-attack and conical ones. The diameter and width of shearer were respectively estimated 1.5 m and 0.8 m on the basis of the thickness, strength, and hardness of the coal seam. Based on all important points, "double ended ranging drum shearer" model EL600 was selected as the most appropriate one to be practicable for Parvadeh1 longwall mine. The mentioned technical viewpoints and most crucial parameters were also considered during the application of the MCDM system, in order to select a most suitable shearer loader system for Parvadeh1 mine. Accordingly using the MCDM system, EL 600 shearer loader was also selected among the four alternatives from the technical viewpoints. It means that the results of the MCDM system are completely in accordance with the results of the analytical procedure.

4 CONCLUSION

The integrated results obtained from the analytical procedure proposed by Bakhtavar and Shahriar (2013) and VIKOR multi-criteria decision making system were used in order to decide on the most appropriate shearer loader system for application in Tabas Parvadeh1 longwall mine. During the decision making process, the analytical procedure was initially used to find effective criteria. The most crucial criteria were found from the analytical procedure and then considered during the MCDM system on the basis of the mechanical properties of C1 coal seam together with the critical characteristics of shearer loader. Both analytical procedure and the MCDM system indicated that EL 600 two drums shearer system can be appropriately applicable among the four considered alternatives from the technical viewpoints.

Review of Graphical Methods Utilized in System Reliability Assessment

Sistem Güvenilirliği Değerlendirilmesinde Kullanılan Grafiksel Yöntemlerin İncelenmesi

D. Tuncay, N. Demirel
Middle East Technical University, Mining Engineering Department, Ankara

ABSTRACT In modern mining activities, mine productivity highly relies on the availability of high capacity machines. Reliability assessment of these machines has significant impact on understanding the failure behaviors, thus determining maintenance policies accordingly. Reliability analysis of complex systems, such as mining machinery, requires knowledge about failure behavior of their components for more accurate results. In order to combine the failure information of system components to analyze system reliability, there are various methods that can be utilized. Reliability block diagrams (RBD) and fault tree analysis (FTA) are two of the commonly used graphical methods in system reliability analysis. In this paper, general information on RBD and FTA is presented and reliability analysis of a sample system is conducted, utilizing both methods.

Keywords: Fault tree analysis, **r**eliability assessment, reliability block diagram

ÖZET Modern madencilikte, madenin verimliliği, büyük ölçüde yüksek kapasiteli maden makinalarının kullanılabilirliğine dayanmaktadır. Bu makinaların güvenilirlik değerlendirmeleri, arıza davranışlarının anlaşılmasında ve bu sayede bakım onarım politikalarının uygun şekilde belirlenmesine yardımcı olur. Maden makinaları gibi karmaşık sistemlerin güvenilirlik analizlerinin daha gerçek sonuçlar vermesi için, bu sistemleri oluşturan bileşenlerin arıza davranışları hakkında bilgiye sahip olunmalıdır. Bu arıza bilgilerinin birleştirilip sistem güvenilirliğinin belirlenmesi için kullanılan çeşitli yöntemler mevcuttur. Güvenilirlik blok diagramları (GBD) ve hata ağacı analizi (HAA) sistem güvenilirlik analizinde yaygın olarak kullanılan iki grafiksel analiz yöntemidir. Bu bildiri GBD ve HAA hakkında genel bilgileri içermektedir ve örnek bir sistem için, her iki yöntem kullanılarak güvenilirlik analizi yapılmıştır.

Anahtar Kelimeler: Hata ağacı analizi, güvenilirlik değerlendirmesi, güvenilirlik blok diagramı

1 INTRODUCTION

Reliability is commonly defined as the probability of a product not to fail under a certain condition during a defined duration. Reliability analysis is the calculation and evaluation of the reliability of a system, sub-units of a system or the critical parts of a system (Uzgören and Elevli, 2010).

The purpose of a reliability engineer is to examine the relation between the system operation and failure by studying:

- The reasons for system failure,
- The ways to develop reliable systems,
- The ways to measure and test reliability in design, operation and management, and
- The ways to maintain reliable systems by maintenance, fault diagnosis and prognosis.

The problems of a reliability engineer to solve are: representation and modeling of the system, quantification of the model and representation, propagation and

quantification of the system behavior uncertainties. (Zio, 2009).

The reliability of a system depends on the analysis of the failure times, times between failures and number of failures of a system during a given time. The main goal in reliability analysis is to define a statistical model which fits these data best.

After determining the probability distributions of component failures, these distributions are used for system reliability analysis. There are various methods for determining system reliability. Two of the graphical methods that will be mentioned are: reliability block diagram (RBD) and fault tree analysis (FTA). Both methods can be used alternatively to demonstrate the relations of system components, their effects on system reliability and quantify the system reliability, utilizing the failure probabilities of individual components.

2 RELIABILITY BLOCK DIAGRAMS

A system is a network of components connected in series, parallel or other combinations. Reliability block diagram is a schematic and logical representation of a system that helps investigating the stated connections among components and estimating the overall system success (Kumar *et al*., 2006).

Most systems in RBD are in series or in parallel configurations. A network in series indicates that the system success can only occur if all components are in working condition. The reliability of a series system (Figure 1) can be calculated as given in Equation [1].

$$R_s=R_1.R_2.R_3...R_k \quad [1]$$

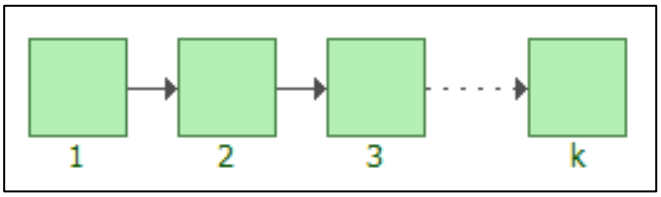

Figure 1. A series system

In parallel systems, the system continues to operate until every component fails. This indicates, the components cannot stop system operation individually. The equation used to calculate reliability for parallel systems (Figure 2) is given in Equation [2]

$$R_p=1-(1-R_1)(1-R_2)...(1-R_k) \quad [2]$$

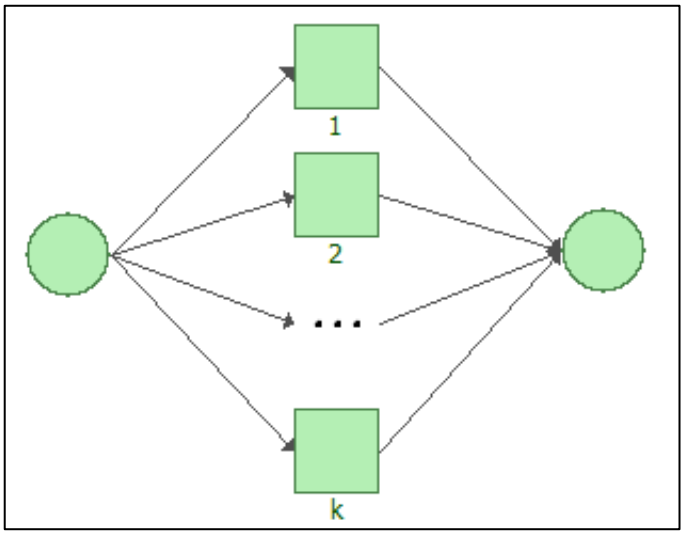

Figure 2. A parallel system

Another special configuration is the k-out-of-n system that indicates system operation when at least k components out of n components stay operational i.e. failure in (n-k) components can be tolerated. The reliability of the k-out-of-n system (Figure 3) can be expressed using Equation [3].

$$R_{k/n} = \sum_{i=k}^{n} \binom{n}{i} R^i (1-R)^{n-i} \quad [3]$$

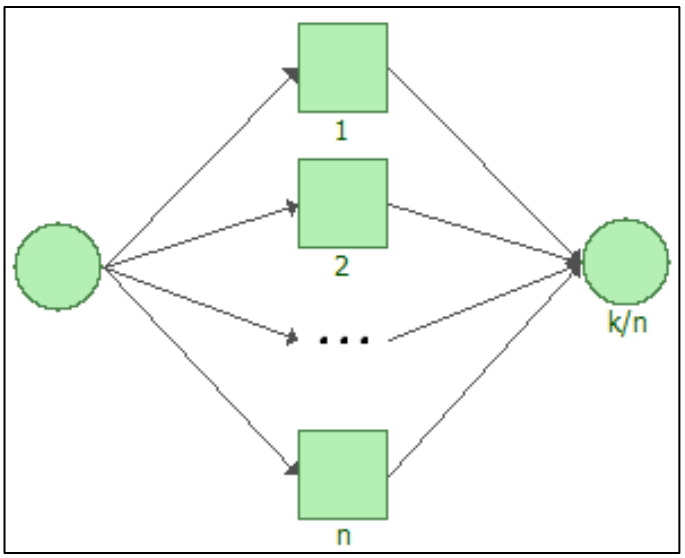

Figure 3. k-out-of-n system

3 FAULT TREE ANALYSIS

Fault tree analysis (FTA) is an analytical technique used to analyze a system to determine all the credible ways in which a single undesired event (top event) can occur. FTA is a top to down, failure oriented symbolic logic model used to determine the probability of the top event by identifying failure paths leading to it (Ericson II, 1997).

FTA is firstly applied to the Minuteman Launch Control System in 1961 by H. Watson in the Bell Labs together with U.S Air Force (Lee *et al*., 1985). Then, Boeing Company used it for complete quantitative safety analysis of the Minuteman weapon system. The Boeing Company enhanced the technique, developed the first FT computer codes and used it for many other products. Then the FTA was discovered by nuclear power industry and enhanced and refined further (Ericson II, 1999).

FTA consists of the generation of the fault tree, determination of the failure probabilities of each event, determining probability of the top event by propagating failure probabilities and determining cut sets and path sets. The cut set is any set of events where if they all occur, the top event occurs. The path set is a group of sets which guarantees that the top event cannot occur if none of them occurs.

Fault tree analysis can be used for different purposes: to understand the logical path leading to the top event, to determine the prior contributors to the top event, to anticipate actions to prevent the top event, to monitor the performance of the system, to optimize resources, to help with the system design, to determine the cause of the top event and determine a solution. FTA can be used throughout the life cycle of the system. FTA has a wide variety of uses in decision making as seen above from design process through system implementation and improvement (Stamatelatos and Vesely, 2002).

The terminology in fault tree analysis is of great importance for defining the problem. There are some standard definitions and mechanics provided to define the problem completely. Some of these standard definitions are as follows (Ericson II, 1997):

- Tree: A fault tree composed of all events and logic connections which lead to the occurrence of the undesired incidence, i.e. top event.
- Top Event: The ultimate undesired event that is being investigated. A fault tree can only have one top event.
- Branch: A section of the fault tree with events and logic gates.
- Module: An independent branch with a sub-top event that does not occur anywhere else.
- Node: A general term used to define every event on the tree; failure, gate, condition etc.
- Basic Event: A node that represents a failure event that failure probability is given as input.
- Gate: A logical Boolean operator with a specific function that combines input events (AND, OR, Inhibit, Priority AND and Exclusive OR gates).
- MOE (Multiple Occurring Event): An event that occurs in multiple places in the fault tree causing branch dependencies.
- Cut Set: A set of events that’s occurrence cause the top event to occur (failure path).
- Minimum Cut Set: A cut set with the minimum number of events that still cause the top event to occur.
- Critical Path: A cut set with the highest probability which consequently has the biggest effect on the probability of the top event. Improvements in this path results in most dramatic system improvements.

The logic operators (Gates) are the main components in FTA and indicate the relations between events (component failures) and top event (system failure). Logic operators used in fault tree analysis are defined as (Ericson II, 1997):

- OR Gate: Occurrence of at least one input is enough for the output to occur (Series Configuration).
- AND Gate: All input events must occur for the output event to occur (Parallel Configuration).
- Inhibit Gate: Inputs must occur and a condition should be satisfied for the output event to occur.

- Exclusive OR Gate: Only one input should occur for the output event to occur.
- Priority AND Gate: All input events must occur in a specific sequence for the output to occur.

The symbols assigned to these operators are shown in Figure 4.

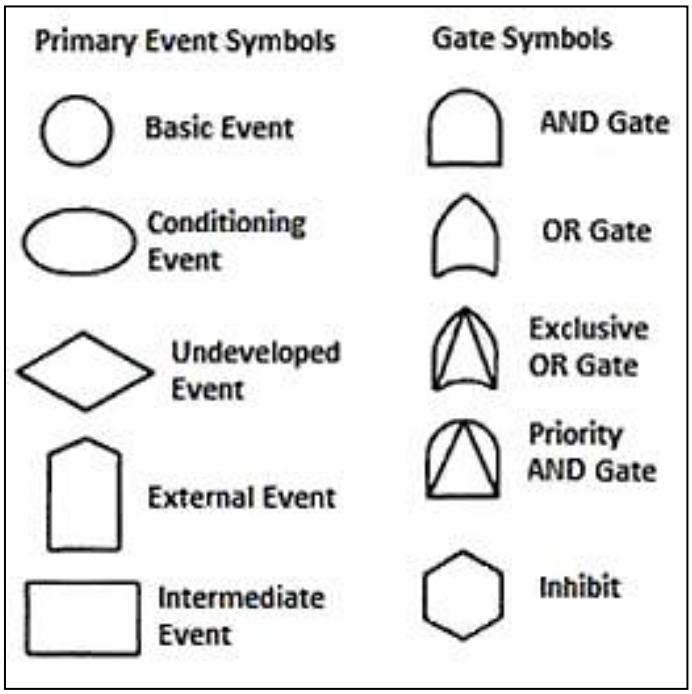

Figure 4. Operator symbols in fault tree analysis (Vesely *et al.*, 1981)

The graphical representation of the most common gates (AND, OR, VOTING), and their probability relations are explained in Table 1.

Table 1. The graphical representation of the gates and the probability relations (modified from Samanta *et al*., 2002)

Logic gate	Logic symbol	Probability relation
OR		$P(y) = P(\bar{x}_1 + \bar{x}_2 + \bar{x}_3)$ $= P(\bar{x}_1) + P(\bar{x}_2) + P(\bar{x}_3) - P(\bar{x}_1)P(\bar{x}_2) - P(\bar{x}_1)P(\bar{x}_3) - P(\bar{x}_2)P(\bar{x}_3) + P(\bar{x}_1)P(\bar{x}_2)P(\bar{x}_3)$
AND		$P(x_1x_2x_3) = P(\bar{x}_1)P(\bar{x}_2)P(\bar{x}_3)$
Voting gate		$P\{\bar{x}_1\bar{x}_2 + \bar{x}_1\bar{x}_3 + \bar{x}_2\bar{x}_3\}$ $= P(\bar{x}_1\bar{x}_2) + P(\bar{x}_1\bar{x}_3) + P(\bar{x}_2\bar{x}_3) - P(\bar{x}_1\bar{x}_2)(P(\bar{x}_1\bar{x}_3) - P(\bar{x}_1\bar{x}_2)(P(\bar{x}_2\bar{x}_3) - P(\bar{x}_1\bar{x}_3)(P(\bar{x}_2\bar{x}_3) + P(\bar{x}_1\bar{x}_2)P(\bar{x}_1\bar{x}_3)P(\bar{x}_2\bar{x}_3)$

For these probability relations to be valid, the events should be independent since the assumption, $P(x_1,x_2) = P(x_1)P(x_2)$ is valid for independent variables.

Since the fault tree analysis is highly dependent on the knowledge and expertise of the analyst, it is difficult to make a clear definition on how to construct a fault tree. Fault tree requires detailed analysis and may require comprehensive assumptions, but other than those, the main steps to be followed are as follows (Öktem, 2006):

- Determining the Top Event: The undesired event to be analyzed is chosen.
- Combining the Known Causes: Existing faulty states and failure events are determined with the available knowledge. Even though the failure list can be lacking, it is important for the fault tree construction.
- Construction of Fault Tree: Independent events that may cause the top event are determined. These events are connected with an OR gate and the construction continues from top to bottom trying to find other failure causes.
- Revision, Addition, and Testing: Fault tree construction is a trial and error process no failure causes should be overlooked.
- Evaluation of the Results: The completed fault tree is evaluated according to the purpose of the analysis. The evaluation can include various stages: listing minimum cut sets, grading minimum cut sets, and calculation of probabilities etc.

4 SAMPLE CASE STUDY

4.1 Determining Appropriate Probability Density Functions for Components

Assume there is a system composed of 5 components namely: A, B, C, D, and E and these components have individual failure data. The failure data are randomly generated by Monte Carlo simulation. First failure probability density functions should be determined for each component's generated failure data. From the failure data of 5 components, following failure probability distributions are obtained (Table 2).

Table 2. Component failure distributions

Components	Distribution	Distribution Constants	
A	Weibull-2P	β	1.17
		η	546.25
B	Weibull-2P	β	0.84
		η	941.83
C	Weibull-2P	β	1.73
		η	264.32
D	Exponential	λ	9.4E-3
E	Exponential	λ	2.20E-3

Weibull distribution is widely used for failure data and can be with 2 or 3 parameters. 2 parameter Weibull distributions have scale and shape parameters that determine the life characteristics (Reliasoft 2014). β is the shape parameter and η is the scale parameter. Lower shape parameters ($\beta < 1$) suggest that the failure frequency is high at start and decreases continuously which is similar to an exponential distribution which occurs when β equals to one. Shape parameters, greater than one, suggest that the failure frequency increases to maximum and then decreases with time. The scale parameter is an estimate of the mean and gives the time when the failure probability is 63.2%.

Exponential distribution suggests a failure behavior starting with high failure frequency and decreasing continuously. The exponential distribution has one parameter which is the failure rate (λ) which is the inverse of mean (Reliasoft, 2014).

There can also be a location parameter (γ) for both Weibull and exponential distributions, that indicates the distance from origin of the distribution start point. Positive location parameter suggests no failure occurs before a certain time, called as failure free time.

4.2 Determining System Configuration

Configuring the system requires a good understanding of the system and the relations between components. There can be series and parallel configuration in the system. Series configuration means failure in one component results in failure of the system or the sub-system. In a parallel configuration, for the system to fail, all components in the configuration should fail. In some cases, there can be a type of configuration where system failure occurs if a given number of components fail. For the sample case; failure of component A causes system failure. Failure of component B combined with failure of C or failure of 3 out of 5 D components also causes system failure. Another way for the system to fail is either two of the E components should fail or one E combined with a subsystem composed of a D and an E component with parallel configuration should fail.

4.3 Constructing the Reliability Block Diagram

According to the defined system network configuration, the reliability block diagram is constructed as seen in Figure 5.

Extra starting and ending blocks are placed on two sides of the diagram. These blocks are assigned as “cannot fail” and do not affect the reliability calculations. Similarly, the extra node connecting D* and E* is also assigned as “cannot fail”.

D* and E* components have the same failure distributions of D and E respectively but to be able to distinguish those components during analysis, different names were assigned.

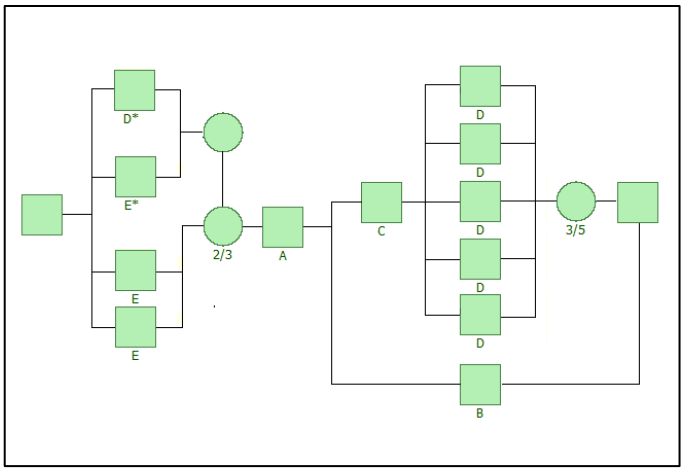

Figure 5. Constructed reliability block diagram of the system

4.4 Constructing the Fault Tree and Reliability Analysis

Considering the defined relations between components, by utilizing logic gates, the following fault tree is constructed (Figure 6).

VT gates are voting gates where the gate connecting five D components have a vote number of 3 and the other voting gate has 2. The top event is defined as the system failure.

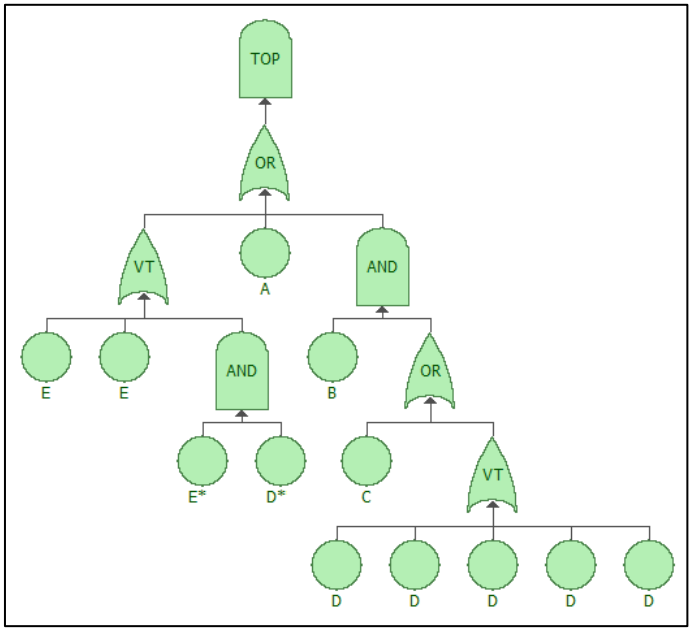

Figure 6. Constructed fault tree of the system

The reliability calculations are carried out following the equations assigned for different gates and they are the same for both RBD and FTA. Weibull++7 (2011) and Blocksim 7 (2011) software were utilized for the analysis of the sample system. The obtained reliability vs. time plot can be seen in Figure 7.

It can be seen from Figure 7 that around 160 hours, the system reliability drops down to 50%. The mean life time of the system is estimated as 207 hours.

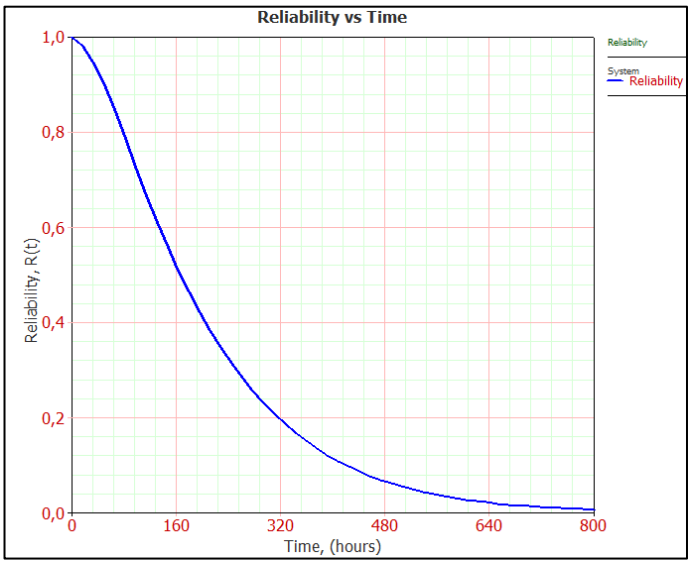

Figure 7. System reliability change with respect to time

Another practical data obtained from fault tree analysis are “Reliability Importance Values” (RI). RI values are calculated considering the reliability of the component, reliability of the system and the component’s location in the fault tree configuration. RI values are calculated for a given time and can be helpful when determining a maintenance policy. The RI values of the components at the system’s estimated lifetime (207 hours) can be seen in Figure 8.

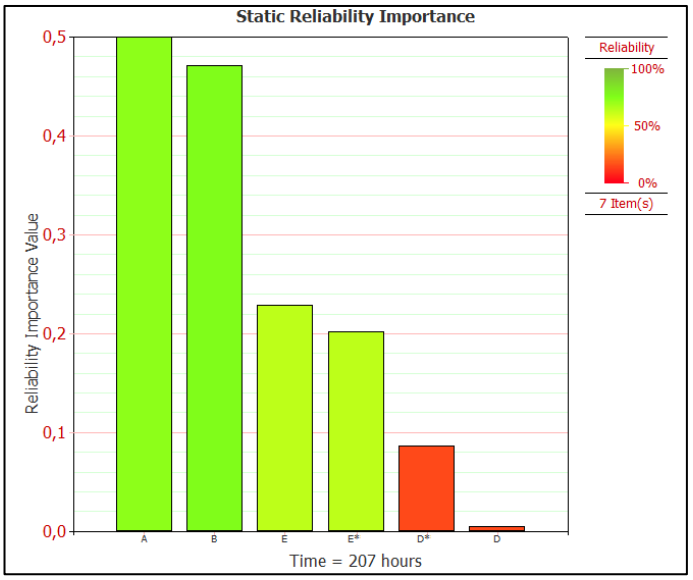

Figure 8. RI values of components at 207 hours

The higher RI values indicate that an improvement on that components reliability will be more significant for system reliability compared to other components. It can be

seen that even though component D has a low reliability, its RI value is smaller compared to component A which has the highest RI value despite its high reliability. This is due to their location in the system configuration and their effect on system reliability. Component A has direct effect on system reliability since its failure result in system failure. This can be easily seen in the sample system but in more complex systems, it may not be so obvious.

For different time intervals, RI values must be checked since different components may have a higher importance for different times. RI vs. time plots can also be obtained to see if any component gains importance over another component.

For example, as seen in Figure 9, for around 85 hours component C has higher RI value compared to D*, but after 85 hours, D* has a higher RI value due to its failure distribution.

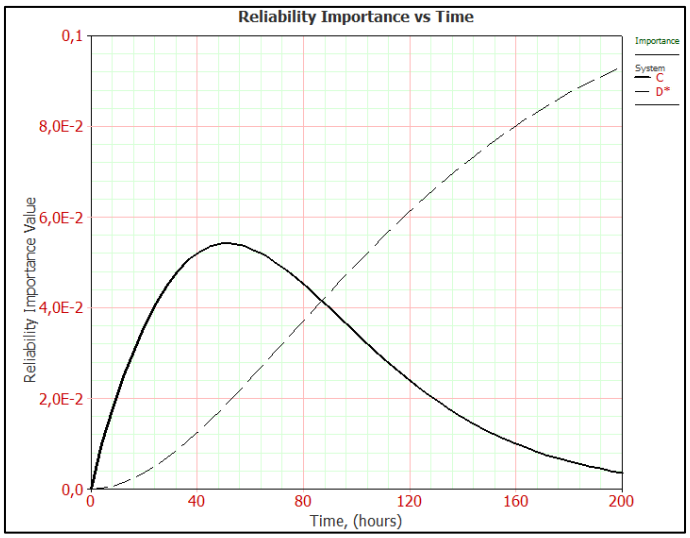

Figure 9. RI changes with respect to time for components C and D*

5 CONCLUSIONS AND RECOMMENDATIONS

Reliability analysis of mining machines is important for determining failure behavior of the machines and consequently predicting possible failures beforehand. For complex systems, there are different methods that can be utilized for system reliability assessment. Reliability block diagram and fault tree analysis are two of the graphical methods which are useful tools for demonstrating component configurations within the system and determining system reliability considering those relations.

The sample study was used to illustrate the use of these methods and to show the possible outcomes of the analyses that can be beneficial for preparing maintenance plans thus improving machine availability.

The main conclusions derived from this paper can be listed as:

- Reliability block diagrams and fault tree analysis are effective tools in determining complex system reliability.
- Reliability Importance (RI) factor can be utilized effectively to detect the critical elements in varying operation periods.
- At different times, different components have higher importance values meaning those components may require special attention to prevent failure.
- Having a good understanding of the system at hand and proper classification of failure data accordingly are important for reliability analysis.

The items that can be recommended for the future studies can be listed as follows:

- Results of reliability analyses should be utilized to prepare a maintenance plan considering the critical components. Preparing an appropriate maintenance plan considering the component reliabilities will increase the machines availability, thus decreasing the direct and indirect costs caused by unplanned down times of the machinery.
- Optimum preventive or corrective maintenance intervals should be decided considering maintenance costs, repair efficiencies and losses in revenue due to breakdowns.
- There can be units that take time to be repaired in case of failure and may require detailed scheduled maintenance considering the repair and maintenance times.
- Maintenance personnel should be specially trained to keep failure logs precisely in order to prevent inaccurate data. If possible, a practical and detailed maintenance data sheet should be prepared to acquire more information about machine lifetime behavior.

Review of Trend Tests for Detection of Wear-Out Period for Mining Machineries

Maden Makinalarının Aşınma Periyodunun Tespit Edilmesinde Kullanılan Eğilim Testlerinin İncelenmesi

O. Gölbaşı, N. Demirel

Middle East Technical University, Department of Mining Engineering, Ankara

ABSTRACT Machinery systems are extensively utilized in all mining stages from beginning to end of ore production. They are capital-intensive systems and substantial amount of money is spent annually to keep their functionalities in desired levels. Therefore, implementation of effective maintenance strategy has a vital importance to prevent unexpected breakdowns due to failures and to minimize operational cost. These maintenance strategies can be constituted effectively regarding functional and structural dependencies between system components and forecasting their expected lifetimes and deterioration rates over time. However, forecasting of expected failures can fail due to aging trend in system components. This paper summarizes qualitative and quantitative trend tests in detection of wear-out period where system starts to age. In the paper, two separate graphical methods are investigated in qualitative analysis of data trend behavior where hypothesis testing techniques such as Crow/AMSAA, Laplace, Lewis-Robinson, and Reversal Arrangement and indirect trend test using imperfect maintenance concept are examined as quantitative tests. Implementation of all test are supported via their theoretical backgrounds and numerical examples.

Keywords: Wear-out period, qualitative and quantitative lifetime trend tests, imperfect maintenance

ÖZET Makina sistemleri, cevher üretiminin başından sonuna kadar tüm madencilik aşamalarında yaygın olarak kullanılmaktadır. Bu makinalar sermaye-yoğun sistemler olup, makinaların işlevlerini yeterli seviyede tutmak için her yıl önemli bir miktar para harcanmaktadır. Bu sebepten dolayı, etkili bakım onarım stratejileri uygulanışı, arızalardan kaynaklı beklenmedik duraksamaların önlenmesi ve operasyonel masrafların en aza indirgenmesinde kritik bir öneme sahiptir. Bu bakım-onarım stratejileri, sistem bileşenleri arasındaki fonksiyonel ve yapısal bağımlılıkların göz önüne alınarak ve bu bileşenlerin beklenen yaşam süreleri ve kötüleşme hızlarına yönelik tahminlerle etkili şekilde oluşturulabilir. Fakat, muhtemel arızalara dair tahminler, sistem bileşenlerindeki yaşlanma eğilimden dolayı başarısız olabilir. Bu bildiri, sistemin yaşlanmaya başladığı yıpranma periyodunun tespitinde kullanılan nitel ve nicel eğilim testlerine yönelik bir özet sunmaktadır. Bildiride, iki adet grafik yöntemi veri eğilim davranışının nitel analizinde incelenirken; Crow/AMSAA, Laplace, Lewis-Robinson, Reversal Arrrangement gibi hipotez testleri ve noksan onarım konsepti kullanılarak yapılan dolaylı eğilim testi de nicel testler olarak incelenmiştir. Bütün testlerin uygulanışları, teorik arka planları ve sayısal örneklerle desteklenmiştir.

Anahtar Kelimeler: Aşınma periyodu, nicel ve nitel yaşam eğilim testleri, kusurlu bakım-onarım

1 INTRODUCTION

Mining is a capital-intensive sector where substantial amount of money is spent in maintenance and purchase of machineries for sustainability of mining operations in order to supply raw material to various industries. Performance and reliability of machineries have a major effect on production since any lack of functionality in these systems can cause production losses and delays in planned production schedule.

In their operational life, machines are exposed to breakdowns in several times due to failure of components and they are recovered via corrective maintenance. Occurrences of failures are ordinary and expected events. However, failure rate can change due to operational age of machines. Variations in expected number of failure for unit time can cause disappearance of randomness. In the lack of randomness, it becomes hard to forecast failure arrival time and constitute a fixed maintenance policy. Majority of systems, even human body, generally follows a failure rate path called as bathtub curve. This curve can be divided into three parts as infant mortality, useful period, and wear-out period (Figure 1).

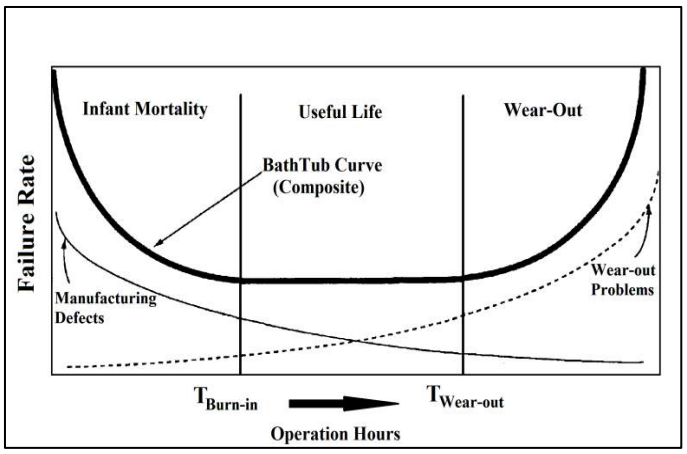

Figure 1. Sample Bath Tub Curve

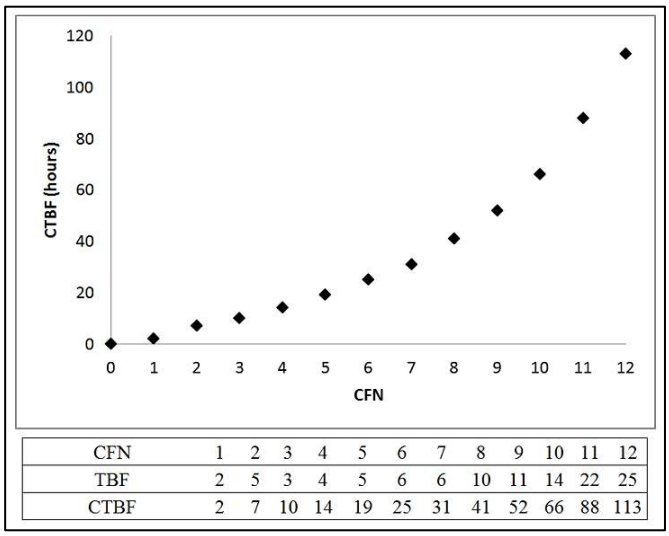
In early times of systems, failure rate is high at the beginnings and falls dramatically at the following operational hours. This period is also called infant mortality or burn-in period. Failures are expected to appear in high frequency since there can be errors due to design, operational, installation or redundant-maintenance conditions. After stabilization of system functionality and accommodating to production, failure rate gets smaller and reach to an almost-constant level. In the sequel, failure rate remain constant for a long time and it is called as useful life, i.e. normal life. Failures occur randomly during this interval. Following this period, system enters a period with increasing failure rate due to wear-out conditions of system components. In the latest stage of this period, randomness of system failures highly disappears. In this period, implementation of only corrective maintenance after failure without any preventive action can cause long-term breakdowns. Therefore, maintenance actions such as, preventive replacements and condition monitoring, become crucial to detect oncoming failures.

Detection of wear-out start is important to re-arrange maintenance strategy for systems. There are various qualitative and quantitative techniques to be utilized in decision of system failure trends. In this sense, Section 2 will discuss how to assess trend condition of failure rate using graphical method quickly where Section 3 will mention about quantitative trend detection methods.

2 QUALITATIVE TREND TESTS

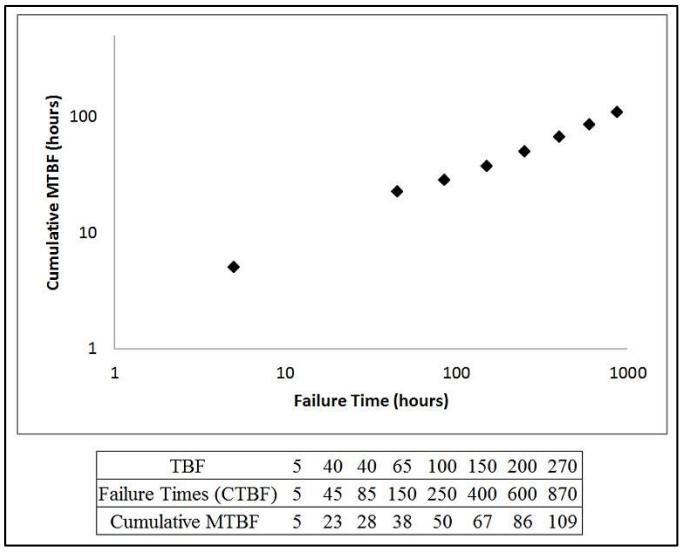
Qualitative methods offer quick way of detecting changes in failure rate. If the failure rate is nearly constant in a specified time period, time between failures (TBF) data is called as non-trend data or vice versa. Occurrence of data trend can be verified using graphs by plotting cumulative failure numbers (CFN) versus cumulative time-between-failure (CTBF) and failure times versus cumulative mean-time-between-failures (MTBF) in log-log scale (Duane graph). Using datasets of two sample systems, these two graphical methods are illustrated in Figure 2 and Figure 3, respectively.



CFN	1	2	3	4	5	6	7	8	9	10	11	12
TBF	2	5	3	4	5	6	6	10	11	14	22	25
CTBF	2	7	10	14	19	25	31	41	52	66	88	113

Figure 2. Qualitative Trend Test using CTBF versus CFN Plot

Figure 2 shows that CTBF, i.e. system time, follow a curvilinear path with upward trend. It can be evidence of that failure rate is falling over time with rising time between failure values and system is in the early life period in bathtub curve. Therefore, this system is far away from wear-out period. In the case of non-trend condition, graph line is expected to straight.



TBF	5	40	40	65	100	150	200	270
Failure Times (CTBF)	5	45	85	150	250	400	600	870
Cumulative MTBF	5	23	28	38	50	67	86	109

Figure 3. Qualitative Trend Test using Failure Time versus Cumulative MTBF Plot

Figure 3 illustrates Duane plot for another system. Failure times in the plot are the points in time horizon where failures take place. It neglects repair times and it is the same as CTBF in Figure 2. Cumulative MTBF is time-based mean survival time. For instance, third failure appears at 85th operation hour. Therefore, Cumulative MTBF is 28 hour as division of 85 to 3. This graph is plotted in the log-log scale and expected to be straight if there is no data trend. Figure 3 is an example of system with non-trend failure behavior.

Although these graphs offer easy and effective way in trend analysis, they are generally interpreted subjectively. They sometimes need to be validated quantitatively, especially for large data sets and complex systems. Section 3 will discuss background of the hypothesis testing methods and imperfect maintenance approaches in interpretation of data trend in quantitative way.

3 QUANTITATIVE TREND TESTS

3.1 Hypothesis Testing Methods

Hypothesis testing methods can be utilized to verify the results of qualitative techniques. Crow/AMSAA, reversal arrangement test, Laplace test, and Lewis-Robinson test are generally used in observation of data trend for repairable systems. These methods test validity of various stochastic processes to discuss presence of data trend. For instance, Crow/AMSAA and Laplace methods test whether the data can be fitted in homogenous Poisson process (HPP) or not where reversal arrangement test and Lewis-Robinson methods check suitability of data for renewal process (RP). Validity of HPP or RP in these tests is good evidence of non-trend behavior. It is why these methods test stochastic processes to find out trend behavior. Otherwise, data show trend behavior and it can be treated using non-homogenous Poisson process (NHPP). Detailed expressions of the tests can be investigated from Kobbacy and Murthy (2008), Stephens (2011), Wang and Coit (2005), and Bendat and Piersol (2010). In all tests, X_i, T_i, and N notate ith time between failure (TBF_i), cumulative time between failures up to ith failure ($\sum_1^i TBF_i$), and total number of failures, respectively.

Crow/AMSAA test, i.e. military test, investigates whether the data can be fitted in HPP or NHPP, analyzing value of parameter β. Best estimate of β using maximum

likelihood estimation is given in Equation 1 (Wang and Coit, 2005).

$$\hat{\beta} = \frac{N}{\sum_{i=1}^{N-1} \ln\left(\frac{T_N}{T_i}\right)} \quad (1)$$

According to the test, null hypothesis which agrees on non-trend data behavior is rejected if $2N/\hat{\beta} < \chi^2_{2N,1-\alpha/2}$ or $2N/\hat{\beta} > \chi^2_{2N,\alpha/2}$, where χ^2 is the score of chi-squared distribution for given confidence interval and degree of freedom.

Reversal arrangement test checks whether the data can be modelled using renewal process or not. Presence of renewal process (null hypothesis) is rejected if $U_{RA} > z_{\alpha/2}$ or $U_{RA} < -z_{\alpha/2}$. U_{RA} can be evaluated using Equation 2 (Wang and Coit, 2005). In the formula, U is the total number of counts for the condition $X_j > X_i$ for each X_i where $j > i$.

$$U_{RA} = \frac{U - N(N-1)/4}{\sqrt{\frac{(2N+5)(N-1)N}{72}}} \quad (2)$$

Laplace test examines whether data is well fitted in HPP or NHPP, as in Crow/AMSAA test. Acceptability of HPP (null hypothesis) is rejected if $U_L > z_{\alpha/2}$ or $U_L < -z_{\alpha/2}$. Test statistics, U_L, is stated in Equation 3 (Wang and Coit, 2005)..

$$U_L = \frac{\sum_1^{N-1} T_i - (N-1)\frac{T_N}{2}}{T_N\sqrt{\frac{N-1}{12}}} \quad (3)$$

Finally, Lewis-Robinson test analyze whether data is fitted in renewal process or not. Division of Laplace test statistics, U_p, to coefficient of variance is the hypothesis test statistic as given in Equation 4 (Wang and Coit, 2005). Coefficient of variance can be expressed as $\sqrt{Var[X]}/\bar{X}$ where X is TBF dataset. Again, null hypothesis rejected if $U_{LR} > z_{\alpha/2}$ or $U_{LR} < -z_{\alpha/2}$.

$$U_{LR} = \frac{U_L}{CV[X]} \quad (4)$$

As discussed at the beginning of Section 3.1, these tests utilize HPP, NHPP, and renewal process to reveal potential data trend behavior. It should be remind that renewal process assumes that system is recovered in to as good as new condition after maintenance activities. Any distribution can be fitted in renewal function. HPP is special version of renewal process where time between failure values is good fitted in exponential distribution. On the other hand, NHPP assumes that maintenance recovers the system to as bad as old condition and failure rate is allowed to rise. Therefore, trend behavior of data is good explained using NHPP. Although mathematical background of the processes is out of scope for this paper, reader can utilize Rausand and Hoyland (2004) for detailed investigation.

Numerical Example

Trend testing methods discussed in Section 3.1 will be evaluated using sample failure statistics given in Table 1.

Table 1. Time between Failures Data

#	Time between Failures (hours)	Cumulative Time between Failures (hours)
1	15	15
2	8	23
3	25	48
4	14	62
5	18	80
6	21	101
7	25	126
8	23	149
9	20	169
10	32	201
11	9	210
12	15	225
13	45	270
14	47	317
15	33	350
16	24	374
17	27	401
18	31	432
19	19	451
20	22	473

Trend behavior of the data in Table 1 is initially assessed with Crow/AMSAA test. Parameters to be utilized in Equation 1 are calculated as in Table 2. Best estimate of $\hat{\beta}$ is found to be 0.9 and rejection criterion, $2N/\hat{\beta}$, is between the interval specified by the scores of chi-squared distribution. Therefore, null hypothesis of the test is accepted, agrees on non-trend behavior of the data set.

Table 2. The Test Values of Crow/AMSAA

Test Parameters	Parameter Values
N	20
T_N	22
$\sum_{i=1}^{N-1} ln(\frac{T_N}{T_i})$	21.8
$\widehat{\beta}$	0.9
$2N/\widehat{\beta}$	43.7
$\chi^2_{40,0.025}$	24.4
$\chi^2_{40,0.975}$	59.3
Decision:	Accept H_0

The data was also evaluated using reversal arrangements test with Equation 2. In the formula, U is the total number of reversal. For instance, $X_{10} = 32$ is given in Table 1. Number of reversals for X_{10} is found as 3, which is the total counts for $X_j > X_{10}$ for $j > 10$. This is repeated for each X_i and the reversals are summed to find out U parameter. U is found as 123, given in Table 3. Test statistic of the method, U_p, is then calculated as 1.82 and it is between standard normal distribution scores, ± 1.95. Therefore, the test accepts null hypothesis and rejects presence of data trend.

Table 3. The Test Values of Reversal Arrangements

Test Parameters	Parameter Values
N	20
U	123
U_p	1.82
$\pm z_{0.025}$	± 1.95
Decision:	Accept H_0

Failure behavior of the system is also evaluated with Laplace test. The test fails to reject null hypothesis and defense non-trend behavior of the data set since test parameter U_L is between ± 1.95, as shown in Table 4.

Table 4. The Test Values of Laplace Method

Test Parameters	Parameter Values
N	20
T_N	22
$\sum_{i=1}^{N-1} T_i$	4004
U_L	-0.82
$z_{0.025}$	1.95
Decision:	Accept H_0

Last interpretation method for the data is Lewis-Robinson test. It is simply division of U_L parameter found in Laplace test to coefficient of variance of the time between failures values. Non-trend behavior of the system is also validated with this test since the test parameter U_{LR} is in the range of $\pm z_{0.025}$ score (Table 5).

Table 5. The Test Values of Lewis-Robinson

Test Parameters	Parameter Values
U_L	-0.82
$CV[X]$	0.43
U_{LR}	-1.89
$z_{0.025}$	1.95
Decision:	Accept H_0

It is seen that all hypothesis testing methods prove non-existence of trend for the given data set. It is important that Crow/AMSAA and Laplace methods test whether data is fitted to HPP. HPP is a special type of renewal process where data is distributed exponentially. These methods can fail to find trend behavior of a system if its data is non-exponentially distributed, even though data follow non-trend behavior. Therefore, if Crow/AMSAA and Laplace methods defense trend behavior rigorously

where other tests reject the condition, distributional characteristics of data set should be checked. If the distribution is strictly different from exponential distribution, it can be better to choose Crow/AMSAA and Laplace after double checking with the graphical trend test.

3.2 Trend Detection Using Imperfect Maintenance

As mentioned in Section 3.1, HPP and renewal processes assume that system is in as good as new condition after repairing activities where NHPP supposes that system is only back to the condition just prior to failure after maintenance, i.e. as bad as old condition. These conditions are called as perfect and minimal repairs, respectively. In many maintenance activities, system is recovered to a level between as good as new and as bad as old conditions. It is called as imperfect repair. Effect of these repair types on failure rate can be viewed in Figure 4.

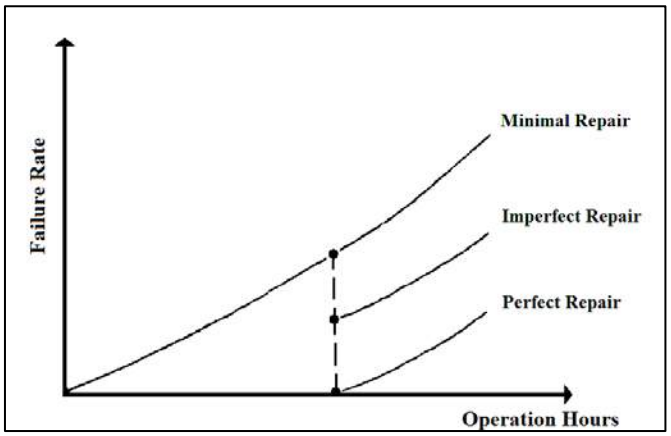


Figure 4. Failure Rate Change after Repair Types (Modified after Blischke and Murthy, 2000)

Determination of imperfect repair effect on system can be beneficial to detect whether system is in deterioration period or not. Imperfect maintenance can be modelled using various models. One of the common model is virtual age method by Kijima *et al.* (1988). The proposed method is expressed using two type models: i) Maintenance activity eliminate damage between only n^{th} and $(n-1)^{th}$ repairs, ii) maintenance activity eliminate cumulative damage, not only a period. Mathematical expressions of the models are given in Equation 4-5, respectively. V_n is virtual age of system before n^{th} repair, A_n is degree of repair and X_n is n^{th} time between failure. If A_n is exact 0 or 1, imperfect repair is turned to perfect or imperfect repair, respectively.

$$V_n = V_{n-1} + A_n X_n \quad (5)$$

$$V_n = A_n(V_{n-1} + X_n) \quad (6)$$

Imperfect repair phenomenon is adapted to renewal process and called as general renewal process (Jacopino *et al.*, 2004). This process allows analyzing of system reliability with introducing restoration factor ($RF=1-A_n$).

In order to validate trend results in Section 3.1, dataset given in Table 1 was analyzed using general renewal process via Reliasoft Weibull software. Instantaneous failure rate of the system was found as in Figure 5. Parameters β and η are reliability characteristics of the system, also called as Weibull process. Restoration factor, ($RF = 1-A_n=1$), refers perfect repair. Moreover, failure rate in the figure exhibit nearly constant behavior. It can be concluded that system is recovered effectively after maintenance activities and trend for time between failure data isn't observed.

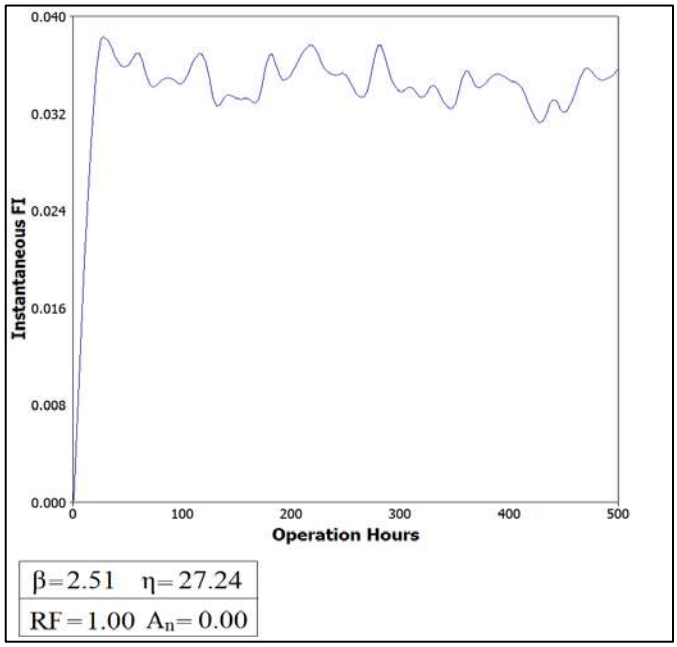

Figure 5. Instantaneous Failure Rate using General Renewal Process

This section considers only general renewal process using Kijima'a virtual age model. For detailed analyzing of various imperfect repair type, Pham and Wang (1996) and Wang and Pham (2006) can be investigated.

4. CONCLUSIONS

Failure data offer beneficial statistics to forecast number of breakdowns in a time interval. It is generally easy to implement forecasting methods for system in useful life with a constant failure rate. In degradation period, machine exhibit lower performance with unexpected failures. Detection of machinery behavior is critical for constitution of effective maintenance strategies. This paper briefly summarizes qualitative and quantitative methods utilized to examine changes in failure intensities and potential data trend.

Tool Wear Estimation in Erath Pressure Balance (EPB) Machine Tunneling

M. Hedayatzadeh
Politecnico di Torino university

D. Peila
Politecnico di Torino university

ABSTRACT: The use of mechanized excavation especially tunnel boring machines (TBMs), has grown more and more in tunnel projects. One of the advantages of TMB compared to conventional method is that these machines can be used in several geological conditions. In the recent years, The Earth Pressure Balance (EPB) shield method was successfully used in urban areas and its application is developed. One of the decisive issues for successful EPB tunneling using conditioning agent is the wear estimation and the assessment of the effects of abrasive ground on the costs and schedule of a project. The estimation of primary wear as well as secondary wear is important for performing a successful project. Among the parameters that can be affected on wear, the soil conditioning is very important. Soil conditioning has been increasingly used to improve the performance of tunnelling process adding foaming agent. It can reduce the wear of machine cutter head face plate and tools, and all wear parts of the muck removal system. In order to assess the impact of the soil conditioning on tool wear, this paper introduces a new test apparatus with new propeller built to measure soil abrasion. Moreover, a specific test procedure has been designed and several sets of tests was conducted in the "Tunnelling and Underground Space Center" of Polytechnic university of Turin, in collaboration with UTT Mapei S.P.A. The primary examination shows that utilizing soil conditioning can reduce the wear of tool. More tests are underway to evaluate the effect of soil conditioning as well as other parameters on wear tool that lead to introduce the model and index for predicting the wear in soft ground tunnelling.

Keywords: Soil conditioning, tool wear, Shield tunneling, soil abrasivity

1. INTRODUCTION

In the last few years, one of most significant issue in soft ground tunneling has been the abrasiveness of soil influencing EPB tool life. In technical references there are a large number of methods to determine the abrasivity of hard rock. This fact arises from long tradition of predicting e.g. TBM performance rates and tool wear (Nilsen, Dahl, Holzhäuser & Raleigh; 2006, pp:36-38). In soil and soft ground tunneling very few methods are defined. Nilsen et al and Jakobsen and Dahl converted NTNU/SINTEF´ existing abrasivity measurement technique for hard rock and made it applicable for measuring soil abrasivity (Thewes & Budach; 2010). Thuro et al converted the LCPC abrasive-meter to measure soil abrasivity (Ozdemir & Nilsen; 1999; pp:21-35). Gharahbagh and Rostami and Rostami et al developed a new soil abrasivity measuring technique that takes into account in situ soil properties (Nilsen, Dahl, Holzhäuser & Raleigh; 2006, pp:43-45). In soft ground tunneling excavated by EPB shields, soil conditioning play significant role in satisfied fulfillment of tunneling process. Furthermore the presence of the conditioning agent changes the mechanical behavior of the soil that enters in the buck chamber and is extracted through the screw conveyor (Report 1B-98; 1998; pp168; NW.U.of.Sci&Tech) and (Gharahbagh,Rostami & Gilbert; 2010). The study of the effect of soil conditioning on tool wear has been limited to few

applications carried out by Peila et al and Rostami (Peila, Oggeri & Vinai; 2007; pp.1622–1625) and (Peila, Oggeri & Vinai; 2009).

2. TOOL WEAR

Modern researches have established that there are four main types of wear besides a few processes that can be considered (Gharahbagh,Rostami & Palomino; 2011). Adhesive wear occurs when two smooth bodies slide over each other, and fragments are pulled off one surface and adhere to the other. Later these fragments are pulled off one surface and adhere to the other. Later this fragment may come off the surface on which they are formed and be transferred back to the original surface, or else form loose wear particles. Adhesive wear arises from the strong adhesive forced set up whenever atoms come into intimate contact with similar patches on one of the surface, and there is a probability, small but finite, that when this contact is broken the break will occur not at the original interface, but within one of the material. In consequence a transferred fragment will be formed. Abrasive wear occurs when a rough hard surface or a soft surface containing hard particles, slides on a softer surface and plush a series of grooves in it. The material from the grooves is displaced in the form of wear particles, generally loose one. Corrosive wear occurs when sliding take place in a corrosive environment. In the absent of sliding, the corrosion will form a film on the surface. This film tends to slow down or even arrest the corrosion. However the sliding action wears the film away, so the corrosive attack continues. Surface fatigue wear is observed during repeated sliding or rolling over a track the repeated loading and unloading cycles to which the materials are expected may induce the formation of surface or subsurface cracks, which eventually will result in the breakup of the surface as form of where It shown by brittle materials, which break up in the form of large fragments. In both surface fatigue wear and surface fracture where the amount of damage is augmented if the slides of the forward-backward nature.

In addition to these wear mode, erosion should be taken into account in soft ground tunneling that is the special type of abrasive wear. Erosive wear is a process in which a particle carried in a fluid medium hits a solid surface and remove materials from it. Two types of erosion are mainly encountered, low speed and high speed erosion. Among these types of wear, the main phenomenon in soft ground tunneling is abrasion wear. The lubricant and foam of conditioning can play a significant role in wear reduction.

3. SOIL CONDITIONING

In soft ground tunneling, the tool replacement is very expensive. As already discussed the wearing of tools must be considered with great care. Soil abrasiveness is influenced by many characteristic of soil such as soil features (homogeneity, density, porosity), sedimentary features (mineralogical composition and grain shape) and the grains mechanical characteristics (uni-axial compressive strength and abrasiveness) moreover the average life of tools is strictly related with the percentage of hard minerals in the soil. To determine a wear index of a soil, different laboratory tests have been proposed by various researches mainly based on tools rotating inside the soil. A good discussion of the available tests can be found in Gharahabagh et al. (Peila, Oggeri & Vinai; 2007; pp.1622–1625) and Nilsen (Ozdemir & Nilsen; 1999; pp:21-35). It should be highlighted that these researches did not analyze the influence of soil conditioning used in EPB tunneling. On the other hand the correct design of soil conditioning for the management of an EPB machine is of key importance for achieving good result in the tunneling process. Furthermore the presence of the conditioning agents changes the mechanical behavior of the soil that enters in the buck chamber and is extracted though the screw conveyor (Gharahbagh,Rostami & Gilbert; 2010). Soil conditioning is usually obtained by adding foam to the soil to change its properties. The

foam bubbles are inserted between the soil grains thus changing the properties of this new materials . This change has also great influence on the wear and therefore is necessary to study it.

4. WEAR TEST EXPERIMENTAL APPARATUS

The experimental apparatus was designed to examine weight and torque reduction both on natural and conditioned soils with different conditioning sets. The test is conducted by a metal disc which rotates with a constant speed rate around its axis into a tank filled with the soil. During the test the torque applied to the disc by an electric engine is recorded. A rotation rate of 320 rpm was chosen. This value is different from the cutter head or the screw conveyor rotation rate but it is a compromise between the duration of the test (that should be less than 15 min to guarantee that the bubbles are maintained and are “alive” inside the soil) and the time needed for a reasonable wear of the disc. Based on the above, easily wearing material was chosen for the disc. After some tests an aluminum disc was chosen (a tensile strength of the material: 440MPa; elastic modulus: 3.3 GPa). After each test, the weight loss of material can be measured. In figures 1 and 2 the most important geometrical features of the experimental apparatus are reported.

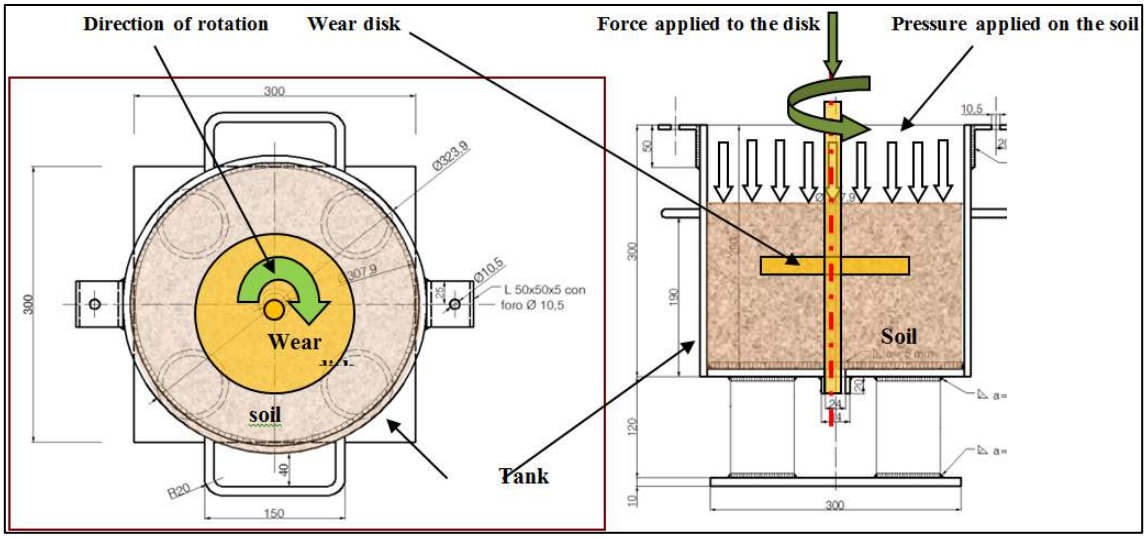

Figure 1. Scheme of the proposed test

Figure 2. Global views of the test device assembled in the laboratory

In order to evaluate weight loss of simple disk, some tests were conducted on different granular soil with different grain size curves represented in figure 3 and with the relevant parameters summarized in Table 1. The soils were conditioned to their optimal level as defined following the procedure presented by Peila et al using the slump test [6]. The conditioning agent is the commercial product Polyfoamer. As a whole 30 test was conducted by three conditions including dry, wet (with different values of water content) and conditioned. Results are summarized in Figure 4 where it is possible to see the great effect of the conditioning agent with significant reduction of wear and torque

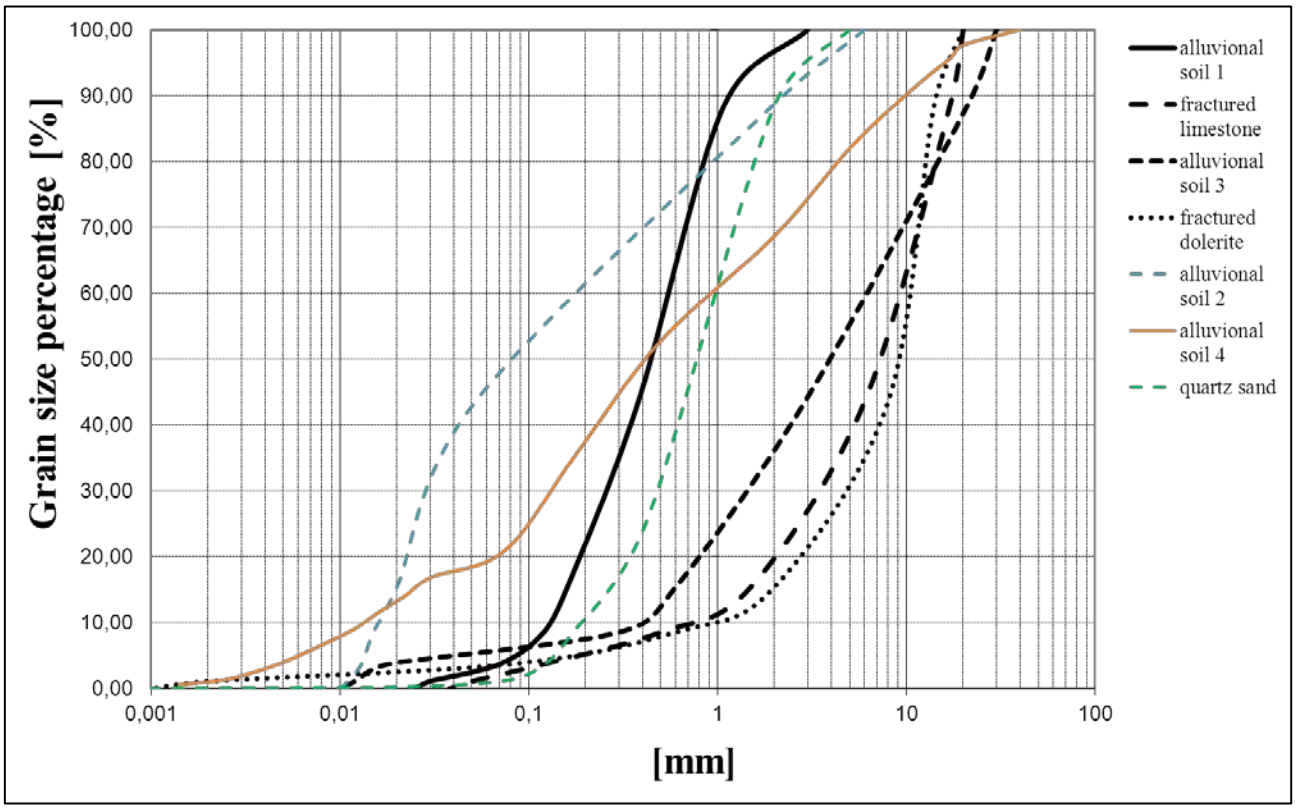

Figure 3. Granumetrical curve of soils

Table 1. Studied soils data

Soils	*D10*	*D60*	*U*	*Notes*	*Test of optimal conditioning*
Fractured limestone	0.70	9.00	12.80	Fractured rock mass, with sharp grains of Limestone.	FIR[%]=50, FER[%]=15 WATER[%]=3
Alluvional soil - 1	0.13	0.55	4.20	Alluvional soil, with rounded grains. Quartz content 20-25%	FIR[%]=80, FER[%]=15 WATER[%]=15
Alluvional soil – 2	0.017	0.18	14.80	Alluvional soil, with rounded grains. Quartz content 50-60%	FIR[%]=40, FER[%]=10 WATER[%]=0
Alluvional soil – 3	0.40	6.00	15.00	Alluvional soil with rounded grains. Quartz content 30-35%	FIR[%]=40, FER[%]=15 WATER[%]=8
Alluvional soil – 4	0.014	0.90	64.30	Alluvional soil with rounded grains. Quartz content 30-35%	FIR[%]=60, FER[%]=12.5 WATER[%]=3
Fractured dolerite	1.00	10.00	10.00	100% of hard minerals	FIR[%]=50, FER[%]=11 WATER[%]=18
Quartz sand	0.20	10.00	50.00	Quartz content of 95-100%	FIR[%]=40, FER[%]=13 WATER[%]=5

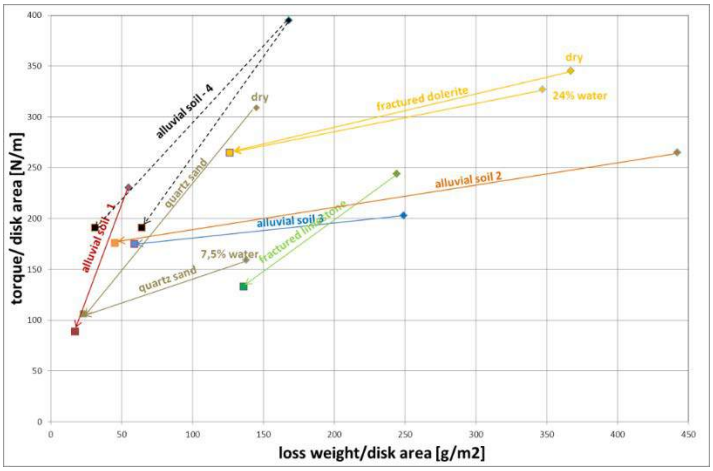

Figure 4. Results achieved with the carried out tests. The obtained results are presented to compare the values obtained with the natural soils and the conditioned ones [6].

In the second step of the research, in order to find the impact of various sets of conditioning on wear and torque four tests was conducted on granular soil with D_{10} = 0.11, D_{60} = 2 and Quarts content in about 50% (characteristics of soil , granumetrical curve and microscopic picture of soils are shown in figure 5 by changing the conditioning set . The four test conditions are listed below:

1. Test (1Gs): Dry granular soil.

2. Test (2Gs): Conditioning agents: Polyfomer(FP), FER = 15, FIR = 30%, w = 5%.

3. Test (3Gs): Conditioning agents: Polyfomer(FP), FER = 15, FIR = 20%, w = 2%.

4. Test (4Gs): Conditioning agents: Polyfomer(FP), FER = 15, FIR = 50%, w = 10%.

Figures 6, 7 and table 2 show the obtained results

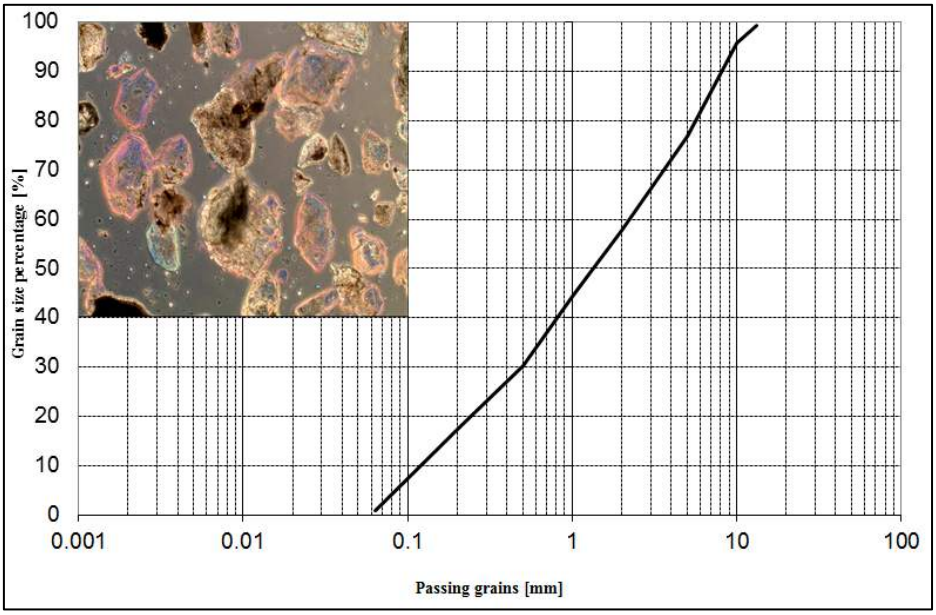

Figure 5. Granumetrical curve of granular soil and Microscopic picture of the soil of the granular soil. The blue color grains are those of quartz.

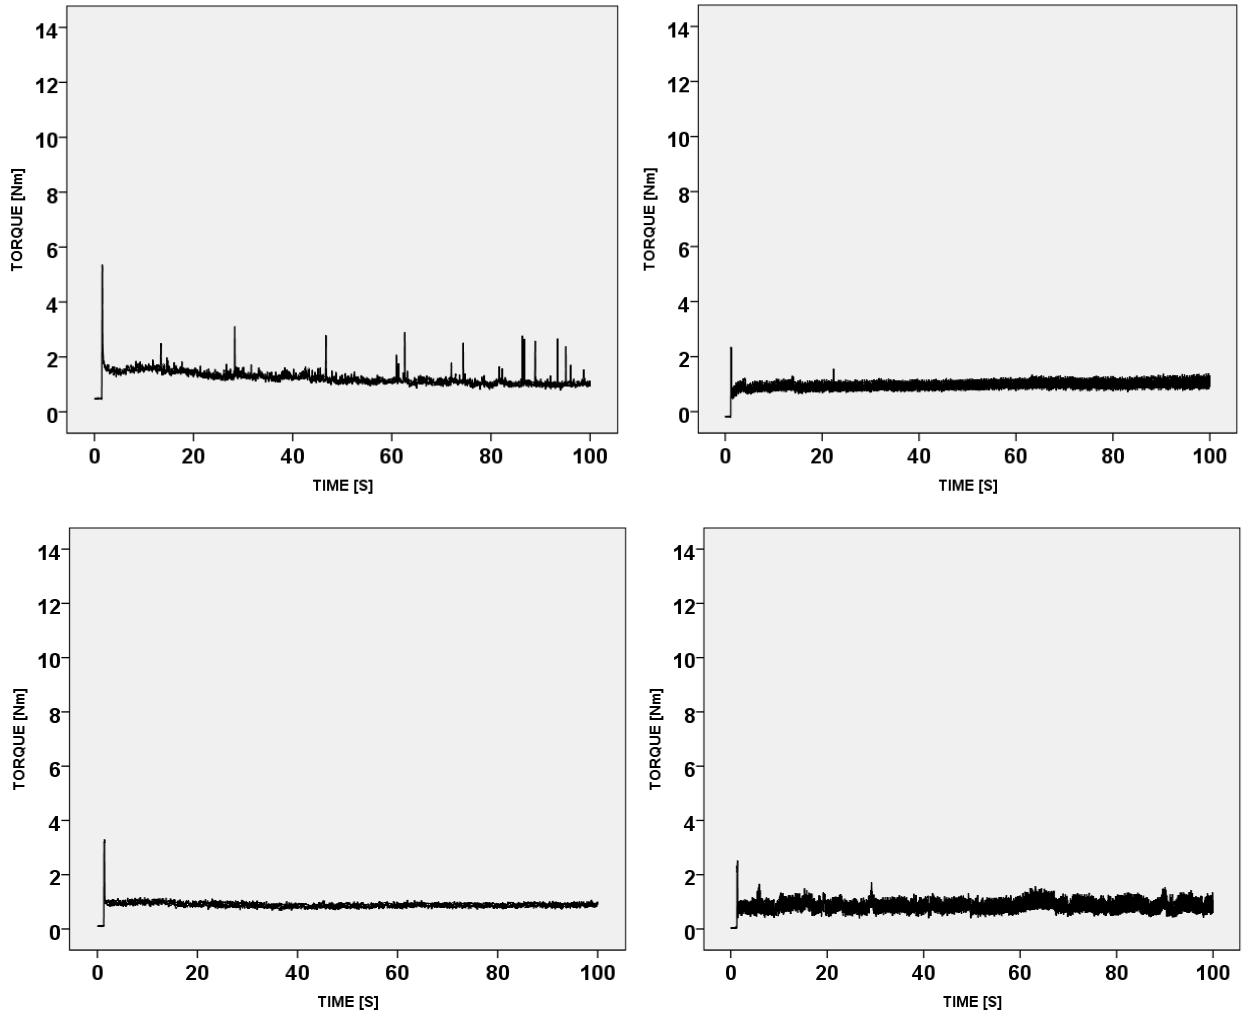

Figure 6. Correlations between torque and time in four condition of granular soil

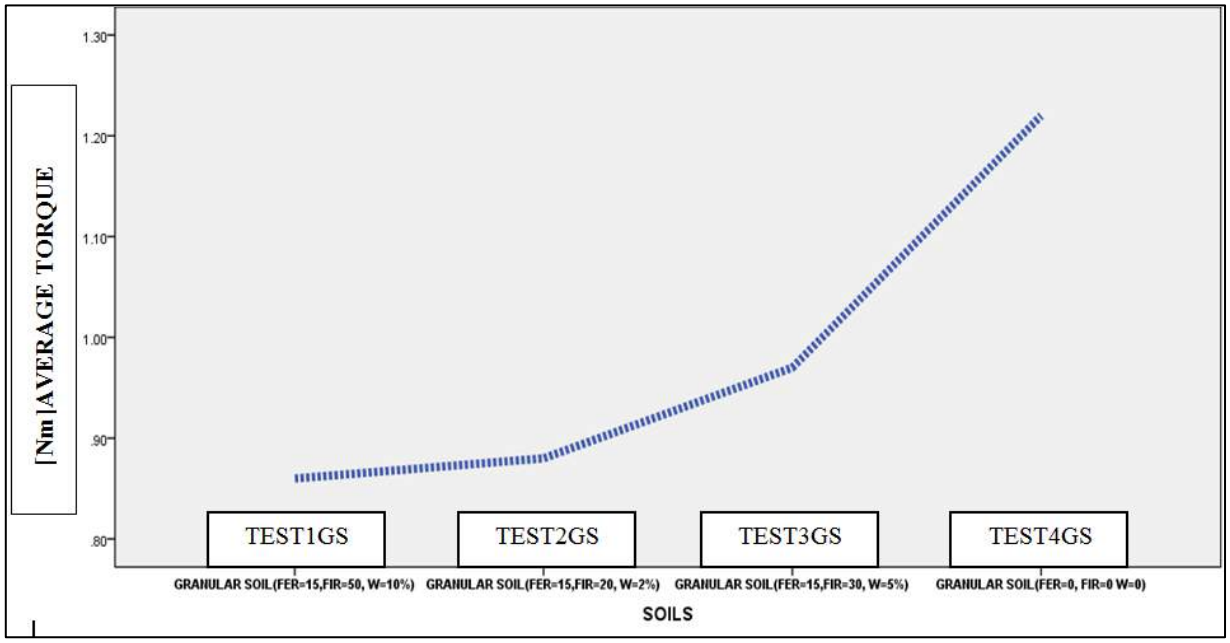

Figure 7. Correlation between torque and all type of soil

As can be seen in the figure 7, the conditioning reduces the torque and wear. This is due to the fact that with conditioning the angle of internal friction deceases. The reason for reduction of the angle of internal friction is due to the presence of bubbles that interact between the grains that facilitate their movements.

Table 2. Results of the carried out tests

Torque	Minimum value of torque [N.m]	Maximum value of torque [N.m]	Average with initial traction of torque [N.m]	Average without initial traction of torque [N.m]	Reduction of weight [g]
Test (1Gs)	0.470	5.34	1.22	1.17	1.01
Test (2Gs)	0.190	2.35	0.97	0.90	0.59
Test (3Gs)	0.097	3.29	0.88	0.78	0.80
Test (4Gs)	0.031	2.51	0.86	0.80	0.001

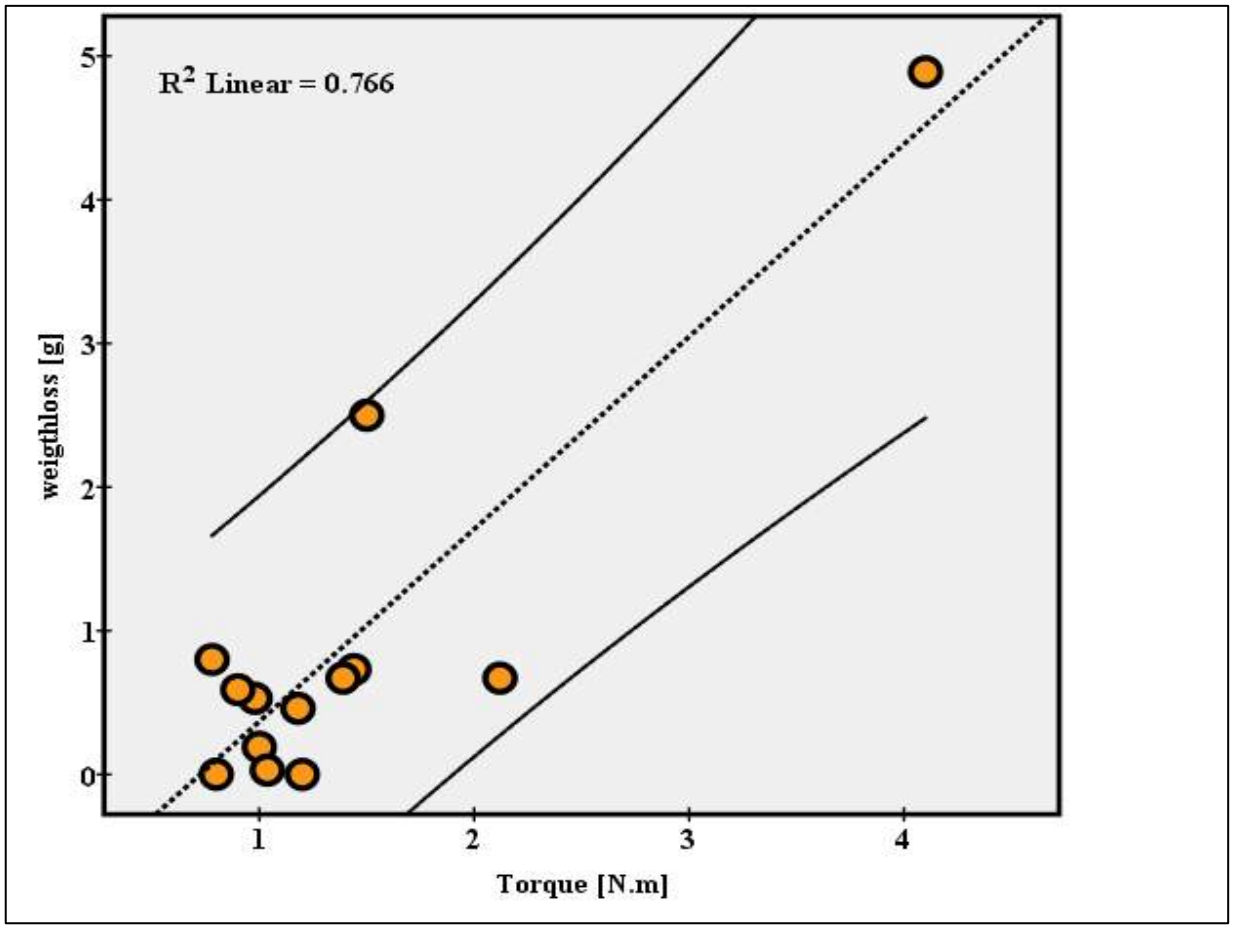

Figure 8. Relationship between torque and weight loss in conditioned soil

As illustrated in figure 8 there is a good relationship between torque and weight loss because increasing in torque means that the internal friction is high so the amount of weight loss will increase.

In order to simulate what exactly is happening for cutter head in EPB tunneling the new propeller was constructed to consider surface and lateral force that can be affected on disk cutter in EPB machines. This new propeller (figure 10) has some advantage in comparison with old one:

1. Changeable blade (flexibility to choose the different type of materials of the blades).
2. Possibility of study on both surface and lateral wear.

With new propeller some tests were conducted on the quartzite sand with D10 = 0.2, D60 = 10 and quartz content of 95-100%. The photo of grains and geometrical curve of studied soil are illustrated in figure 9.

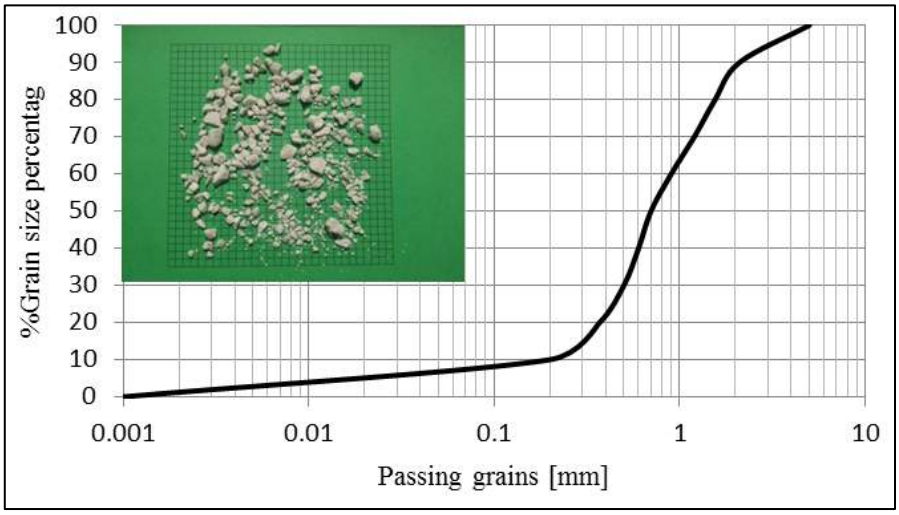

Figure 9. Photo of quartzite grains and its granumetrical curve

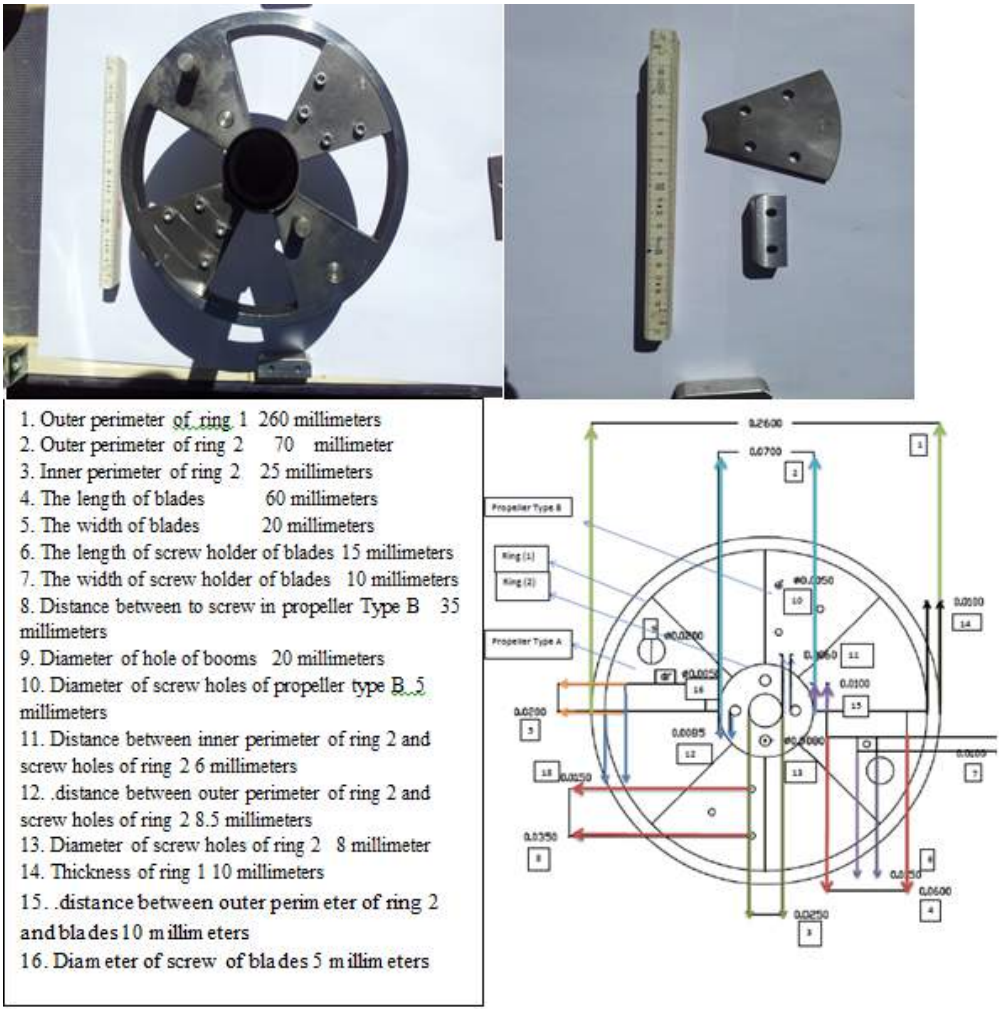

Figure 10. Photographs and drawing of improved propeller

Table 4. Result of three number test with new propeller conducted on quartzite

Number of tests	Weight loss [g]	Test duration [min]	Water[%]	Conditioning
1	0.22	15	0	No
2	0.13	15	5	No
3	0.07	15	5	FIR=30, FER=13%

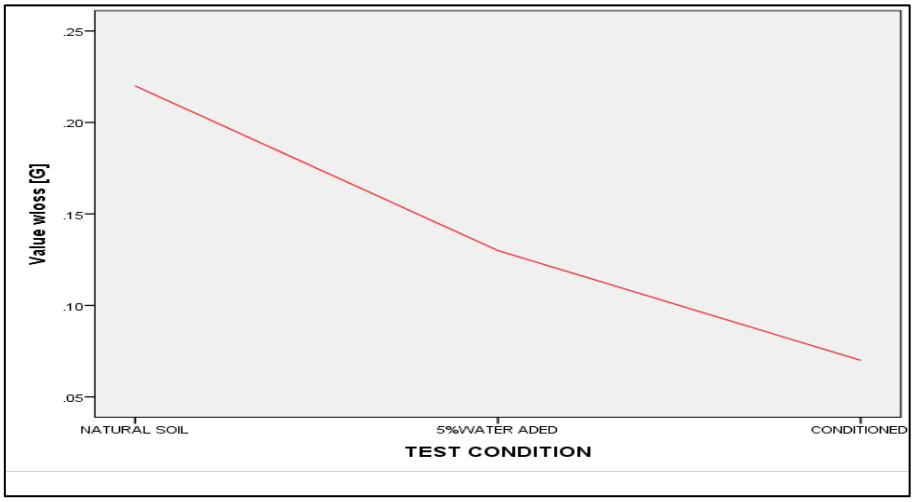

Figure 11. Relationship between weight loss and test condition

As can be extracted from figure 11 there is a reduction in weight loss from dry to conditioned soil. The primary results gained from new propeller shows that the test can be used for further test, hence the more test is under way.

5 CONCLUSION

The proposed wear test device with full disk and the newly improved propeller and test methodology have observed to be a feasible tool to measure the wear reduction that can be achieved by conditioning cohesionless soil for EPB tunneling.

The results obtained are quite consistent with the properties of the soil and the expected results show that the addition of water is generally not enough to reduce the tool wears and the torque. On the other hand when foam is added with the correct conditioning parameters (which are previously found out with slump tests following already established procedures and methodologies), wears and torque are greatly reduced. This effect is positive since facilitates the EPB operations from a technical and economical points of view.

Sensitivity Analysis of the Underground Mining Machines Based on Power Generating System

Yeraltı Maden Makinalarının Güç Üretim Sistemlerine Göre Duyarlılık Analizi

C. Doğruöz

A. Nieto
Penn State University, Mining Engineering Department, USA

R. Schatz, S. Lvov
Penn State University, Electro-Chemistry Department, USA

ABSTRACT There is a variety of equipment used in the mining industry for a long time in underground mines all around the world. Some machines require substantial amounts of power and need direct connections to external generators in underground, while others can be powered via diesel engine. Some of the most significant underground mining equipment was analyzed and sensitivity analysis was figured out in this study to determine whether it is feasible to incorporate current battery technology into these machines. Currently, diesel engines are the standard power source for light duty mining equipment however they are not a perfect solution. They are a source of ignition, noisy, and emit fine particulates as well as carbon dioxide into the mine. For that reason, current battery technology is being explored as a safer alternative in the mining machines. In this study, underground mining methods and tethered electric powered machines were the focus of the investigation and the sensitivity analysis. The most common of these methods, room and pillar and longwall were reviewed and mining vehicles were selected based on their significance in each method. Because of their tasks, dimensions and energy requirements, locomotives and load-haul-dump (LHD) vehicles are the most important equipment as they are used for each of the mining methods. The main objective of this study is to compare battery powered equipment to tethered electric and diesel vehicles in order to assign sensitivity analysis of LHD and locomotives in underground mining.

Keywords: LHD sensitivity analysis, tethered electric powered vehicles, underground mining vehicles

ÖZET Dünya'da maden endüstrisinde birçok yeraltı maden işletmesinde uzun zamandır çeşitli madencilik ekipmanları kullanılmaktadır. Bu anlamda yeraltı madenciliğinde, bazı maden makinaları dizel motorlu güç kaynağı kullanırken diğer maden makinaları ve harici jeneratörler ise önemli derecede güç kaynağına ihtiyaç duymaktadır. Bu çalışmada, yeraltı madenlerinde çok önemli bir yere sahip olan bazı maden makinalarının ekonomik analizleri yapılmış ve günümüzde mevcut batarya teknolojilerinin bu makinalara uygulanabilirliği konusunda duyarlılık analizleri çalışılmıştır. Günümüzde hafif iş makinalarında standart olarak dizel güç kaynaklı motorlar kullanılmaktadır fakat bu ekipmanlar en uygun çözüm olmamaktadır. Aksine bu ekipmanlar gürültülü, ateşli ve karbondioksit emisyonu açısından madenlerde kullanımı sıkıntılı güç kaynaklarıdır. Bu sebeple, mevcut batarya teknolojisinin maden makinalarında kullanımı araştırılmaktadır. Bu çalışmada, yeraltı madencilik yöntemleri

ve kablolu elektrik güç kaynaklı maden iş makinaları araştırmanın ve duyarlılık analizinin odak noktası olmaktadır. En çok kullanılan yeraltı işletme yöntemlerinden oda topuk ve uzun ayak yöntemleri gözden geçirilmiş ve her bir işletme yöntemi için en uygun maden araçları seçilmiştir. Her bir maden yöntemi için yeraltındaki işlevleri, ebatları ve enerji ihtiyaçları göz önüne alındığında, lokomotifler ve LHD maden makinaları en önemli maden ekipmanlarındandır. Bu çalışmanın temel unsuru batarya kaynaklı ekipmanların kablolu elektrik güç kaynaklı ve dizel araçlara kıyasla yeraltında çalışan LHD ve lokomotifler için duyarlılık analizlerinin hesaplanmasıdır.

Anahtar kelimeler: LHD, duyarlılık analizi, batarya kaynaklı elektrikli makinalar, yeraltı maden makinaları

1. INTRODUCTION

Soft rocks usually are part of the sedimentary minerals classification. This is further categorized into three subdivisions; clastic, organic, and chemical. Coal, shales, potash, salt, and trona encompass the majority of soft-rock ores. The most common geographical layout for these ores consists of laterally extensive beds in a nearly horizontal inclination but with, at most, a shallow dip angle (Nieto, 2011). In underground mining, especially for coal mining, mining equipment has a significant role in industry. The best equipment combination should be employed to ensure efficient mining. Furthermore, the more efficient the machines are at extraction, the higher the profit margin will be. Therefore, the ability to use a greater number of battery powered than diesel powered machinery in the same area of the mine is of significant interest.

Current mining methods are so diverse that any ore type can be extracted by adapting existing extraction methods. Underground methods require an extensive evaluation of the geological variables (Hartman, Mutmansky, 2012). Underground mining methods are classified into three groups: unsupported, supported and caving. Unsupported methods include room-and-pillar, stope-and-pillar, shrinkage stoping, sublevel stoping and vertical crater retreat; the supported group includes cut-and-fill and the caving category includes longwall, sublevel caving (Nieto, 2011).

Every mining method has benefits and risks that must be understood when determining the technique to be used for a given set of variables (Hustrulid, 1982). This is especially important when determining duration of mine operation, operating costs and required capital as an uninformed decision can result in significant loss of profit. Room and pillar and longwall are among the most utilized in coal mining and are expanded upon below. Using battery powered mining vehicles in underground soft rock methods can be more economic and is a safer technology for underground mining methods.

The room and pillar mining method is popular for tabular and lenticular deposits and is frequently applied in soft-rock mines. The most important parameters for this method are the position of the ore-body, elevation of the mining horizon, slope of the ore and depth of the deposit. This method is used if there is no need to drill or blast which is usually the case in soft rock mining. Continuous miners are the preferred equipment for this method. This type of autonomous miner uses a large rotating drum to break the material in front of the platform. After that an internal part loads the broken ore onto the onboard conveyor. The material is then sent to a separate haulage system which carries the material to the surface, usually consisting of a shuttle car and locomotive or a belt conveyor (Nieto, 2011). For the room and pillar underground mining method, using the battery powered mining vehicles can be more efficient due to the relatively larger space in the underground rooms. LHDs will have enough space to easily maneuver even with the large battery packs at the rear of the vehicle. High maneuverability allows for greater ease in

charging the vehicles or the maintenance of the equipment.

The longwall mining method is generally combined with the room-and-pillar technique to generate the most efficient and highest-producing underground coal mines. Initially the main entries follow the conventional room and pillar techniques and are created using continuous miners. In this method, a series of panels, branching perpendicular from the main entries, are bounded by a two-to-three entry room-and-pillar border, leaving a huge solid block of coal within it (Buchan, 1998). A longwall shearer, armored face conveyor and shield wall are moved to the end of the panel before longwall mining commences. The shearer moves back and forth across the coal block, excavating only the ore, causing the material to fall onto the conveyor and be transported away to the main belt conveyor system. The shields advance along with the shearer to hold up the roof directly above the equipment. The excavated area behind the shields is allowed to collapse. Mining progresses as continuous miners develop additional longwall panels and the shearers are moved from one to the next throughout the course of the mine life (Nieto,2011). Though longwall equipment requires too much power, LHDs and locomotives are irreplaceable and possess power requirements within the range to be considered for conversion to battery power (Schatz et. al., 2014).

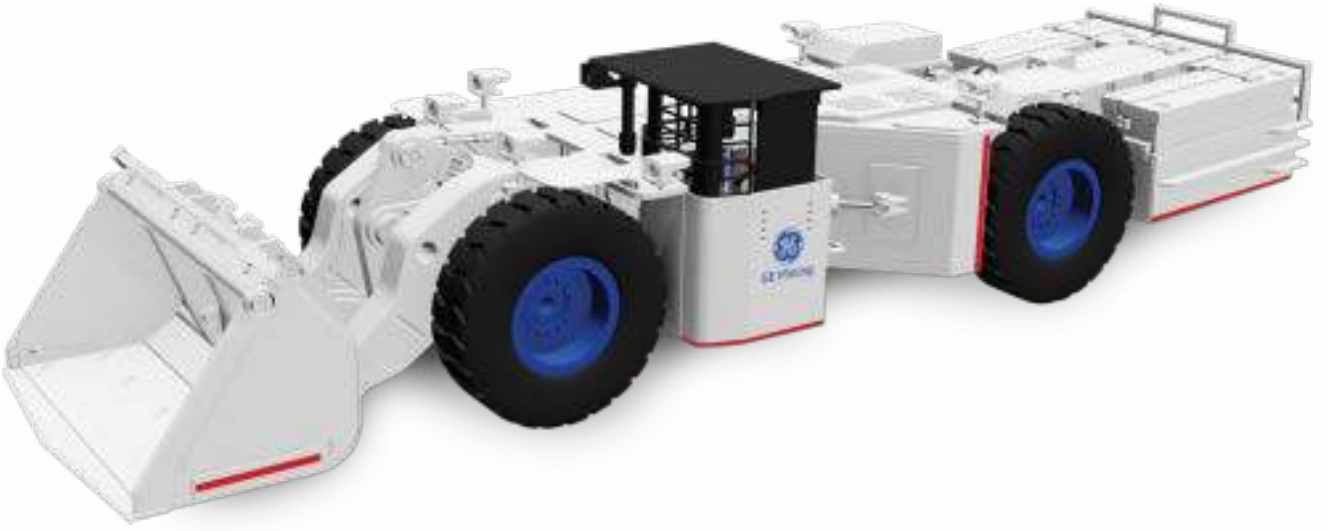

Figure 1. Load-Haul-Dump vehicle © General Electric Co. 2014

2. UNDERGROUND MINING VEHICLES

In underground coal mining, the most common vehicles are locomotives, load-haul-dump vehicles (LHDs), continuous miners, and longwall equipment. As mentioned before, continuous miners, and longwall equipment require too much energy to make battery conversion feasible. The locomotives and LHDs are most commonly powered by diesel engine. Several companies, however, have shown a large interest in powering these vehicles solely from battery power. According to the mining methods and all other parameters such as material strength, ore type, rock mass etc, it is very important to choose the best suited vehicles and power systems.

Transportation of miners and materials underground is one of the most significant operations in the mining sector. For this reason, locomotives are mainly used in underground mines due to their capabilities. There are different types of locomotives such as diesel powered, battery powered and trolley locomotives. Locomotives have been used for many years in underground mining and because of their reliability and are preferred as an easy, economical transportation vehicle (Hartman, 2004, Konietzky, Schlegel, 2007).

Load-haul-dump mining vehicles, Figure 1, are used to haul waste rock and ore from the production face in underground mines to haulage trucks, crushing stations, and ore dumping points (Bhattacherya et. al., 2006).

LHDs are a specialized loading machine manufactured solely for the underground mining industry. They are also known as a scoop tram as they are used to scoop extracted ore, such as coal, with a bucket and load it into the car. The ore is then dumped in the bottom of the mine to undergo primary crushing before being hoisted to the surface out of the mine.

Most LHDs are diesel powered because they require a large amount of energy and move around a lot. If the vehicle were to be powered by an electrical cable, it would pose a constant trip/entanglement hazard. This could be avoided, however, by replacing the diesel engine with a battery pack. Below in Table 1, battery pack specifications for a 112 kW LHD vehicle for the three types of cell chemistries namely lead acid, lithium ion and sodium metal halide are estimated. They are compared on an isometric basis of 5000 L (Table 1).This was approximated by finding the engine compartment volume for a Caterpillar CL115 LHD vehicle, which would be vacant if the diesel engine were to be replaced.

Table 1. Estimated parameters for alternate cell chemistries for 112kW LHD

Parameters	**VRLA**	**NaMx(Na-$NiCl_2$)**	**Li-ion (LFP)**
Run Time (h)	4	8.5	17
Volume (L)	5000	5000	5000
Weight (kg)	14,310	8,200	13,490
Battery Cost (USD)	64,500	274,050	665,000
Capacity (kWh)	430	945	1,900

The NaMx cells would provide enough energy to last one 8-hour shift and would be the lightest of the three packs at just over 8,000 kg. An LFP pack would last more than two shifts but costs 60% more than the NaMx battery pack. Since a VRLA pack would only last 4 hours, requiring the operator to replace the battery during the shift. However, the battery is significantly cheaper than the other two and may make up for the inefficiency of lasting only half a shift.

In underground soft rock mines, mostly coal mines, the mining equipment most commonly used, besides extraction equipment, are haulers, loaders, and locomotives. As mentioned above, these vehicles may also be used in hard rock underground mining operations. In underground hard rock mining other light duty vehicles are used include low profile haulers or load haul dump (LHD), and drilling jumbos. Haulers are mainly used to muck and haul material to dump points over relatively short distances. Drilling jumbos are mainly used in hard rock mining for drilling holes for either installing bolts or blasting. Transportation of miners and materials in underground mining is a key operational task. Locomotives are mainly used in underground mines to accomplish this task. There are different types of locomotives such as diesel powered, battery powered and trolley locomotives. Locomotives have been used for many years in underground mining and because of their reliability they are preferred as a simple and economical solution for material and personnel transportation purposes (Miller, 2002).

Figure 2. Underground mining locomotive adapted to be fuel cell powered (4 ton -7.2 kW).

3. SENSITIVITY ANALYSIS OF MINING VEHICLES

In general, as it is known, sensitivity analysis is used to determine how different values of an independent variable will impact a particular dependent variable under a given set of assumptions. In this study, sensitivity analysis is a process which helps us to understand what will happen to the value of economical analysis in underground mining vehicles if any of our key inputs or assumptions were to change. The main process for conducting a sensitivity analysis includes changing each input variable one at a time, and specifying the effect that has on the total project value. It is usually investigated at the effect on the net present value (NPV), but it could be equally looked at the internal rate of return (IRR) or the payback period as a measure. In sensitivity analysis, the key point is that only one variable is changed at a time in the financial model, leaving all other variables constant. This allows us to see what effect each different assumption would have if it proves to be incorrect. For this method, we usually pick four to six particular values which we will use to do sensitivity cases.

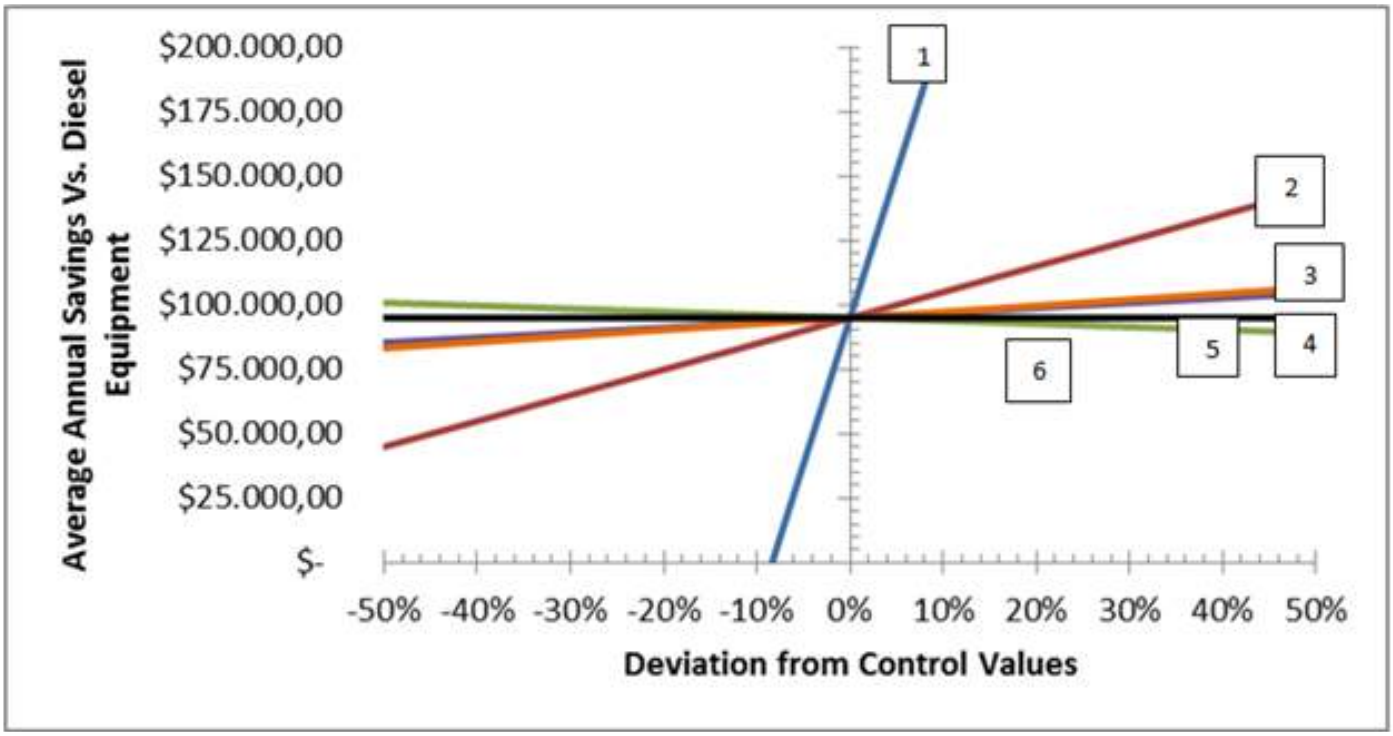

Figure 3. Battery Vs Diesel-Adjustment of tons moved(blue as no.1), ore density(red as no.2), electricity price(green as no.6), battery equipment capital(purple as no.4), and Diesel maintenance cost(Orange as no.3)| reference line (black as no.5)

The sensitivity analysis for costs took many of the parameters that are very volatile during the operation of the mine. These costs include energy prices, both electric and diesel, equipment capital and maintenance costs. It was found that there were several different methods of calculating cost variation. Maintenance costs for example could be calculated as keeping one cost fixed and adjusting the other, adjusting the ratio, seen in Figure 3. It could also be varied by adjusting one cost and keeping the other at a fixed ratio , seen in Figure 3(orange as no.3). It was found that the two methods had significantly different impacts on costs.

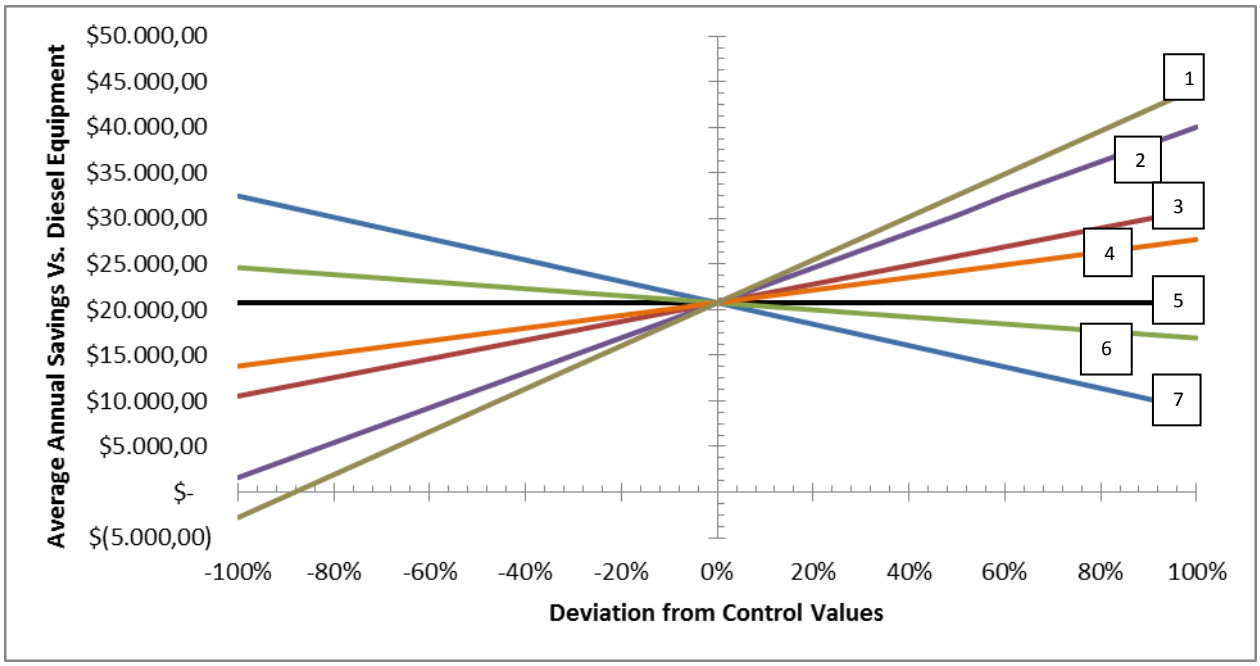

Figure 4. Adjustment of electricity cost(blue as no.7), cost of fuel(red as no.3), cost of battery pack(green as no.6), Equipment capitol (battery equipment costing 5% more than diesel)(purple as no.2), cost of maintenance (ratio of diesel to battery constant)(orange as no.4), and cost of Diesel Maintenance(tan as no.1), reference line (black as no.5)|.

Another, interesting comparison was the energy costs with respect to electricity price(blue as no.7) and diesel price(red as no.3) in figure 4. Figure 4 also shows that cost difference is more sensitive to electricity prices than to diesel fuel fluctuations. The cost differentiation for adjusting capital cost was used fixing the cost of battery equipment to 5% higher than diesel costs, however, this ratio is not a guarantee.

4.CONCLUSION

The energy costs with respect to electricity price and diesel price show that the cost difference is more sensitive to electricity prices than to diesel fuel fluctuations. It should be noted that in the future the price of diesel is expected to rise significantly while increases in electrical costs may be mitigated by alternative forms of generation such as advances in solar or wind energy technology. Comparing the effect of capital cost on cost savings, varying the price increase from 5% to 25%, showed significant impact on the average annual cost savings. It was also found that in order for battery equipment to remain less costly, they must provide at least extra one year of service than diesel equipment.

Taking revenue into account only improved the value of battery equipment due to increased uptime and productivity. The revenue was found to be especially sensitive to the amount of tons each vehicle hauls. Decreasing the amount of battery haulage by 5% or 0.2 tons per hour amounts to a $40k loss of profit per year.

CSIR-Central Institute of Mining and Fuel Research, Dhanbad 826015, Jharkhand, India

ABSTRACT Production from underground coal mining in India has been decreasing since last two decades. Presently, greater emphases are given on opencast mining to meet the energy demand of the country but the future requirement of coal would be met by underground mining as the coal will be available at greater depth which will not be economically viable to exploit by open-pit mining methods. Blasting-off-the-solid (BOS), in Indian underground mines, has been a widely practised method for winning coal while developing mine galleries in Bord & Pillar system. The blast holes are drilled in solid coal without free face in BOS method of mining and are blasted with permitted type of explosives and delay detonators. The coal reserves are being exploited very fast and mine owner cannot ignore to take the coal beneath the structures/houses. Although, the use of explosives in underground mines are not too much, but it causes annoyance to the inhabitants residing over the underground mines. Ground vibrations from blasting have been a continual problem for the mining and construction industries, the public living near the mining activities and the regulatory agencies responsible for setting safety and environmental standards. Questions frequently arise about blast vibration effects and specifically about whether vibrations can or could have caused cracking and other damages in homes and other structures. The general growth of mining activities in India, the presence of underground mines beneath the populated areas and the greater awareness have all necessitated an in-depth study for investigation into the causes of alleged damages to the houses. In this paper, Geophysical Resistivity Imaging technique has been used to document the change of subsurface structures/features between the surface and underground face, where blasting is carried out to extract the coal in underground coalmines. Resistivity Imaging survey conducted at three mining sites revealed that there was no significant change in sub-surface strata conducted during pre and post blasting conditions. The slight change in resistivity values up to 35 ohm.m up to a few meters peripheral area of the blasting face in the mine may be either due to the effect of blast vibration and/or same void created by blasting or increase in porosity of overlying sub-surface strata.

Keywords: BOS; Bord & Pillar; Resistivity Imaging; underground mines; Blast vibration

1 INTRODUCTION

Production from underground coal mining in India has been decreasing since last three decades. Presently, around 91% of the coal production comes from opencast mining and only 9% of coal production is from underground mines. It is reported that opencast production will reach to its maximum level within next 15-20 years and there will be no option except to go for underground mining with mass production technology to sustain production and productivity level for coping up with the energy demand of the country. To meet the enhanced requirement of coal in future at greater depths, the Indian mining industry has to adopt in a big way the mechanised underground mining methods.

Blasting-off-the-solid (BOS), in Indian underground mines, has been a widely practised method for winning coal while developing mine galleries in Bord & Pillar system (Room & Pillar system). The blast holes are drilled in solid coal without free face in BOS method of mining and are blasted with permitted type of explosives and delay detonators. The permitted explosives are classified based on the classification of

gassiness of the underground mine. Keeping in view the dangers associated in such blasting operations, the mine regulatory agency has also restricted the explosive weight in a shot hole in accordance with the degree of gassiness of the mine.

In future, also, blasting-off-solid will play an important role in underground coal production. The mines which were planned earlier to be away from residential areas are now approaching to those areas. The coal reserves are being exploited very fast and mine owner cannot ignore to take the coal beneath the structures/houses. Although, the consumption of explosives in underground mines are not much, but it causes annoyance to the inhabitants residing over the underground mines. A few court cases have been lodged in the recent past by the villagers for compensation of the alleged damages to their houses due to underground mining.

Ground vibrations from blasting have been a continual problem for the mining and construction industries, the public living near the mining activities and the regulatory agencies responsible for setting safety and environmental standards. Questions frequently arise about blast vibration effects and specifically about whether vibrations can or could have caused cracking and other damages in homes and other structures. The answer depends primarily on vibration levels and frequencies and to a lesser degree on site and structure specific factors.

The residents may feel blast vibrations produced by the underground blasting beneath the residential or industrial structures and there may be apprehensions of likely damages to their houses/structures. The residents of the villages residing over the underground mines may ask the mine owners to stop the mining operations beneath their houses because, in every population, there are always some persons who will react no matter how low the vibration is. But the sheer apprehensions of damages should not stop the mining of the precious mineral.

The general growth of mining activities in India, the presence of underground mines beneath the populated areas and the greater awareness have all necessitated an in-depth study for investigation into the causes of alleged damages to the houses. In this paper, Geophysical Resistivity Imaging technique has been used to know the change of subsurface structures/features between the surface and underground face, where blasting is being carried out to extract the coal in underground coalmines.

2 STUDY SITES

Under this programme of study, three underground mines were selected as experimental sites. The selected mines were Kalidaspur and Narsmunda mines of Eastern Coalfields Limited (ECL) and Orient Mine no.3 of Mahanadi Coalfields Limited (MCL). The impacts of 129 blasts conducted at the aforesaid mines were monitored at the structures and 391 blast vibrations data were recorded on or near the structures. Resistivity multi-electrode (Electrical imaging) system (an advanced version of DC resistivity four electrodes) was used to know the change of subsurface inhomogeneities like solid strata, cavities, fractures, caves etc due to underground blasting in proposed three coalmines of different regions of India.

3 METHODOLOGY

The Resistivity Imaging (RI) is a geophysical method that measures subsurface resistivity distribution from the ground surface. These measurements are normally made by passing electric current into the ground through two metallic electrodes and measuring the resulting voltage difference at two potential electrodes. From these measurements, the true resistivity of the subsurface can be estimated. The ground resistivity is related to various geologic parameters such as the mineral and fluid content, porosity, degree of fracturing, the percentage of the fractures filled with groundwater, and the degree of water saturation in the rock. Surveys using multi-electrode arrays are usually carried out using 48 or more electrodes in a series connected to a multi-core cable. A program on a laptop computer and an electrode-

switching unit automatically select the relevant four electrodes for each measurement. Apparent resistivity measurements are recorded sequentially. High definition pseudo-sections with dense sampling of apparent resistivity variations at shallow depths (10–150 m) are obtained in a short time which allows detailed interpretation of the 2D resistivity distribution in the ground. This survey used a resistivity meter (SYSCAL Junior Switch) with 48 electrodes deployed in three different arrays like Pole-Pole (PP), Wenner-Schlumberger (WS) and Wenner (W) in this proposed study.

Despite some limitations, this technique is very useful in delineating subsurface geology. The use of 2D and 3D electrical surveys are now practical commercial techniques with the relatively recent development of multi-electrode resistivity surveying instruments (Griffiths et al., 1990) and fast computer inversion software (Loke, 1994). The resistivity measurements are normally made by injecting current into the ground through two current electrodes and measuring the resulting voltage difference at two potential electrodes. From the current (*I*) and voltage (*V*) values, an apparent resistivity value is calculated (shown in Fig.1). The calculated resistivity value is not the true resistivity of the subsurface

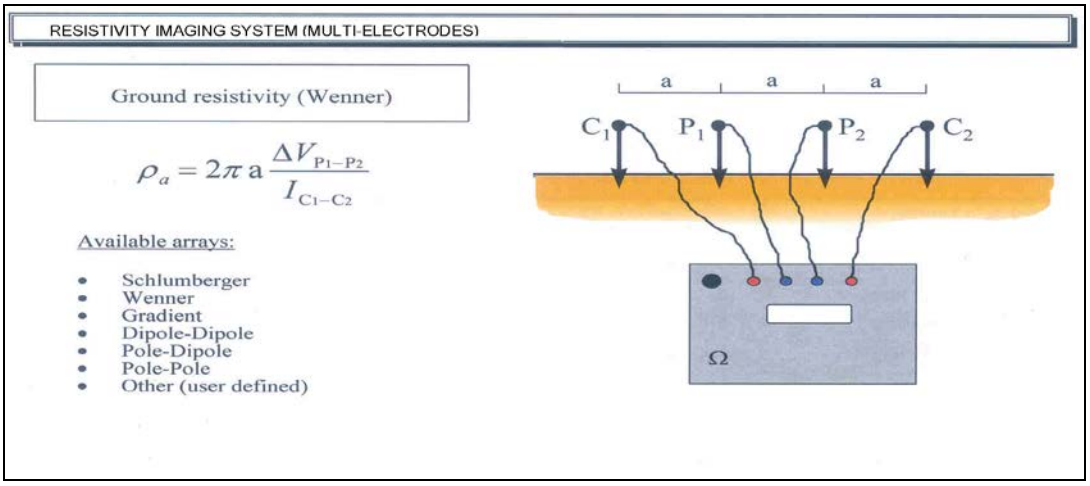

Figure 1: Principle of Resistivity Imaging Survey

To determine the true subsurface resistivity, an inversion of the measured apparent resistivity values using a computer program must be carried out (Loke, 1999). To interpret the data from a 2D imaging survey, a 2D model for the subsurface, which consists of a large number of rectangular blocks, is used. A computer program is then used to determine the resistivity of the individual blocks so that the calculated apparent resistivity values agree with the measured values from the survey.

The computer program RES2DINV.EXE (Loke, 2000) was used in this survey to determine the appropriate resistivity values. The Syscal Junior made by IRIS Instruments was used for the present study. It is a high-powered, fully automatic resistivity meter for DC electrical surveys applied to groundwater exploration, environmental studies, civil engineering, and structural geology investigations. A newly developed hybrid array utilizing Wenner & Schlumberger arrays (Pazdirec and Blaha, 1996) has been used for surveying.

The purpose of selecting multiple layers was to distinguish the different lithological units and to convert the resistivity values into a geologically reasonable picture. Table 1 gives the resistivity values of common rocks (Keller and Frischknecht, 1966; Daniels and Alberty, 1966), which are typically encountered at the sounding sites.

Table 1 - Resistivities of some common rocks

Rock type	Resistivity in Ω-m
Granite	$5 \times 10^3 – 10^6$
Basalt	$10^3 – 10^6$
Slate	$600 – 4 \times 10^7$
Quartzite	$100 – 2 \times 10^8$
Sandstone	$8 – 4 \times 10^3$
Shale	$20 - 2 \times 10^3$
Clay	1 – 100
Alluvium	10 – 800
Groundwater (fresh)	10 – 100

4 RESULTS AND DISCUSSION

4.1 Kalidaspur Project

Six experimental blasts were conducted at below ground working of Kalidaspur project. The maximum vibration recorded was 5.73 mm/s with dominant peak frequency of 61 Hz at the vertically above point of the blasting face (36EL/12R face). The total explosive weight used and explosive weight per delay was 4.995 kg.

Wenner-Schlumberger (WS) resistivity imaging surveys were also carried out the same day at same location. The study of Inverse Model Resistivity Section shows that resistivity values in pre-blasting condition ranges from 2.94 ohm.m (minimum) to 101 ohm.m (maximum), while it ranges from 2.93 ohm.m (minimum) to 101 ohm.m (maximum) in post blasting condition. The underground depth coverage by WS arrays at the site was 45.6 m, while the actual depth of working face (developed) was approximately at 77.40 m just vertically below the central point of the resistivity section. The observed apparent resistivity sections along with an inversion model are presented in Figure 2. The recorded images of resistivity survey indicate that there is no apparent change in the resistivity values after blasting from those of before blasting. The interpretation of layered wise resistivity values of different underground strata at surface position of 120 m deciphered that there was no recognisable change in overlying strata condition.

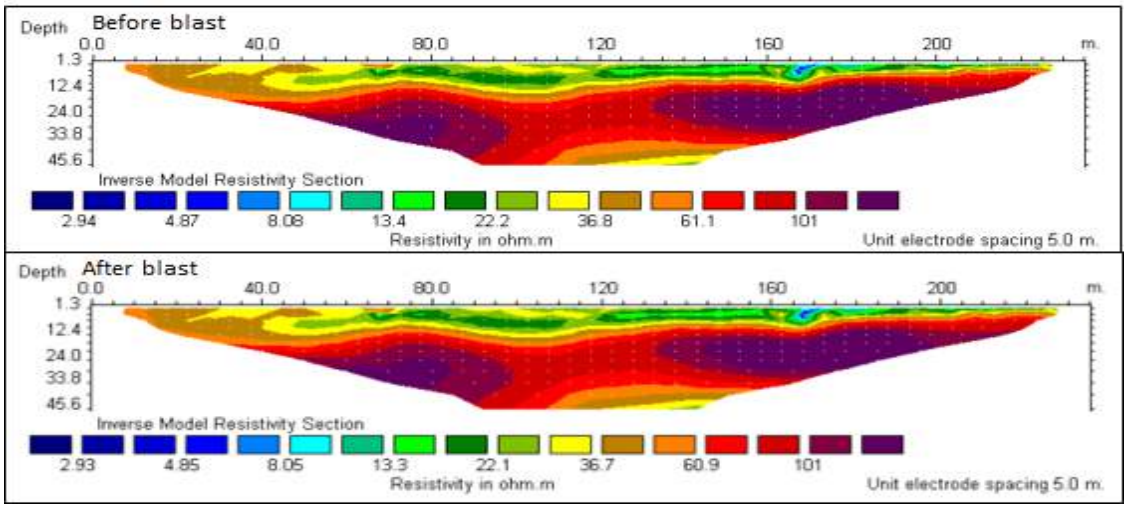

Figure 2: Resistivity image section recorded before and after blasting at Kalidaspur project on 12.04.2005.

Five experimental blasts were conducted at below ground working of Kalidaspur project. The maximum vibration recorded was 10 mm/s with dominant peak frequency of 3.5 Hz at the vertically above point of the blasting face (19L/12-13D-Roof). The

interpretation of the Wenner-Schlumberger (WS) resistivity imaging surveys conducted on the same day shows that the underground depth coverage of WS arrays at the site is 45.6 m, while the actual depth of working face (depillared from the mine plan) was approximately 72.90 m just vertically below the central point of the resistivity section. Figure 3 shows that resistivity values in pre-blasting condition ranges from 15.70 ohm.m (minimum) to 79.5 ohm.m (maximum), while it ranges from 15.8 ohm.m (minimum) to 78.9 ohm.m (maximum) in post blasting condition. Recorded resistivity images show the negligible changes in the resistivity values after blasting. The interpretation of layered wise resistivity values of different underground strata at surface position of 120 m deciphered that there was no recognizable change in overlying strata condition.

Two experimental blasts were conducted at below ground working of Kalidaspur project. The maximum vibration recorded was 1.22 mm/s with associated dominant peak frequency of 20.9 Hz at 25 m horizontally away from the vertically above point of the blasting face ($7^1/_2$LS/9R). The total explosive weight and explosive weight per delay was 4.625 kg. The depth of cover in this blast was 70 m.

Wenner-Schlumberger (WS) resistivity imaging surveys was conducted for shallow depth cover (up to 50 m). As the depth of cover in this blast was 70 m, therefore the Pole-Pole (PP) resistivity imaging survey was conducted on the same day. The underground depth coverage of PP arrays at this location was 66.20 m. Interpretations of results obtained from resistivity imaging survey indicates change in resistivity values after blasting as compared to before blasting. The study of Inverse Model Resistivity Section shows that resistivity values in pre-blasting condition ranges from 4.39 ohm.m (minimum) to 57.90 ohm.m (maximum) to 2.82 ohm.m (minimum) to 55.40 ohm.m (maximum) in post blasting, which is presented in Figure 4.

It is observed that the resistivity values were slightly of lower range after blasting indicating some minor change in compactness of the rock formation. The interpretation of layered wise resistivity values of different underground strata at surface position of 120 m deciphered that there was no recognizable change in overlying strata condition, except slight change in resistivity values. Changes were observed only up to a few meters peripheral area of the blasting face in underground mine. It is either due to effect of blast vibration or due to increase of porosity in overlying sub-surface strata.

.

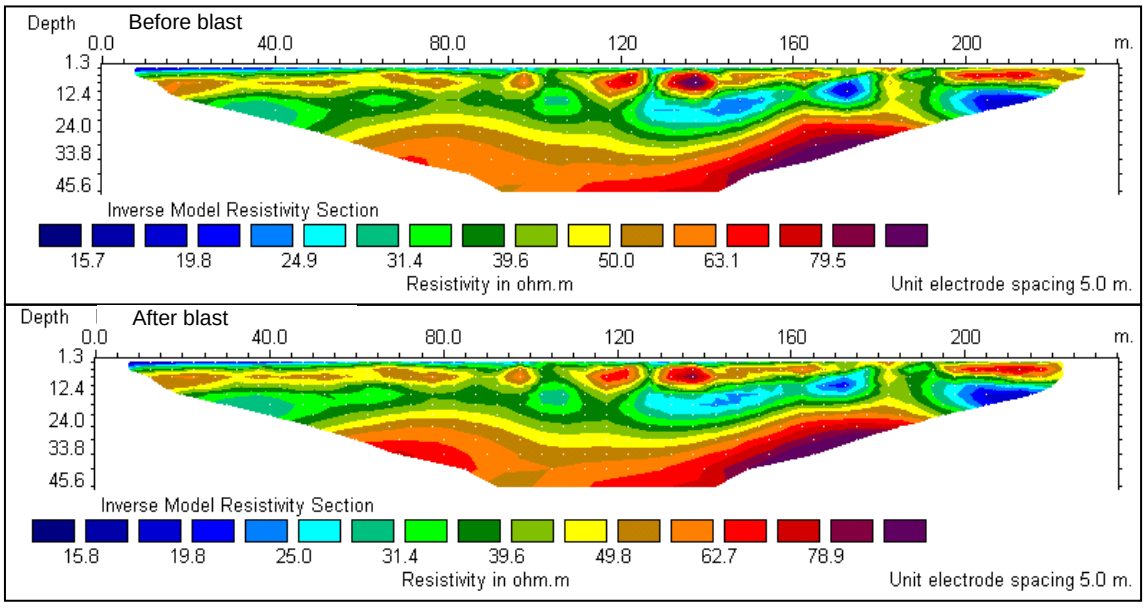

Figure 3: Resistivity image section recorded before and after blasting at Kalidaspur project on 14.04.2005

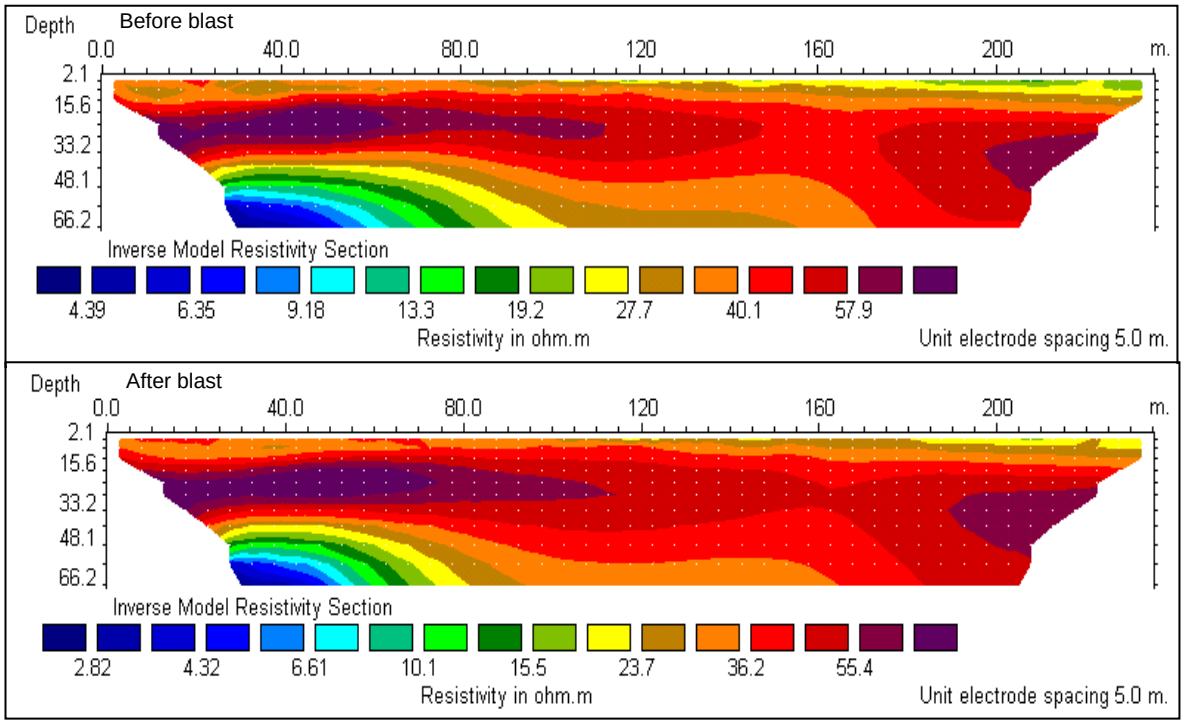

Figure 4: Resistivity image section recorded before and after blasting at Kalidaspur project on 28.03.2006

Two experimental blasts were conducted at below ground working of Kalidaspur project. The maximum vibration recorded was 3.21 mm/s with dominant peak frequency of 41.3 Hz at vertically above point of the blasting face ($20^{1}/_{2}$E/8R). The total explosive weight and explosive weight per delay was 6.29 kg. The depth of cover in this blast was 71.5 m.

Pole-Pole (PP) configuration inverted resistivity survey was conducted for deeper depth of cover (more than 50 m). The underground depth coverage of PP arrays at this site was 72.7 m and depth of working face (depillared) was approximately 71.50 m just vertically below the central point of the resistivity section. Interpretations of results obtained from resistivity imaging survey indicates change in resistivity values after blasting as compared to those of before blasting. The study of Inverse Model Resistivity Section of Kalidaspur project shows that resistivity values in pre-blasting condition ranges from 2.50 ohm.m (minimum) to 178 ohm.m (maximum), while it ranges from 2.37 ohm.m (minimum) to 174 ohm.m (maximum) in post blasting condition, which is presented in Figure 5.

It is observed that the resistivity values were slightly lower range after blasting. The interpretation of layered wise resistivity values of different underground strata at surface position of 120 m deciphered that there was no recognisable change in overlying strata condition, except slight change in resistivity values. Changes observed were only up to a few meters peripheral area of the blasting face in underground mine. It is either due to effect of blast vibration or due to increase of porosity in overlying sub-surface strata. The change of resistivity value for all the experiments conducted at Kalidaspur Project is presented in Figure 6.

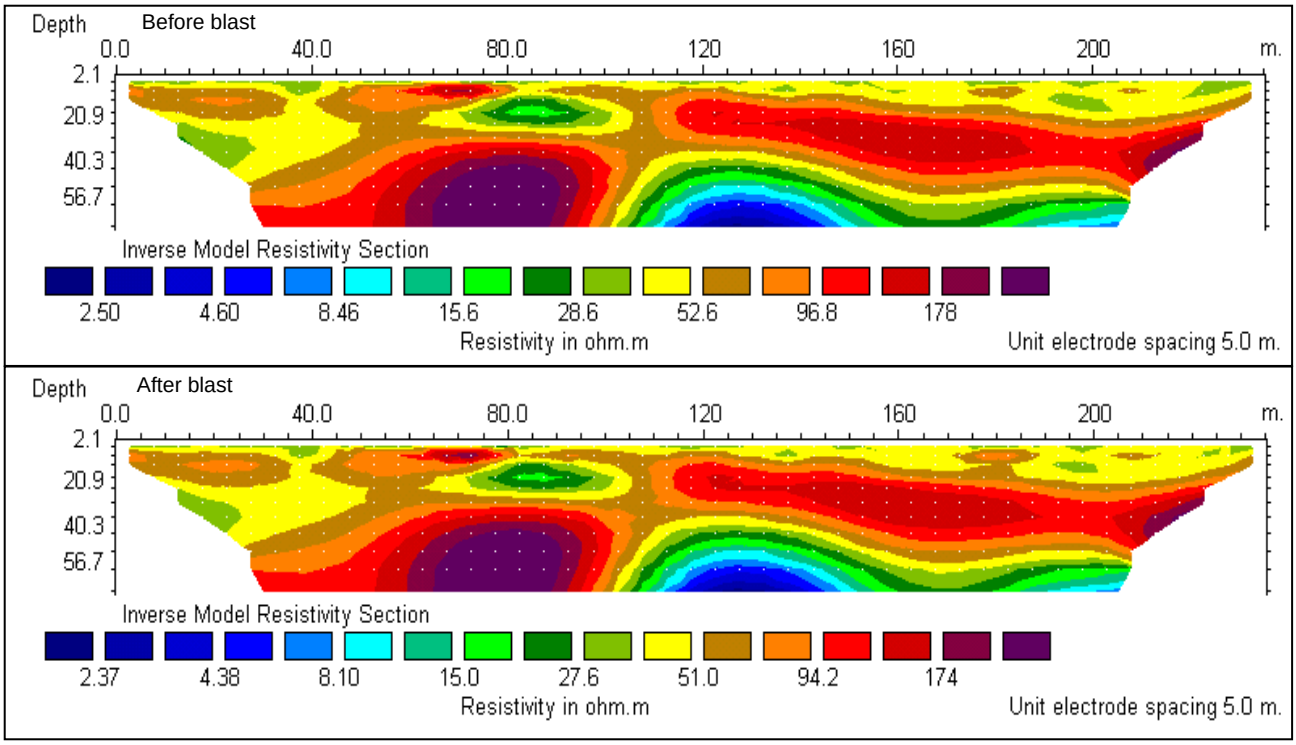

Figure 5: Resistivity image section recorded before and after blasting at Kalidaspur project 19.05.2006

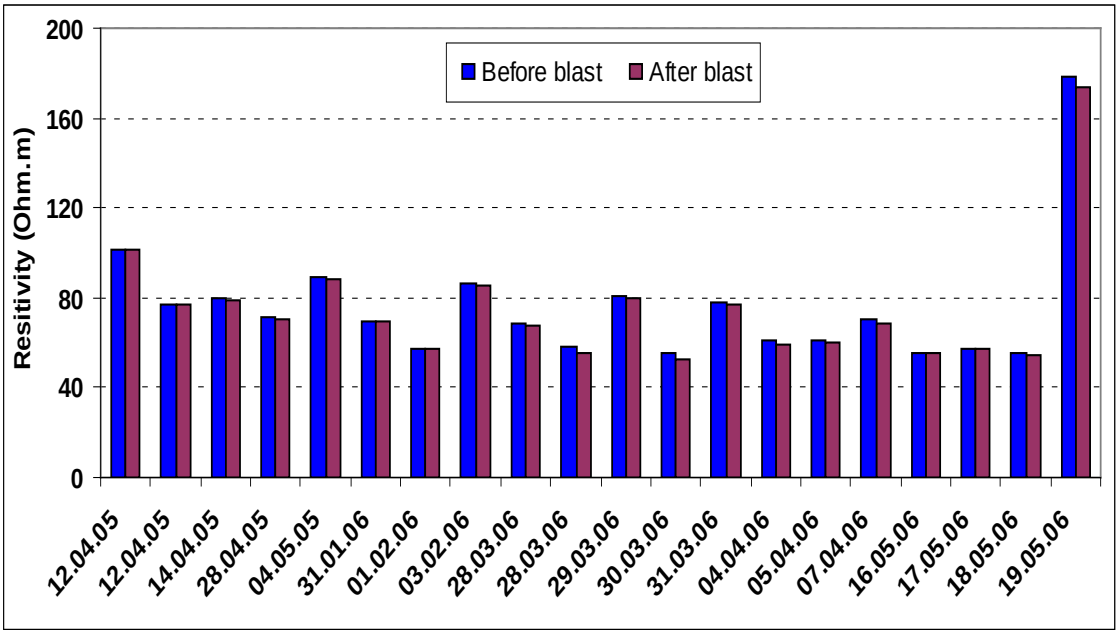

Figure 6: Change in resistivity recorded before and after blasting for all the experiments conducted at Kalidaspur project

4.2 Narsamuda colliery

Three experimental blasts were conducted at below ground working of Narsamunda colliery. The maximum level of vibration recorded was 4.06 mm/s with dominant peak frequency of 53 Hz at the vertically above point of the blasting face. The total explosive weight and explosive weight per delay were 5.55 kg and 1.85 kg respectively in this blast. The depth of cover was 50 m.

Wenner-Schlumberger (WS) resistivity imaging surveys were carried out on the same day of experimental blast for shallow depth (less than 50 m). The underground depth coverage of WS arrays at this site was 39.4 m and depth of working face (developed) was approximately 50 m just

vertically below the central point of the resistivity section. The study of Inverse Model Resistivity Section of Narsamuda colliery shows that resistivity values in pre-blasting condition ranges from 15.7 ohm.m (minimum) to 114 ohm.m (maximum) (Figure 7), while it ranges from 16.7 ohm.m (minimum) to 96.8 ohm.m (maximum) in post blasting condition (Figure 7). It was observed that the resistivity values were slightly of lower range after blasting. The interpretation of layered wise resistivity values of different underground strata at surface position of 120 m deciphered that there was change of maximum 17.2 ohm.m. Changes observed were only up to a few meters peripheral area of the blasting face in the mine. It is either due to effect of blast vibration or some void created by blasting.

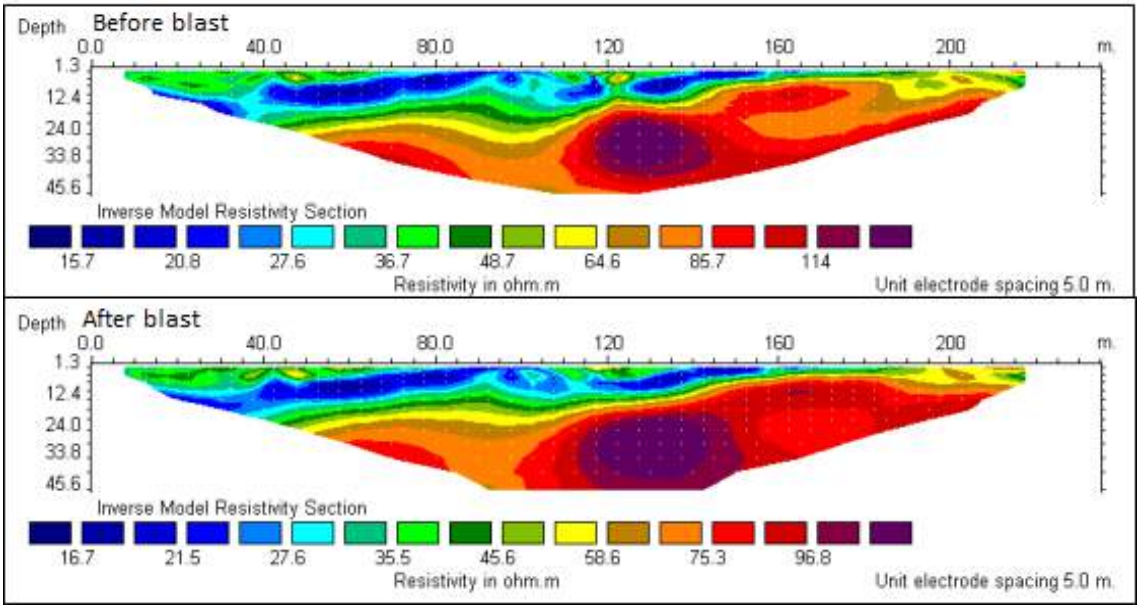

Figure 7: Resistivity image section recorded before and after blasting at Narsamunda colliery 02.03.2005

Further, two more experimental blasts were conducted and the maximum level of vibration recorded was 5.23 mm/s with dominant peak frequency of 47 Hz at the vertically above point of the blasting face (3-cross cut deep of 11 level). The total explosive weight and explosive weight per delay were 5.55 kg and 1.85 kg respectively.

Wenner-Schlumberger (WS) resistivity imaging surveys were also carried out on same day at same location. The study of Inverse Model Resistivity Section shows that resistivity values in pre-blasting condition ranges from 12.1 ohm.m (minimum) to 160 ohm.m (maximum), while it ranges from 13.4 ohm.m (minimum) to 125 ohm.m (maximum) in post blasting condition (Figure 8). The underground depth coverage of WS arrays at the site is 45.6 m, while the actual depth of working face (developed) was approximately 41 m just vertically below the central point of the resistivity section. The change in resistivity values was recorded up to 35 ohm.m. Changes observed were only up to a few meters peripheral area of the blasting face in the mine. It is either due to effect of blast vibration or some void created by blasting. The change in resistivity value (before and after blasting) for all the experiments conducted at Narsamunda colliery is presented in Figure 9.

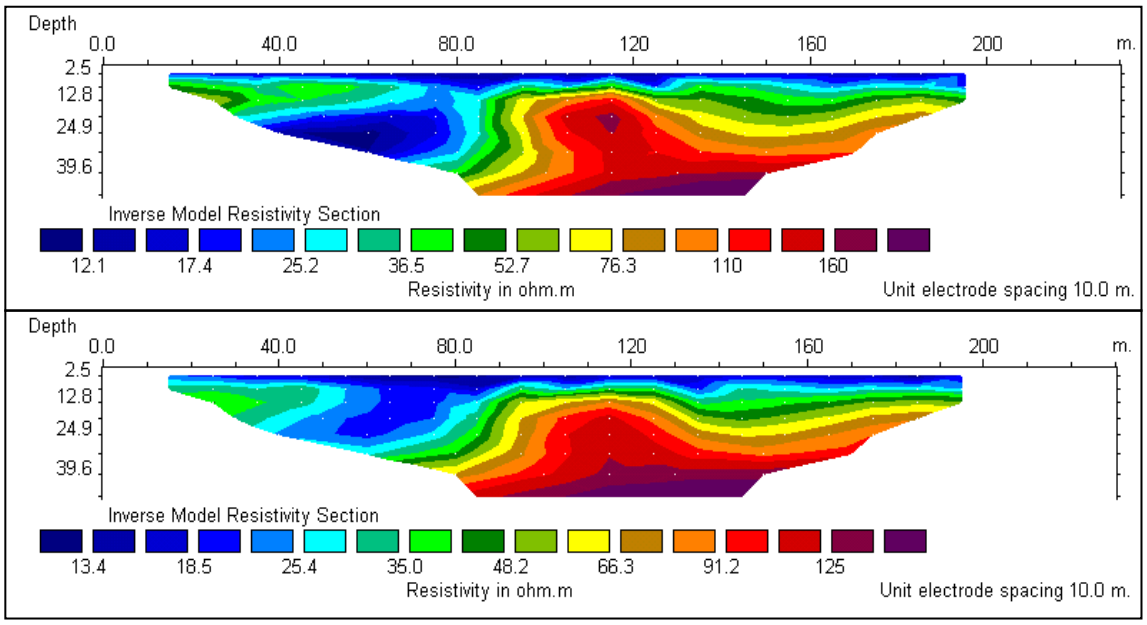

Figure 8: Resistivity image section recorded before and after blasting at Narsamunda colliery 14.02.2006

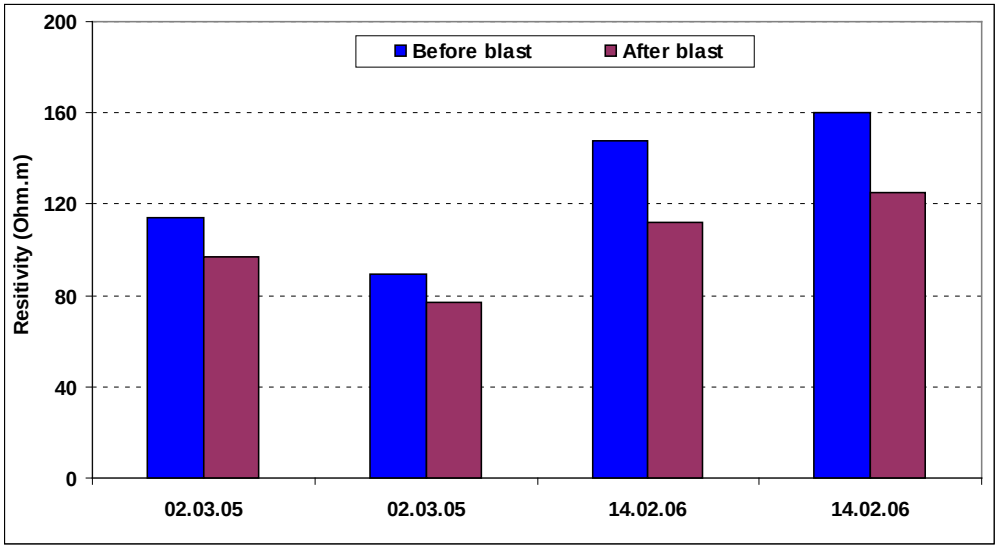

Figure 9: Change in resistivity value recorded before and after blasting at Narsamunda colliery.

4.3 Orient Mine No. 3

An experimental blast was conducted at below ground working of Orient Mine No. 3. The maximum level of vibration recorded was 0.716 mm/s with dominant peak frequency of 145 Hz at the vertically above point of the blasting face (10R/30LN). The total explosive weight and explosive weight per delay were 5.55 kg and 2.22 kg respectively. The depth of cover was 146 m.

Pole-Pole (PP) configuration inverted resistivity survey was conducted for deeper depth of cover (more than 50 m). The underground depth coverage of PP arrays at this site was 146 m and depth of working face (depillared) was approximately 150 m just vertically below the central point of the resistivity section. Interpretations of results obtained from resistivity imaging survey indicates changed in resistivity values of post blasting as compared to those of pre-blasting.

The study of Inverse Model Resistivity Section of Orient mine no. 3 shows that resistivity values in pre-blasting condition ranges from 0.598 ohm.m (minimum) to 1734 ohm.m (maximum), while it ranges

from 0.598 ohm.m (minimum) to 1708 ohm.m (maximum) in post-blasting condition (Figure 10). It is observed that the resistivity values were slightly of lower range after blasting. The interpretation of layered wise resistivity values of different underground strata at surface position 120 m deciphered that there was no recognizable change in overlying strata condition, except slight change in resistivity values. Changes observed were only up to a few meters peripheral area of the blasting face in the mine. It is either due to effect of blast vibration or due to increase of porosity in overlying sub-surface strata. The change in resistivity value (pre and post blasting) at Orient mine no. 3 is presented in Figure 11

.

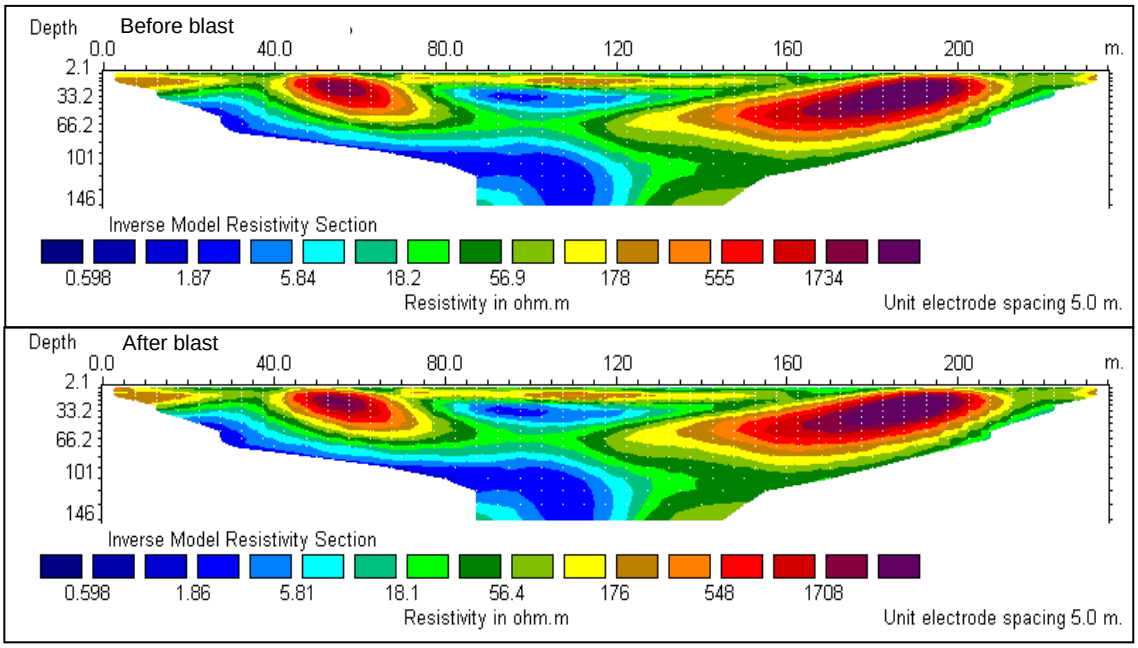

Figure 10: Resistivity image sections recorded before and after blasting at Orient mine no. 3 on 14.09.2006.

5 RESISTIVITY IMAGING DATA VERIFICATION USING BLASTING DATA

In addition to geophysical Resistivity Imaging survey, monitoring of vibrations was carried out at the surface above the underground workings of Kalidaspur project and Narsamunda colliery of Eastern Coalfields Limit and Orient Mine No. 3 colliery of Mahanadi Coalfields Limited. Altogether 391 blast vibration data were recorded from 129 blasts. Vibrations were recorded in terms of peak particle velocity (PPV) in mm/s and frequency in Hz. The maximum explosive weight in a blasting round varied between 1.11 kg and 10.175 kg whereas the depth of cover varied between 41 m and 137 m. In few blasts all the holes were fired instantaneously maintaining charge per delay of 10.175 kg. The maximum vibration recorded was 10 mm/s at the vertically above point of the blasting face (19L/12-13D-roof) of Kalidaspur project. The dominant peak frequency was 73.5 Hz. This was recorded when 10.175 kg of explosive was detonated instantaneously in a blasting round. Thus, the charge weight per delay was 10.175 kg. The depth of cover was 73 m. The recorded PPV of all the experimental sites are presented in Figure 12

.

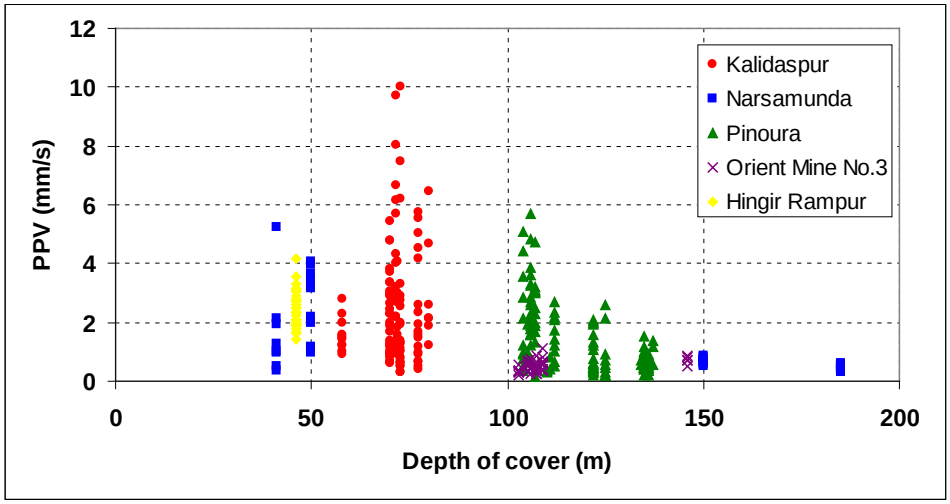

Figure 12: Plot of peak particle velocities recorded at different depth of cover at all the experimental sites.

The dominant peak frequencies of all the vibrations recorded were in the range of 20.3-219 Hz. A representative plot of peak particle velocities with their associated frequencies is depicted in Figure 13. The result confirms the earlier study conducted by Singh et al. (1999, 2007) at different mines in which the dominant peak frequencies of the waves propagating due to underground blasting to ground surface varied from 27 Hz to 156 Hz.

Wenner-Schlumberger, Wenner and Pole-Pole arrays of Resistivity Imaging survey were conducted with a view to determining the change in sub-surface strata conditions during blasting (before and after) in underground coalmine workings of Kalidaspur colliery, Narsamuda colliery and Orient mine No. 3 at various depths. The recorded change in the resistivity values for the aforesaid collieries is presented in Table 2.

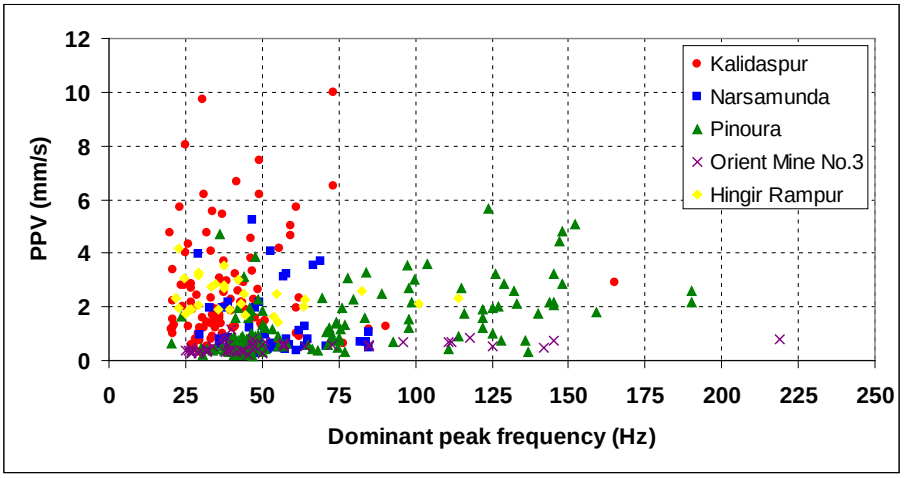

Figure 13: Plot of dominant peak frequencies recorded on ground surface at various locations.

6 CONCLUSIONS

Resistivity Imaging survey carried out at three mining sites led the following conclusions:

- The resistivity imaging survey conducted with the help of Wenner-Schlumberger (WS) Wenner (W) & Pole-Pole (PP) arrays revealed that there was no significant change in sub-surface strata conducted during pre and post blasting conditions.
- The slight change in resistivity values up to 35 ohm.m up to a few meters peripheral area of the blasting face in the mine may be either due to the effect of blast vibration and/or same void created by blasting or increase in porosity of overlying sub- surface strata.

Altogether, 391 blast vibration waveforms were recorded on the surface from 129 blasts conducted at three underground mines. The ground vibrations recorded were of very short duration (less than one second) with low magnitude. Higher frequencies of vibrations were observed in each and every blast irrespective of depth of covers and geo-mining conditions. On the other hand, there was mismatch between the ground vibration frequency and the natural frequency of the houses/buildings, very little energy was transmitted into the structure and hence the reduction in vibration level in the houses/buildings.

There are number of causes other than blasting to create cracks in the houses. A few of them may be due to universal existence of natural, cultural stresses, thermal cycles, humidity-produced changes, material curing and shrinking affecting houses and developing cracks. The non-blasting sources also produce significant vibration levels such as movement of heavy vehicles, trains etc. Environmental changes and human activities produce strains equivalent to 12-15 mm/s and even higher in some cases.

The study clearly demonstrates that there is no chance of damage to surface structures due to blasting being carried out at 50 m and beyond in underground workings. The fear of damage of the structures of the villagers is only an apprehension and not the real cause.

ACKNOWLEDGEMENTS

The authors are thankful to Director, CSIR-Central Institute of Mining and Fuel Research, Dhanbad for the permission to publish this paper. The co-operations extended by the Kalidaspur, Narsamunda and Orient Mine no.3 Collieries managements during field investigations are thankfully acknowledged.

Mine Ventilation, Methane, and Shale Gas

An Initial Investigation of Room and Pillar Ventilation Using CFD to Investigate the Effects of Last Through Road Velocity

T. Feroze, H.R. Phillips
University of the Witwatersrand, Johannesburg, South Africa

ABSTRACT Computational Fluid Dynamics (CFD) has often been used to analyze the air flows in underground mines. In this paper the results of a base-line investigation conducted using a three dimensional CFD analysis to find the depth of air flow in empty headings without any auxiliary devices are presented. The model dimensions are kept constant and air penetration into the heading for four last through road (LTR) velocities is compared. Determination of penetration of air is based on the maximum axial velocity and flow rates are calculated using absolute axial velocity at different depth planes. The results have been compared with experimental results of another researcher published 25 years ago, Meyer (1989).

Further research is continuing to determine the effects of different auxiliary ventilation devices using this CFD methodology, as well as obtaining empirical data in an experimental tunnel established at the University of the Witwatersrand.

Keywords: Ventilation, room and pillar, Computational Fluid Dynamics (CFD), Last Through Road (LTR) Velocity

1 INTRODUCTION

Underground coal mines are always subject to the inherent risks of methane explosions, coal dust explosions and lung diseases if they are not properly ventilated. Generally the out-bye ventilation is well planned by competent and experienced ventilation personnel, often using simulation packages to meet the requirements set by legislation and Codes of Practice. This area is also routinely monitored by production supervisors as well as ventilation officials and in most cases underground instrumentation reports to a surface control room.

Room and Pillar mining is based on creating blind headings until through ventilation is established by holing through when the pillar is formed. Even when longwall mining is the preferred method the access roadways (gate roads) are created by room and pillar mining. This all leads to the development of many blind headings which require ventilation both when being mined and when standing. Localised ventilation may be planned and be the subject of mine standards but implementation on a day to day basis is usually left to the first level of supervisory staff.

Although modeling of ventilation systems for room and pillar has been undertaken for many years, the current study using Computational Fluid Dynamics (CFD) and the ANSYS software package is looking at the effects of correct and incorrect use of line brattices and fans (with and without ducts). This paper describes a base-line study of short blind headings (20 m) where the only ventilation is produced by the air in the last through road (LTR). The variation of penetration depths and distribution of air inside the headings for different velocities of air in the last through road (LTR) is investigated using four different LTR velocities. The results are compared with the field results of the experiments conducted in 1989 in an actual mine, Meyer (1989).

Network design software applications are normally used for the design and planning of primary ventilation but computational fluid dynamics analysis is used for the working face areas, Wu and Gillies (2005). A

number of studies using CFD have been conducted for underground coal mines, some to predict the design and installation of line brattices, Aminossadi and Hooman (2008). In some studies methane behavior in a road way has been studied using CFD, Torano (2009). Heerden and Sullivan (1993) used CFD to simulate the ventilation of both continuous miners and road headers in working areas. A number of CFD studies pertaining to the ventilation of underground mines have been conducted by Wala - notably a CFD simulation of face area ventilation with a blowing curtain (2007) and the effect of machine-mounted dust scrubbers on the performance of face ventilation systems using extended-cut mining with a blowing curtain (2008). Phrushotham and Bandopadhyay (2010) simulated the shock-loss phenomenon of different configurations of air-crossings. Diego (2011) simulated the air loss calculation throughout an installation using CFD. Yuan (2009) simulated the spontaneous heating of coals in gob areas. Meyer and Vanzyle (1999) showed why the U type of flow produced by a jet fan is preferred for better dust and methane control in mines.

2 GOVERNING EQUATIONS

Fluid flows are governed by the Bernoulli's equation or a set of Partial Differential Equations (PDE's) i.e. the conservation of mass, the conservation of momentum (Navier Stokes Equations) and the energy equations. Numerical solvers along with additional equations of the selected turbulence model for turbulent flows are designed to solve these PDE's for fluid dynamics problems. The governing equations are coupled equations, which are nonlinear and are very difficult to solve analytically, necessitating the use of numerical methods. Such a system of equations is converted into algebraic equations which are subsequently solved numerically, using different explicit and implicit numerical techniques. The governing equations used for this simulation are the conservation of mass; equation 1 and conservation of momentum; equations 2 to 4.

2.1 Conservation of Mass

$$\nabla \cdot (\rho \vec{v}) = -\frac{\partial \rho}{\partial t} \quad (1)$$

where,

ρ = Density (kg/m^3), v = Velocity (m/s)

$$\nabla \equiv i\frac{\partial}{\partial x} + j\frac{\partial}{\partial y} + k\frac{\partial}{\partial z}$$

$$\nabla.(\rho \vec{v}) \equiv \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} + \frac{\partial(\rho w)}{\partial z}$$

u, v, w are velocity components in x, y, z direction

2.2 Conservation of Momentum

$$\rho\frac{Du}{Dt} = \frac{\partial(\rho u)}{\partial t} + \nabla \cdot (\rho u \vec{v}) = -\frac{\partial p}{\partial x} + \frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{yx}}{\partial y} + \frac{\partial \tau_{zx}}{\partial z} + \rho f_x \quad (2)$$

$$\rho\frac{Dv}{Dt} = \frac{\partial(\rho v)}{\partial t} + \nabla \cdot (\rho v \vec{v}) = -\frac{\partial p}{\partial y} + \frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{zy}}{\partial z} + \rho f_y \quad (3)$$

$$\rho\frac{Dw}{Dt} = \frac{\partial(\rho w)}{\partial t} + \nabla \cdot (\rho w \vec{v}) = -\frac{\partial p}{\partial z} + \frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z} + \rho fz \quad (4)$$

Where,

$\tau_{xx}, \tau_{yy}, \tau_{zz}$ = Normal Stress in x,y,z direction respectively (Pa).

τ_{ij} = Shear Stress in j direction exerted on a plane perpendicular to the i axis (Pa).

u, v, w are the velocity components in the x,y, and z direction (m/s).

$\frac{D}{Dt}$ = Substantial Derivative

$\frac{\partial}{\partial t}$ = Local Derivative

f_x, f_y, f_z are the body forces in the x,y, and z directions respectively (N)

P = Pressure (Pa)

3 MODEL GEOMETRY AND MESHING

The three dimensional model as shown in Figure 1 was generated in the Ansys Design Modeler software. The width chosen for the LTR and the heading is 6.6 m, while both are 3 m high. The length of the LTR modeled on both the upstream and downstream side of the heading is 10 m and the length of the heading is 20 m. A hexahedral mesh with a size of 0.05 m was created using the Ansys Mesher as shown in Figure 2. A finer mesh of 0.0009 m was created in the near wall region. A total of 10 boundary layers are used in this fine mesh using a growth rate of 1.2 to accurately resolve the boundary layer and to allow a smooth transition between the boundary mesh and the main mesh. The fine mesh at the boundary/walls of the domain kept the y^+ value (calculated using equation 5) at all the walls below 5. The total number of nodes and cells are 11152149, 10960320 respectively.

$$y^+ = \frac{yu_T}{\nu} \qquad (5)$$

Where,

u_T is the frictional velocity $= \frac{\tau_w}{\rho} = (m/s)$

v is the kinematic viscosity (m^2/s)

y = Distance to wall

τ_w is the wall shear stress (Pa)

ρ = Density (kg/m^3)

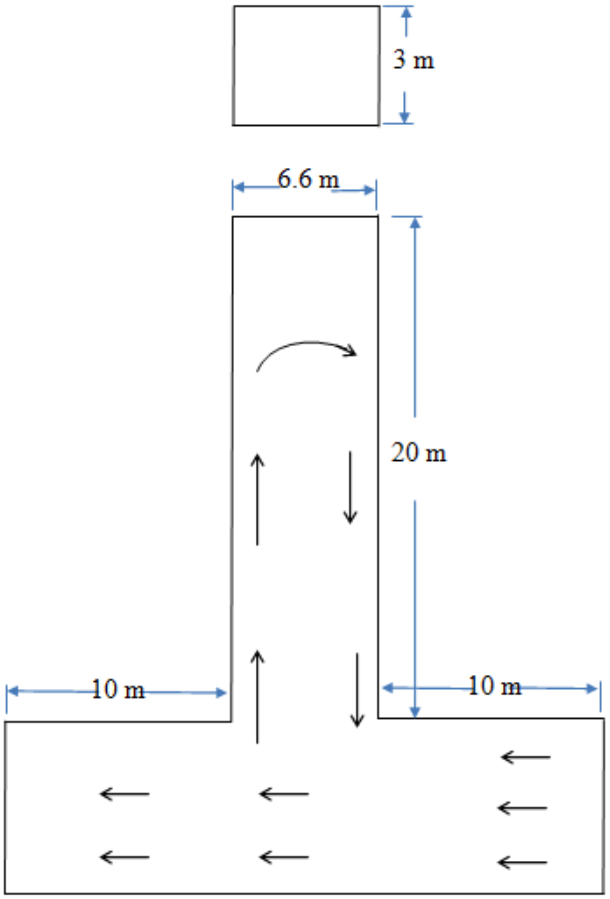

Figure 1. Three dimensional model.

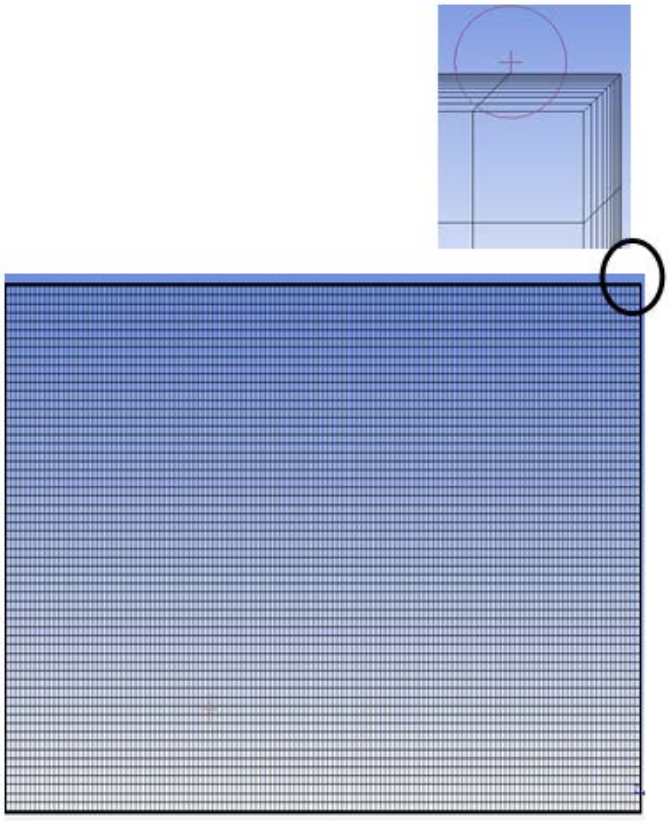

Figure 2. Hexahedral mesh with boundary layers (Inset detailed view of mesh boundary).

4 BOUNDARY CONDITIONS AND NUMERICAL DETAILS

"Velocity Inlet" and "Outflow" boundary conditions were used at the inlet and outlet of the LTR. Since it was intended to validate the CFD results with experimental results obtained in a coal mine located near Johannesburg, the properties of air at 20°C were used. Reynolds numbers for the four LTR velocities (0.78 m / s, 1 m / s, 1.35 m / s, 1.9 m / s) were calculated to be 1.74 x 10^5, 2.23 x 10^5, 3.01 x 10^5, 4.24 x 10^5 respectively. The Reynolds number was calculated using equation 6.

$$\mathrm{Re} = \frac{\rho u D}{\mu} \qquad (6)$$

where,

ρ = Density (Kg / m^3), μ = Viscosity($Pa.s$)

D = Hydraluc Diameter (m), u = m / s

The K-e model is the mostly widely used model for similar problems, involving turbulent flows due to the accuracy of results. This model is a two equation model and solves two additional transport equations besides the governing equations of flow (continuity, pressure and energy) to solve the turbulent flows. K represents the kinetic energy, and, e, represents the turbulence dispersion rate, Ansys Fluent Theory Guide (2014). Therefore, the two equation K-e realizable turbulent model with enhanced wall treatment was used for this study. The iterative process used for the calculation of results was set to run until five orders of residual reduction was achieved (convergence criteria of 10^{-5}) with second order accuracy. At the velocity inlet, turbulent intensity and hydraulic diameter were used as the turbulent quantities.

5 RESULTS AND DISCUSSION

Table 1 shows the maximum axial velocities (velocity component along the direction of the heading) on planes inside the heading, located at depths of 1 m, 5 m, 12 m, 15 m, and 16 m. These velocities have been compiled for each LTR velocity i.e. 0.78 m / s, 1 m / s, 1.35 m / s, 1.9 m / s. If we assume 0.05 m / s as the minimum measurable limit of velocity, the penetration depth with 1.35 m / s and 1 m / s LTR velocities are the maximum i.e. 15 m.

Table 1. Maximum Axial Velocity at Specified Planes.

Planes at Depth (m)	**LTR Velocities (m / s)**			
	0.78	**1**	**1.35**	**1.9**
	Maximum Axial Velocity at Specified Planes (m / s)			
1	0.32411	0.38731	0.59680	0.83610
5	0.23650	0.28110	0.41279	0.70290
12	0.08455	0.17340	0.27185	0.52830
15	**0.02694**	**0.06061**	**0.08572**	**0.02423**
16	0.03304	0.04098	0.04308	0.01561

Figure 3 shows the variation of maximum axial velocities on the specified planes. The velocities are decreasing with the depth of the heading. The maximum decrease rate can be seen for 1.9 m / s LTR velocity.

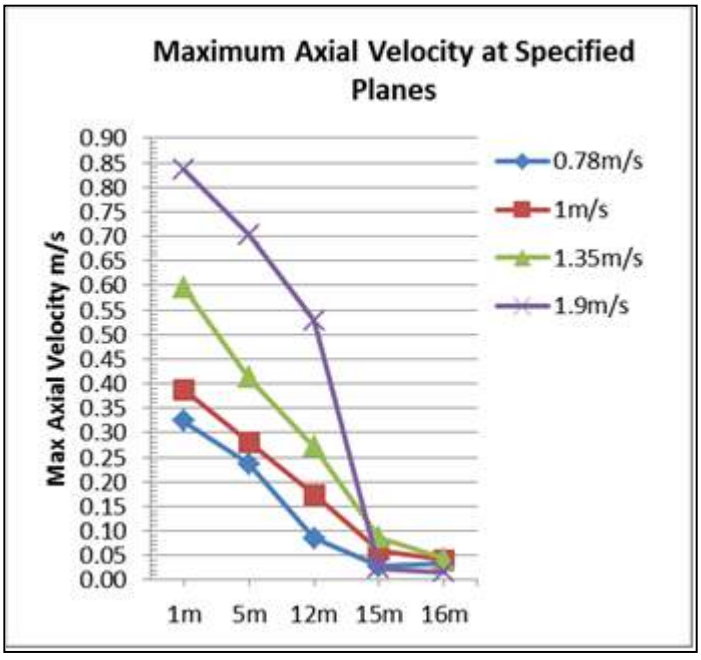

Figure 3. Maximum Axial Velocity at Specified Planes.

Figures 4-7 shows the detailed variation of axial velocity contours on a plane located at 15m depth for each LTR velocity. The

contours have been divided into five regions; showing different velocity ranges. The velocity ranges for these regions are shown with the contours. Positive velocities indicate inflows and the negative flows are the return air flows. The return axial velocity for the case of 1.35 m / s LTR is again the maximum i.e. 0.04294 m / s.

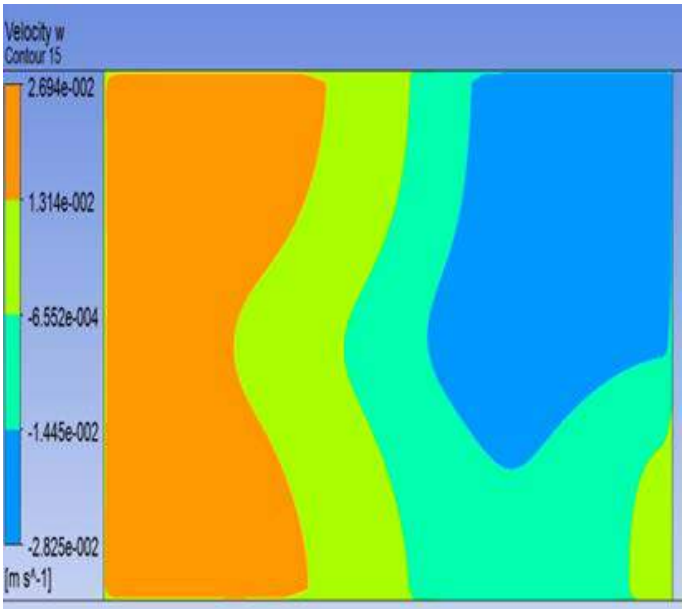

Figure 4. Axial Velocity Contours at 15m plane in the heading for 0.78 m / s LTR Velocity.

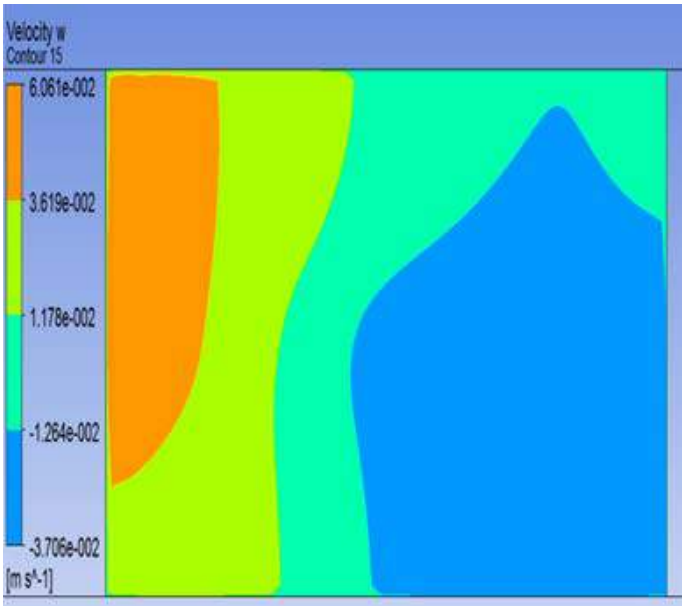

Figure 5. Axial Velocity Contours at 15m plane in the heading for 1 m / s LTR Velocity.

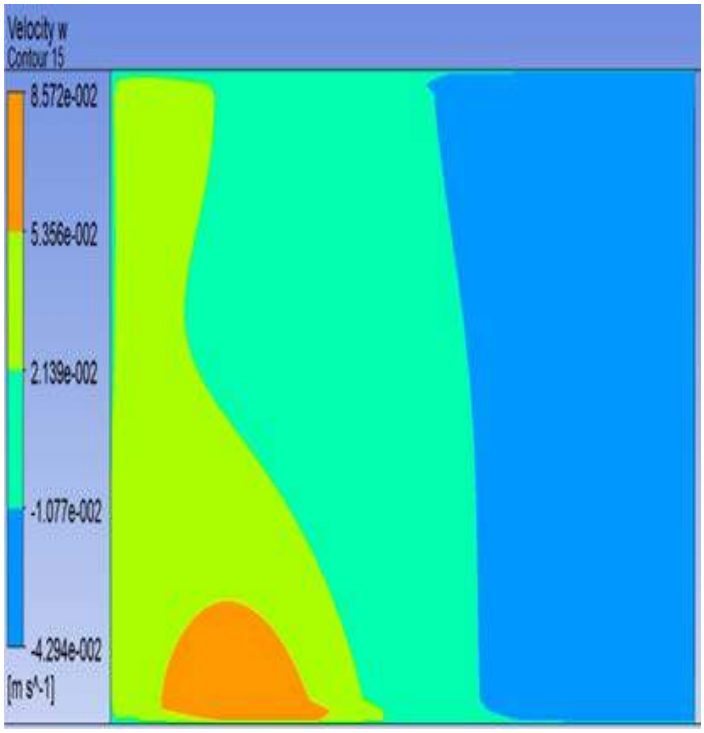

Figure 6. Axial Velocity Contours at 15m plane in the heading for 1.35 m / s LTR Velocity.

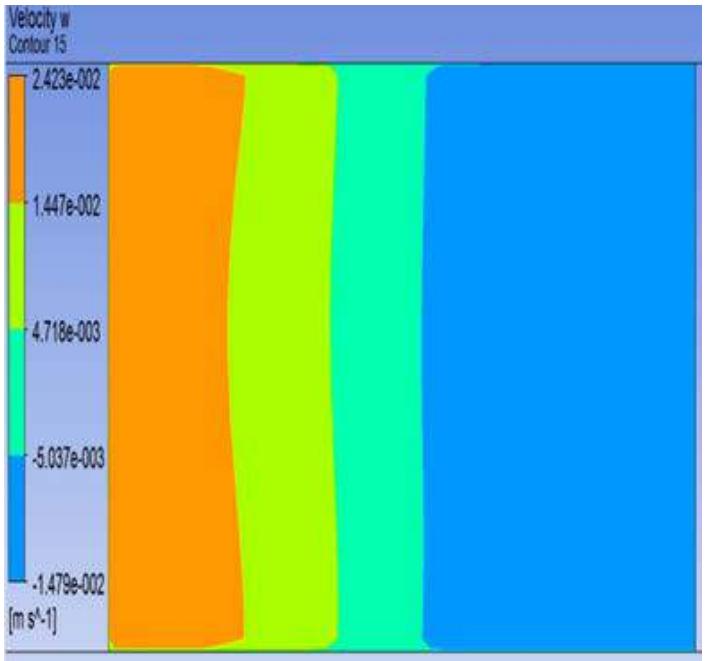

Figure 7. Axial Velocity Contours at 15m plane in the heading for 1.9 m / s LTR Velocity.

Table 2 and Figure 8 illustrate the average positive “flow in” of air through planes set at the specified depths of 1,5,12, and 15 m inside the heading. The air flow rates decrease considerably after the depth of 12 m for all the LTR velocities.

Table 2. Average Positive Flow Inwards at Specified Planes.

Planes at Depth (m)	LTR Velocities (m / s)			
	0.78	1	1.35	1.9
	Average Positive Flow Inwards at Specified Planes (m / s / m^2)			
1	0.44641	0.52216	0.73248	1.09781
5	0.74364	0.87828	1.29108	2.88777
12	**0.21092**	**0.43951**	**0.76674**	**0.21202**
15	0.15206	0.23408	0.22431	0.11558

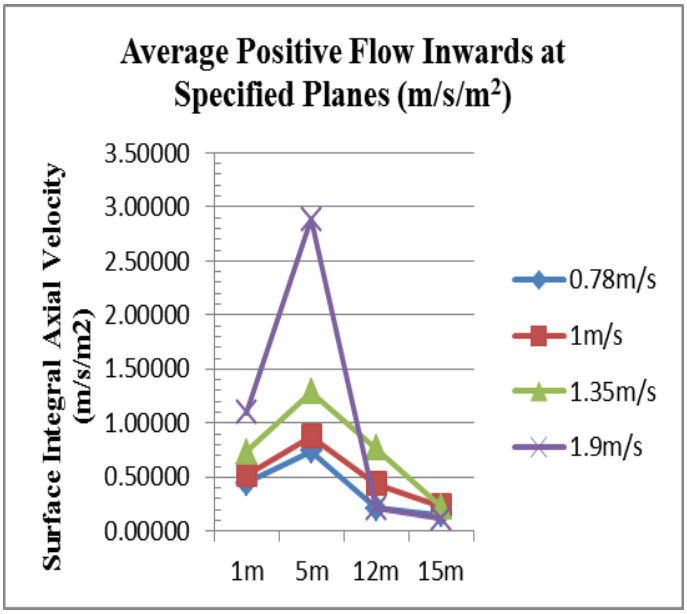

Figure 8. Average Positive Flow In at Specified Planes.

Figure 9-12 shows the velocity contours on a horizontal plane at a height of 1.5 m. It can be seen from these contours that air enters from the downstream side and the flow rate decreases very considerably after the 12 m depth for all the LTR velocities. At a depth of 12 m maximum flow rate is observed for LTR velocity of 1.35 m / s. For LTR velocity of 1.9 m / s, most of the air continues to flow in the last through road and does not ventilate the heading beyond the 12 m depth.

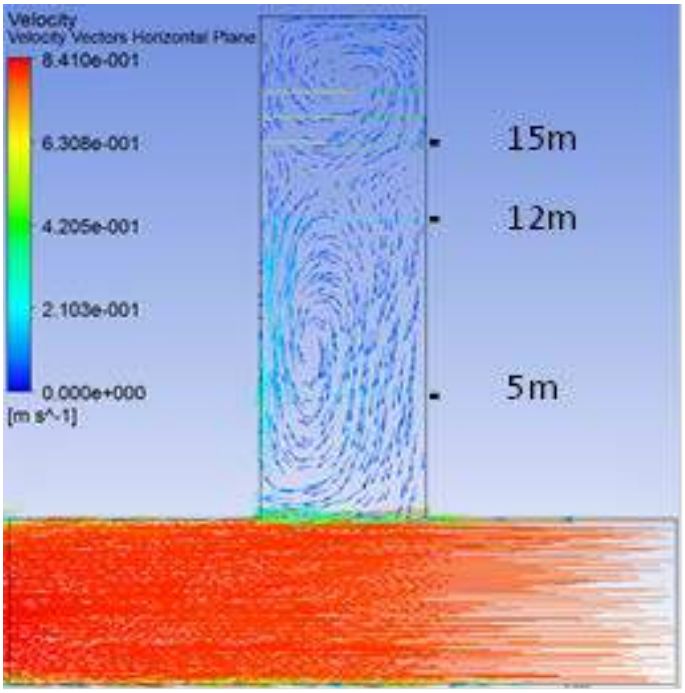

Figure 9. Velocity Vectors on 1.5 m Horizontal Plane for 0.78 m / s LTR Velocity.

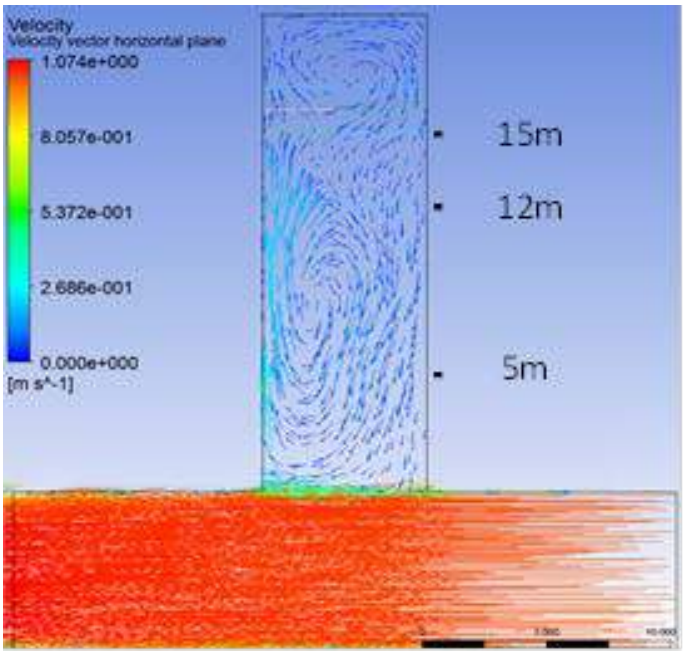

Figure 10. Velocity Vectors on 1.5 m Horizontal Plane for 1 m / s LTR Velocity.

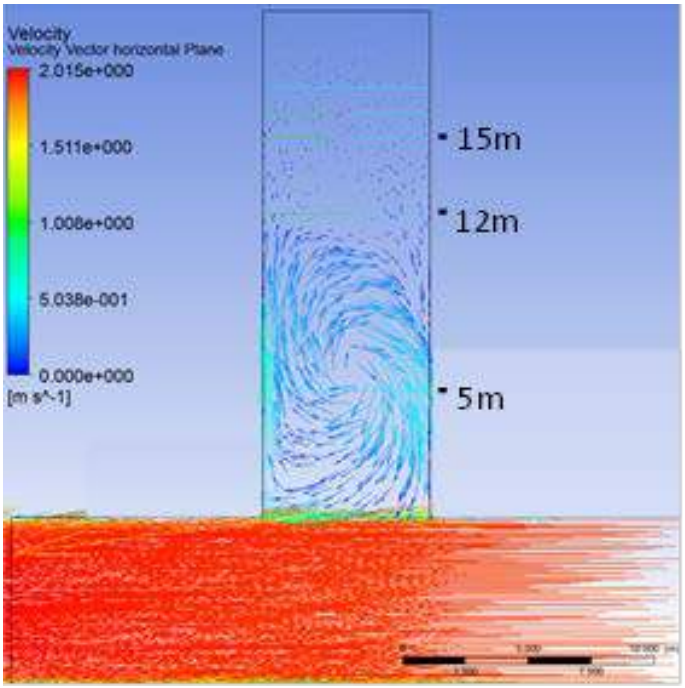

Figure 11. Velocity Vectors on 1.5 m Horizontal Plane for 1.35 m / s LTR Velocity.

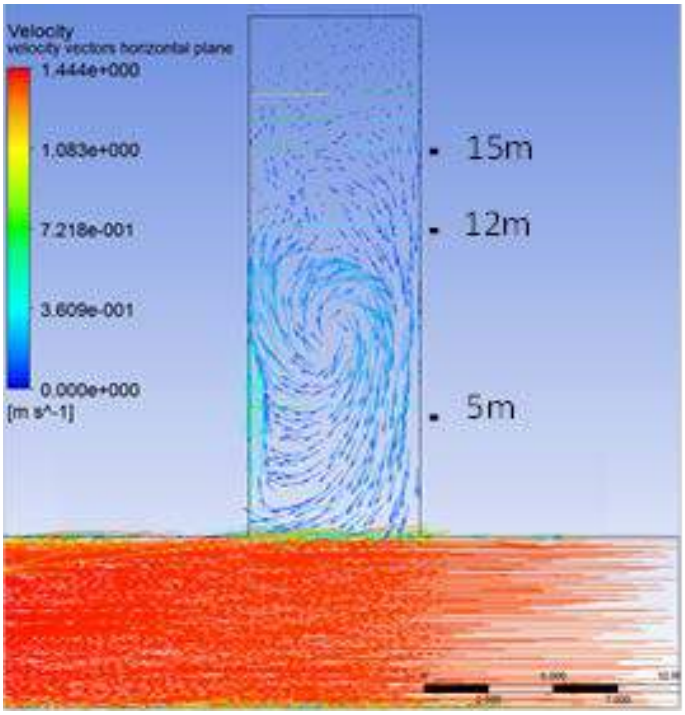

Figure 12. Velocity Vectors on 1.5 m Horizontal Plane for 1.9 m / s LTR Velocity.

6 VALIDATION

In 1989 Meyer conducted a study of the ventilation in Bord and Pillar headings of a coal mine. He selected the headings which were not ventilated by any auxiliary means and, using regulators, varied the LTR velocity to see its effect on the airflow patterns and penetration distance inside the headings (Meyer, 1989). He used smoke generating chemical tubes to visualize the airflow patterns and to measure the penetration distances. Table 3 shows the results of his experiments in a heading with dimensions of 6.6 x 3 x 20 m (the same size that was chosen for the present study). The maximum penetration depth for each LTR velocity was determined and the results of the field trial showed that the maximum penetration depth is achieved with a LTR velocity of approximately 1.35 m / s.

Table 3. Measured Experimental Results of Maximum Penetration Depths for each LTR Velocity, Meyer (1989).

Experimental Results	
LTR Velocity (m / s)	Penetration Depth (m)
0.78	12.2
1	15.8
1.35	16.8
1.9	12.4

A comparison of the present CFD simulation results with those of Meyer (shown in Tab. 3) shows a strong correlation between the two results. The maximum penetration depth is achieved by a LTR velocity of 1.35 m / s.

A 68 m long, well instrumented experimental tunnel, as shown in Figure 13, has been established at the School of Mining Engineering, University of the Witwatersrand to study ventilation aspects using auxiliary ventilation equipment. The experimental data will be used to validate the results obtained from simulations. It is anticipated that the simulations and results from the tunnel will identify shortfalls in face ventilation practice. This should lead to a better understanding of how to provide effective ventilation of working and standing faces in room and pillar mining using a variety of auxiliary ventilation devices.

Figure 13. Tunnel at the School of Mining Engineering, University of the Witwatersrand.

7 CONCLUSION

CFD ANSYS' k-e realizable model with enhanced wall treatment has shown acceptably accurate results when compared with experimental results. A LTR velocity of 1.35 m / s has achieved the maximum penetration depths and a maximum flow rate at 12 m depth, whereas, a LTR velocity of 1.9 m / s gives a maximum flow rate at shallower depths of well below 12 m. Therefore, increasing the LTR velocity beyond a particular level will not do any good as far as the penetration depth is concerned. The validation of the CFD results against the experimental work conducted underground by another researcher 25 years ago is of sufficient promise that work will continue using CFD, scale models, the experimental tunnel and finally a section of a local coal mine. The results of this research will not only define the effects of LTR velocity and the efficacy of auxiliary ventilation devices but can be developed into a training aid to ensure production personnel at the coalface have a better understanding of the impact of their actions on the proper ventilation of working areas of a coal mine.

ABSTRACT Efficiency and safety issues are highly related to the management of the ventilation system in underground mining. This paper presents the design of a geographical information system –also known as GIS– able to store, manipulate and administrate underground environmental data in a long term.

Two important conditions have been taken into account to create the database: the location where the measures have been taken and the fact that the evolution of the underground workings can change the layout of the ventilation system.

The geographic information system has given insight into the working conditions and where are the most critical places concerning the gas concentrations, temperatures and airflow in a case study. Determining the impact of the airflow recirculation in the different working faces.

Keywords: Underground environment, airflow recirculation, GIS

1 INTRODUCTION

Efficiency, safety and health issues are crucial in the underground ventilation system, but sometimes they are overlooked. Currently, more than 60% of mining operation costs are related to ventilation (Reddy, 2009) and there is a direct relationship among hygienic conditions such as gas concentrations and temperature with occupational accidents and worker's efficiency (García et al. 2012).

The usage of a geographic information system, also known as GIS, in mining is quite frequent due to being able to manage any sort of information with spatial components (Bahuguna and Kumar, 2006; Cheng and S. Yang, 2012; Düzgün et al., 2011; Likar and Čadež, 2000). However, the connection of safety and efficiency is hardly considered, despite the GIS is able to insight the real situation inside the mine (Saleh and Cummings, 2011) so procedures can be implemented to ensure the occupational health and safety objectives (Akcil, 2006) and connect it with the efficiency issue through a database of the underground environment features such as airflow, gases concentration or air pressure drop.

The software gathers all the necessary characteristics to manage the information of the ventilation system due to its user friendliness and capability of managing huge quantity of interconnected spatially referenced information, being able to visualize and query historic data and how the ventilation system would react after introducing any change. This fits perfectly with what is demanded for a place like an underground mine, which is evolving and spreading out every day.

2 CASE STUDY: MINE DESCRIPTION

This paper focuses on a mine exploiting potassium from the Catalan basin. The resource is exploited by means of a room and pillar system 500 meters below the surface. The connection between the underground tunnels and the surface is done through a shaft and a ramp, using the shaft for the intake and the ramp for the return.

The main fan is placed at the beginning of the ventilation circuit, leading the airflow by temporary stoppings, curtains and doors. An exhausting system is used in the working faces to supply clean air. Figure 1 shows a scheme of the mine described above and concerning the configurations created by means of the GIS.

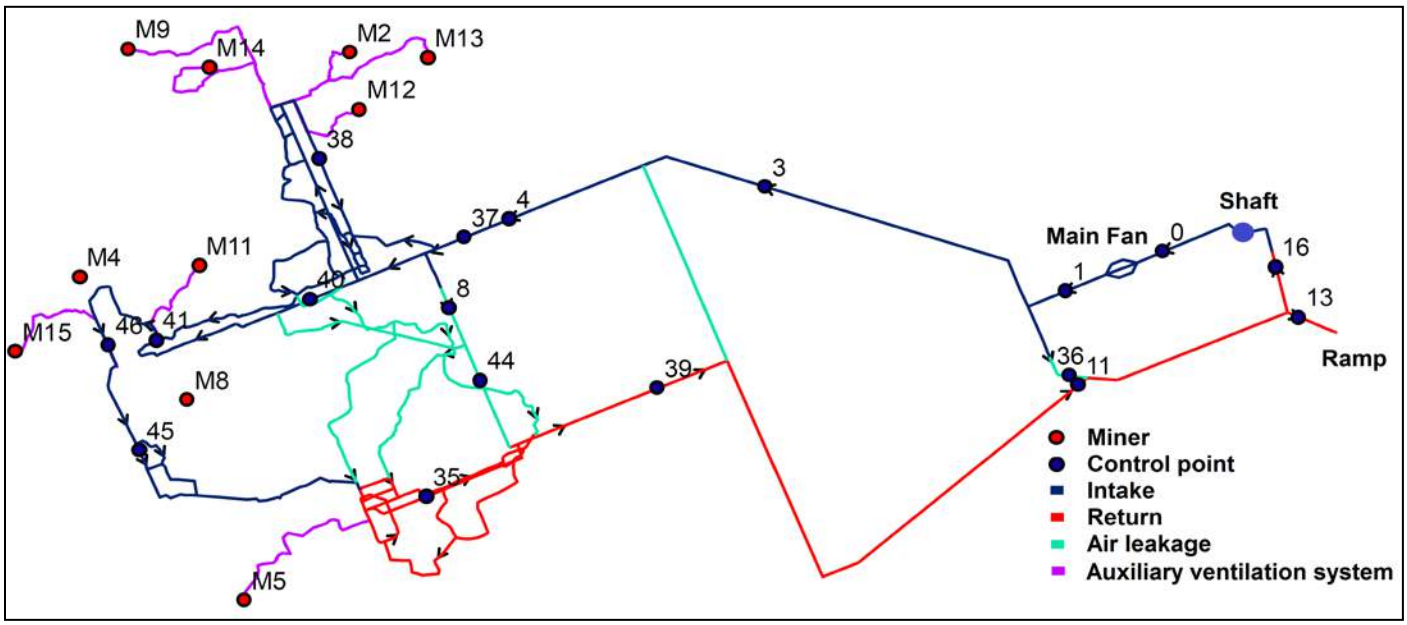

Figure. 1. Scheme of the mine and the ventilation circuit.

3 METHODOLOGY AND DATA

3.1 Data Collection

The data have been taken in situ, using manual methods (sling psychrometer, rotating vane anemometer, gas detector and a laser distance measurer) every month during two consecutive days, one day for the principal ventilation system and the other one for the working faces. In order to obtain reliable measures, the equipment is calibrated regularly (Cook et al., 1990; Lipsey, 1990). Any abnormal value obtained is taken twice.

3.2 Database Design and Management

Initially, the information available consisted in several maps of the ventilation layout in CAD format and the data collected in an excel file. Both types have been merged and transformed to a shape file by means of ArcGis software, using UTM coordinates and taking into account 3 aspects in order to store the information:

- Principal ventilation measure points
- Auxiliary ventilation measure points
- Ventilation layout

This division of the information has been done because it allows an easier management and a better understanding and data analysis. Figure 2 shows the configurations created. Each configuration is a different layout of the ventilation system. The principal ventilation layer includes the intake, the return, the leakages and the points where the measures have been taken. Meanwhile, the auxiliary contains the position of the continuous miner and the pipeline that provides airflow to the working faces. In addition, the mine workings layer stand for all the galleries exploited so far and it helps to get a better understanding of the mine. The principal and auxiliary ventilation layers within each configuration contain the information detailed in Table 1.

Figure 2. Design of the GIS.

Table 1. Ventilation parameters within the GIS.

Principal ventilation	**Auxiliary ventilation**
- Point identification number - Point coordinates (UTM) - Date of the measure - Air velocity (m/s) - Section (m^2) - Airflow (m^3/s) - Dry, wet and effective temperature (ºC) - Gases: CO, CO_2, NO, NO_2 (ppm) and O_2 (%)	- Miner identification number - Continuous miner state - Miner coordinates (UTM) - Date of the measure - Air velocity (m/s) - Section of the pipeline (m^2) - Airflow (m^3/s) - Dry, wet and effective temperature (ºC) - Distance working face – pipeline (m) - Type of fan - Other information - Gases: CO, CO_2, NO, NO_2 (ppm) and O_2 (%)

According to the Spanish law (RGNBSM, itc 04.7.02) the values of NO and NO_2 have to be summarized to know the threshold limit value. In addition the temperature analysis have to be done by means of the effective temperature which can be calculated with the following expression: $te = 0{,}9 \cdot tw + 0{,}1 \cdot td$. Where te is the effective temperature, tw the wet temperature and td the dry temperature.

The data stored has been divided in columns, where each one is a representative parameter of the ventilation system as it can be seen in Table 2. Meanwhile, Figure 3 summarizes the steps followed to create a geographic information system able to manage the underground environment.

Table 2. Part of the data from one of the configurations of the GIS.

Point	X (m)	Y (m)	Velocity (m/s)	Section (m^2)	Cabal (m^3/s)	Td (ºC)	Tw (ºC)

4 RESULTS AND DISCUSSION

The usefulness of a geographic information system in underground environments can be very extensive. The following paragraphs detail some of the possible outcomes.

4.1 Effective Temperature

Table 3 comprise a selection, using the GIS tools, of the measures in the working faces that have been over 30 ºC during 2012, while Figure 4 displays the location of the miners where the measures were taken and the ventilation layout. Combining the graphical information and the data, it can be analyzed the current situation of the mine globally and identify potential future adverse working zones in term of temperatures. This information could be useful for mine planning decisions, efficiency measures or taking safety actions.

Table 3. Selection of the measures over 30ºC during 2012.

Miner	X	Y	Month	Day	Effective temp. ºC
M5	403584	4631491	February	21	34,40
M5	403501	4631512	April	21	32,10
M11	403192	4632604	April	21	31,00
M15	402635	4632536	April	21	30,20
M7	403423	4631908	May	23	30,00

M11	403243	4632742	November	22	31,10

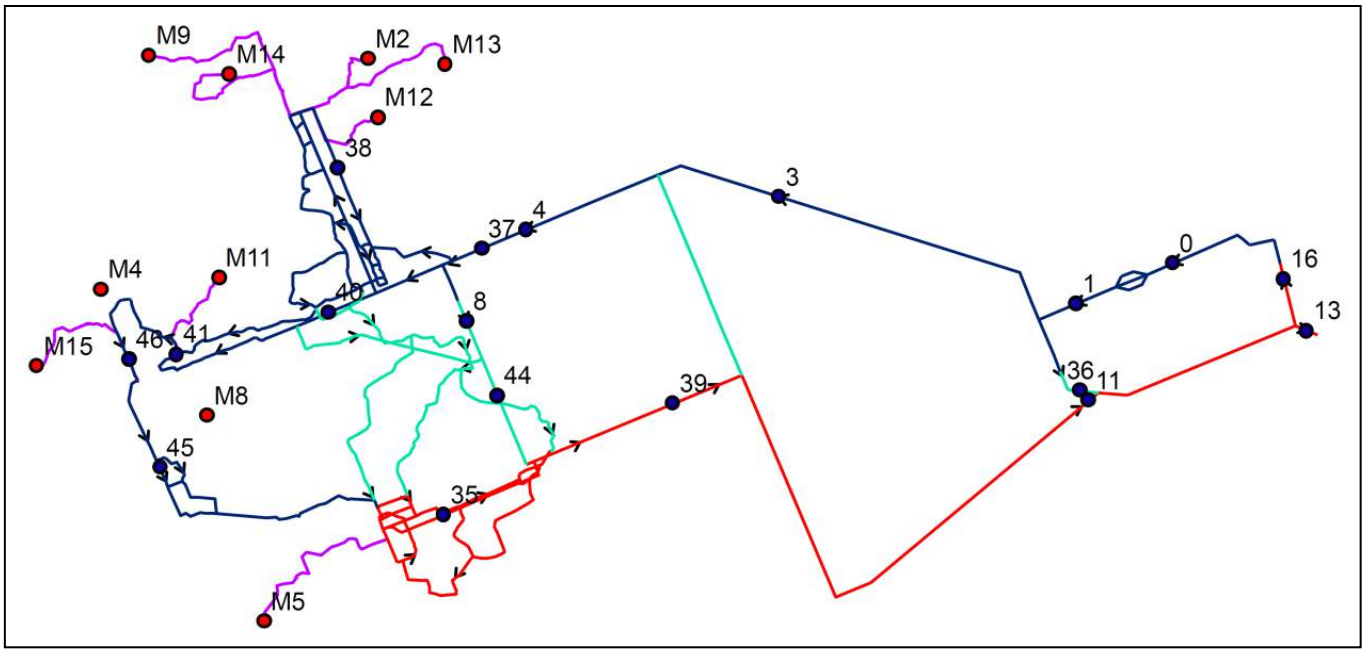

Figure 4. Principal and auxiliary ventilation layout belonging to the configuration 7.

4.2 Environmental conditions in the working faces

Analyzing the different ventilation layouts created by means of the GIS, 3 different zones in terms of airflow recirculation have been identified. In the first zone the miners are provided with clear airflow, in the second one with partially recirculated airflow and in the last one almost all the air is recirculated. Table 4 shows the mean values of 245 measures taken from April 2009 to December 2012 in the different working faces of the mine. The data have been split regarding the 3 zones using the combination of visual information and data of the geographical information system to identify the position of the miners and the data linked to them.

Table 4. Mean values of each zones.

	Airflow (m^3/s)	Effective temperature (ºC)	CO (ppm)	CO_2 (ppm)	NO_x (ppm)
Zone 1	10,59	27,99	6,18	1819,27	7,974
Zone 2	10,03	28,17	5,81	1641,62	8,28
Zone 3	11,32	29,19	8,43	1883,53	9,306

Table 5. Percentage change using the first group as reference.

	Airflow (%)	Effective temperature (%)	CO (%)	CO_2 (%)	NO_x (%)
Zone 1	0,00	0,00	0,00	0,00	0,00
Zone 2	-5,29	0,64	-5,99	-9,76	3,84
Zone 3	6,89	4,29	36,41	3,53	16,70

5 CONCLUSIONS

The GIS created has been confirmed as a powerful tool to provide a safer and healthier work environment as well as improving the efficiency of the ventilation circuit.

The system allows enquiring and analyzing data in a long term, which is totally compatible and complementary with short term environmental control options, such as monitoring and manual systems. Besides, the possibility of improving and complementing the GIS with any other software gives an enormous flexibility to control and assess an evolving environment.

The results have permitted to locate the most sensitive parts of the mine in terms of gases, temperature and airflow, obtaining an environmental pattern based on the mine ventilation conditions, which could be useful to take corrective measures and monitoring their evolution in a long term.

ACKNOWLEDGEMENTS

The authors would like to thank the staff from Iberpotash S.A. for their willingness and high commitment to improve the safety of the mine.

Numerical Study on the Fire Protection System in The Galaje Tunnel

B. Niknam, K. Shahriar, H. Madani
Amirkabiruniversity, Tehran, Iran

ABSTRACT In this work, a numerical 3D simulation of ventilation and sprinkler systems in the Galaje Tunnel, a two-lane, 2250 m long road tunnel in Iran, are developed to evaluate the effects of different designs and of emergency systems, and to assess the performance of safety measures over a wide range of fire scenarios. According to simulation result, sprinkler droplets are too light to penetrate the fire plume and are simply swept away. Simulation results suggested that the longitudinal ventilation system was very effective for blowing all smoke and hot gases in the downstream direction, which could be generally deemed empty, so immediately creating upstream the fire a safe route for evacuation and rescue

Keywords: tunnel, Galaje,fire, ventilation, sprinkler, simulation

1 INTRODUCTION

Fires in road tunnels are extremely hazardous for induced drivers and rescue teams. Recent disasters, like crashes in the Mont Blanc tunnel or San Gottardo [1,2], have shown the need for better integral actions in the case of fire incidents. In particular, the minimum delay time required for starting the jet fans, or the evolution of the smoke patterns inside the tunnel are critical issues when rescue plans are designed. Since major interest is placed on developing systems that minimize both material and personal damages, the design of ventilation systems must be focused on the life protection, while the evacuation of the tunnel is completed. Therefore, these ventilation systems must incorporate an integral operating manual in which the airflow necessary to control the smoke or the direction and schedule of fresh-air supply should be clearly specified. Unfortunately, there is not just one simple procedure to estimate these operating conditions because of the inherent complexity of the problem: a non-linear convection of multispecies mixture of gases inside one particular tunnel geometry, function of heat and energy sources (fire characteristics) and weather conditions (variable boundary conditions).

Three deferent methodologies can be cited as basic tools to study the smoke propagation in case of fire: pseudo thermal scale models, full scale tests and numerical models. In the first case, significant contributions using the pseudo-thermal method can be found in the bibliography though their results are difficult to extrapolate to different operating conditions and are quite limited to low temperature applications. The second method (full scale tests) is really expensive and only few of them have been conducted recently: the EUREKA Project , the Memorial Tunnel Fire Ventilation Test Program and Runehamer fire test. Because they require of large experimental facilities, they are difficult to operate and maintain in order to obtain good results. The last method (numerical modeling), now under development, consists of customizing CFD codes to analyze the fire evolution when the ventilation system operates inside meshed tunnel geometries. However, in order to be completely reliable, these codes must be calibrated and verified through comparison with experimental data .In this paper we use numerical method to study fire characteristic and fire control approach in Galaje tunnel.

2 GALAJE TUNNEL

Galaje tunnel (figure1) is 2,250 m long, 10.6 m wide, and 8.35 m high, with the cross section of 72 m2; of rocky type and is situated on route to Ilam_kermanshah road. The tunnel has a lane in each direction. The road traffic is heavy, many accidents occurred in the road that may be cause to fire in the tunnel

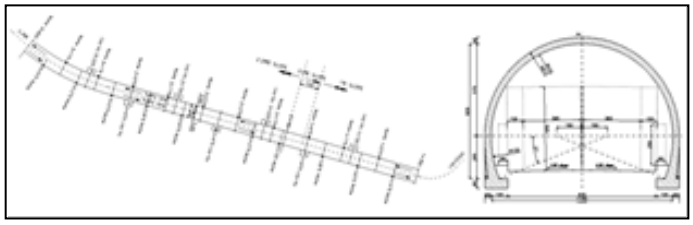

Figure1.Galaje tunnel rout and cross section

3 PROBLEM DESCRIPTION

The ventilation system is used for controlling smoke, hot and toxic combustion gases during a fire emergency, in order to allow safe evacuation and rescue. Ventilation may be provided by natural means (Fig. 2), or by mechanical equipment (longitudinal, semi-transverse or full transverse ventilation systems,(Fig. 4).

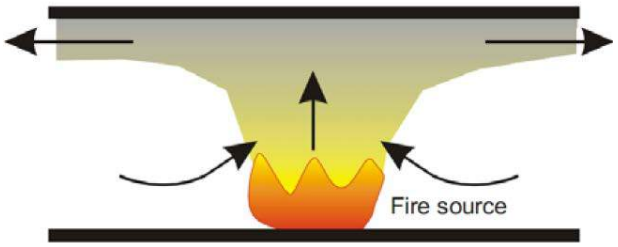

Figure2. Natural fire

With no air current in the fire zone, the smoke progresses in a symmetrical way on both sides of the fire. The smoke remains stratified until it cools down due to the combined effects of the convective heat exchange with the walls and the mixing between the smoke and the fresh air layer, . A natural ventilation system depends on the pressure differential that is created by atmospheric conditions and differences in elevation (Fig. 3).

The longitudinal ventilation system (Fig. 4) creates a longitudinal flow along the roadway tunnel by introducing or removing air from the tunnel at a number of points. Longitudinal flow is provided by jet fans. The ventilation system would be operated to force the smoke and hot gases in the direction of the empty tunnel to provide a clear and safe environment behind the fire for evacuees and fire fighters. If the ventilation capacity is sufficient (Fig. 5b and Fig. 5c), all of the heated air and smoke will flow in the downstream direction. If the ventilation is weak (Fig. 5a), the upper layer of heated air and smoke may flow in the opposite direction causing back layering, .

The occurrence of back layering depends on many factors including the intensity of fire, the grade and geometry of the tunnel, and the velocity of the ventilating air approaching the fire.

The ability of the longitudinal ventilation system to prevent back layering is the current industry standard to measure the adequacy of the system for smoke control (Fig. 6).

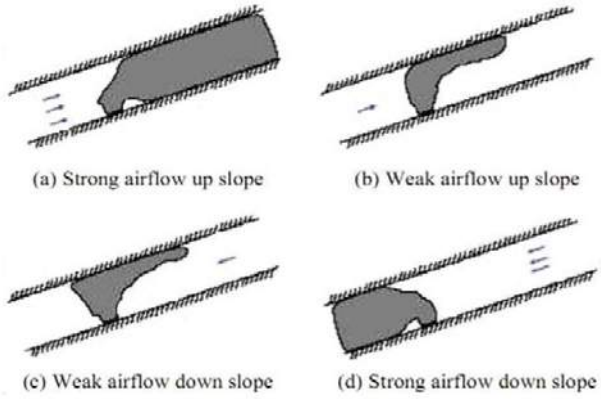

Figure3. Smoke behavior in a sloping tunnel

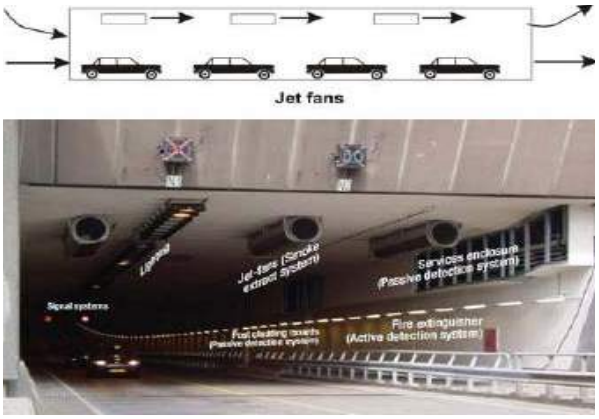

Figure 4. Longitudinal ventilation system

The simultaneous solution of Eqn. (1) and Eqn. (2), by iteration, determines the critical

velocity. The critical velocity, Vc, is the minimum steady-state velocity of the ventilation air moving toward a fire that is necessary to prevent back layering, .

The simultaneous solution of Eqn. (1) and Eqn. (2), by iteration, determines the critical velocity. The critical velocity, Vc, is the minimum steady -state velocity of the ventilation air moving toward a fire that is necessary to prevent back layering, .

$$V_C = k_1 k_g \left(\frac{gQH_t}{C_p T_f \rho_0 A} \right)^{\frac{1}{3}} \quad (1)$$

$$T_f = \left(\frac{Q}{C_p \rho_0 A V_C} \right) + T \quad (2)$$

Where:

A - Area perpendicular to the flow [(m2)]
Cp - Specific heat of air [(kJ/kg K)]
g - Acceleration caused by gravity [(m/sec2)]
H - Height of duct or tunnel at the fire site [(m)]
K1 - 0.606
Kg - Grade factor (see Fig. 7)
Q - Heat fire is adding directly to air at the fire site [(MW)]
T - Temperature of the approach air [(K)]
Tf - Average temperature of the fire site gases [(K)]
Vc - Critical velocity [(m/sec)]
ρ - Average density of the upstream air [(kg/m3)]

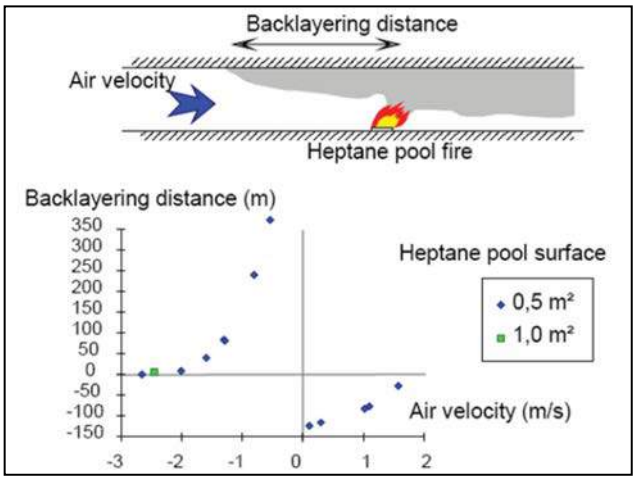

Figure 6. Backlayering distance vs. longitudinal air velocity for two heptane pool surfaces

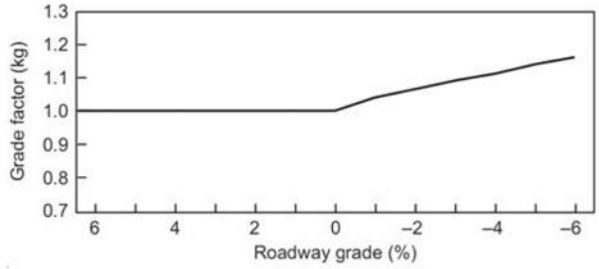

Figure 7. Grade factor for determining critical velocity

For large tunnel fires critical velocity can be taken as dependent of the HRR (Fig. 8).

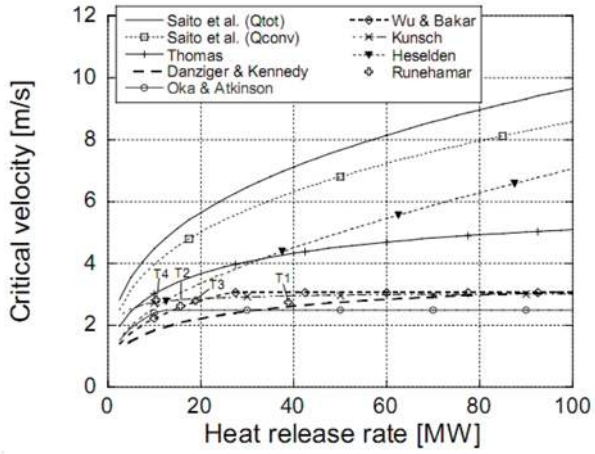

Figure 8. Critical velocities as function of total HRR according to four different relations

Fire Data for Typical Vehicles, according NFPA 502Standard for Road Tunnels, Bridges and Other Limited-Access Highways are shown in the Table 1, .

Table 1. Fire Data for Typical Vehicles

Type of vehicle	**HRR(MW)**
Car	5-10
Multi passenger cars (2-4vehiles)	10-20
Bus	20-30
Heavy goods vehicles	70-200
Tanker	200-300

In Figure 9 the five fire temperature curves are presented graphically (the first two hours), .

In Japan and Australia water extinguishment systems are widely used in tunnels. In Europe, however, there has been a reluctance to use sprinkler in tunnels. According NFPA 502 Standard the major concerns expressed by tunnel authorities regarding fire sprinkler use and effectiveness include the following, :

(a) Typical fires usually occur under vehicles or inside passenger or engine compartments that are designed to be waterproof from above; therefore, overhead sprinklers have no extinguishing effect.

(b) With any delay between ignition and sprinkler activation, a thin water spray on a very hot fire produces large quantities of superheated steam without suppressing the fire. Such steamhas the potential to be more damaging than smoke.

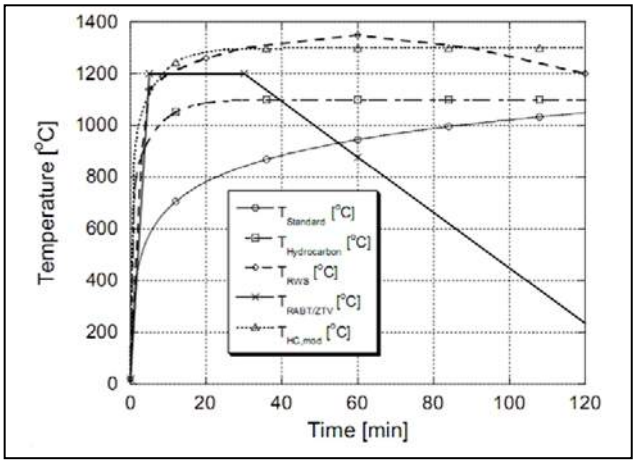

Figure 9. Specific temperature curves of hydrocarbon firesin tunnels

(c) Tunnels are long and narrow, often sloped laterally and longitudinally, usually ventilated, and never subdivided, so heat normally is not localized over afire.

(d) Because of stratification of the hot gases plume along the tunnel ceiling, a number of activated sprinklers are unlikely to be located over the fire. A large number of activated sprinklers are likely to be located at a distance from the fire scene, producing cooling effect that tends to draw the stratified layer of smoke down toward the roadway level.

(e)Even a light spray from sprinklers can catch motorists unaware and can exceed that which windshield wipers could clear. Sprinkler discharge can also cause the roadway to become dangerously slippery.

(f)Water that sprays from the ceiling of a subaqueous tunnel suggests tunnel failure and can induce panic in motorists.

(g)The use of sprinklers can cause the delamination of the smoke layer and induce turbulence and mixing of the air and smoke, thus threatening the safety of motorists in the tunnel.

(h)Periodic testing of a fire sprinkler system to determine its state of readiness is impractical and costly.

4 NUMERICAL SIMULATION

The CFD software package NIST Fire Dynamics Simulator version 5 (FDS5) was used to calculate temperature and smoke concentration fields formed in case of fire with in the Galaje tunnel space . For the calculation of flow and temperature fields of the air formed within the tunnel, large eddy simulation turbulent model was used. Because of certain identical segments of the tunnel and the high length of the entire tunnel (Fig 10), in simulation used segment dimension was: 1200 m x 11.3m x 8.3m (length, wide, high, respectively).The FDS5 domain was divided into cells of dimension 0.5 m × 0.2 m × 0. 2 m. The tunnel is built at grade in concrete. The fire source in the simulation was represented by burning of a flammable liquid in a pool with dimensions 3 x 10 m. The maximum heat release rate per unit area (HRRPUA) of the fire was 6733 kW and the total heat release rate (HRR) was 200 MW same as tanker fire. The initial air temperature in the whole tunnel was set to 15 °C. This calculation determined that the ventilation of tunnel is to be carried out by 22×2 pairs of regularly arranged jet fans and three parallel lines of sprinklers K-11 type. Distance between sprinklers is 3.05 m, according NFPA 13 Standard, . The maximum volumetric flow of fresh air through these jet fans should be 28.55 and 57.1 m3/s.

6 CONCLUSION

The heat release rate of fire is a critical factor in the determination of fire intensity. This factor is in direct relationship with some factors like temperature, smoke distribution, air flow speed, and flame length and fire development. According to figure 11, the heat release rate in Galaje tunnel consists of six phases: ignition, initial, growth, fully-developed, decay and extinguish. The ignition phase begins from time zero and lasts up to 174 seconds. During this phase, fire intensified with liner growth rate As time passes, the fuel temperature reaches its ignition point so that within 174sec<t<260sec, flames appeared , stabilized and fire growth with quadratic rate. With the lapse of time, hot fuel-controlled fire is generated where the fire spread rate depends on the consumption of the substance. As time passes, the entire surface of the substances are engaged with fire and a rapid transfer from the growth phase to a fully-developed phase occurs .In the fully-developed phase, the heat and energy released from the fire will be at a maximum. Oxygen accessibility limits the development of fire during this phase. Thus, this phase is called ventilation-controlled fire . Within 260sec<t<1160sec, Galaje fire begins its fully-developed phase and growth exponentially. Finally, the heat release rate is decreased due to lack of fuel source in the decay phase in which the fire changes from

ventilation-controlled mode to the fuel-controlled modeIn the event of a fire in Galaje tunnel with natural Ventilation (fans turn off-Fig12a), due to difference in densities, hot combustion products rise above the fire and entrain the surrounding cold air forming a plume. The rising plume reaches the ceiling and forms two smoke streams flowing in opposite directions along the ceiling. In tunnels with longitudinal ventilation systems (Fig. 12b and Fig. 12c), the symmetry of the rising plume and the ceiling smoke streams is broken.The rising plume bends and the length of the ceiling layer flowing against the ventilation current is reduced. The reversal of the flow of the plume is referred to as back layering(Fig. 12b). If ventilation system operates only half at the maximum flow rate designed for the ventilation of the tunnel (28.55m3/s) come to a back layering effect. If ventilation system operates only at the maximum flow rate designed for the ventilation of the tunnel (Fig.12c), no will be back layering effect. In fire simulation with sprinklers, sprinklers activation come to destroying the smoke stratification (Fig. 14b) and thereby decreasing the visibility, spreading liquid fuel over a larger area and there by spreading the fire, the risk for explosion, the production of steam affecting the people inside the tunnel. The maximum predicted gas temperature near the ceiling was 1200 °C (Fig. 12), in simulations with activated sprinklers1000°C (Fig. 13). Also, the sprinkler system was not able to reduce temperature directly above the fire in the unshielded simulation. Apparently, sprinkler droplets are too light to penetrate the fire plume and are simply swept away. Simulation results suggested that the longitudinal ventilation system was very effective for blowing all smoke and hot gases in the downstream direction, which could be generally deemed empty, so immediately creating upstream the fire a safe route for evacuation and rescue

Possibilities to Priorly Establish the Structure of Ventilation Networks Affected by Underground Explosions

D. Cioclea, G.A. Găman, I. Gherghe, F. Rădoi, C. Boantă, V.M. Păsculescu
National Institute for Research and Development in Mine Safety and Protection to Explosion – INSEMEX, Petroşani, Romania

ABSTRACT The explosion type phenomenon is an extremely complex physical – chemical process which leads to the physical change of objects and objectives encountered over the propagation pathway and to the chemical change of underground atmosphere from the area of influence.

During the development of the explosion type phenomenon, due to the energy of the dynamic wave, there occur significant mechanical effects at the level of affected mining works and at the level of ventilation constructions. In addition, due to intense burning reactions at high temperatures, there occur major effects concerning the composition and concentration of the underground atmosphere from the area of influence. Changes, respectively perturbations occurred after the event at the level of underground mining works of coal faces, endanger staff and may lead to the occurrence of similar events.

An explosion has direct effect upon the ventilation network by modifying the operational parameters of main ventilation fans. This determines different natural post event reparation of air flows at branch level. At the same time, there is modified the underground atmosphere at coal face level, leading to the increase of a potential risk of occurrence of new underground explosions, respectively to major difficulties related to the retreat of affected working staff or special intervention teams.

Prior establishment of work environment after an event is conducted through simulations over a ventilation network using the Australian software Ventsim Visual Advanced.

Keywords: Ventilation network, underground explosion, Ventsim

1 WORK ENVIRONMENT CHANGES ESTABLISHMENT

In normal conditions of hard coal exploitation, in the underground work environment occur a variety of gases of various concentrations.

The most representative and at the same time the most hazardous ones for working staff are methane, carbon monoxide and carbon dioxide.

Highest gas quantities are usually released from active coal faces during technological processes and during the coal's spontaneous combustion processes.

1.1 Gas Concentration Establishment Before the Event

In order to establish gas concentrations at the level of a coal face, there shall be performed specific measurements during a one week time period. The maximum concentration is recorded during actual exploitation works, and the minimum values are recorded during the resting periods from the end of the week.

After the occurrence of an explosion type phenomenon, the level of concentrations in air is very close or even identical to the one recorded in the resting days.

1.2 Gas Concentration Establishment After the Event

There is considered the air flow circulated at the level of the coal face Q_1

$$Q_1 = \frac{q_a \cdot 100}{c_1} \text{ (m}^3\text{/min)}$$

in which: q_a – absolute gas flow (methane or carbon dioxide) (Cioclea, 2008; Cioclea et al., 2008; Cioclea et al., 2013; Matei et al.,

2003; Matei et al., 2004) specific for the coal face (m^3/min);
c_1 – average methane or carbon dioxide concentration during the resting days from the end of a week (%);

After the event, the circulated air flow at the level of the coal face is Q_2, which is obtained by simulation using VENTSIM VISUAL ADVANCED software (m^3/min).

$$Q_2 = \frac{q_a \cdot 100}{c_x} \quad (m^3/min)$$

in which: q_a - absolute gas flow (methane or carbon dioxide) specific to the coal face (m3/min);
c_x – average concentration of methane or carbon dioxide after the event (%);

The following equation may be written:

$$c_x = c_1 \cdot \frac{Q_1}{Q_2} \quad (\%)$$

2 ESTABLISHING THE CHANGES OF THE WORK ENVIRONMENT AFTER THE OCCURRENCE OF AN UNDERGROUND EXPLOSION

Significant for establishing the work environment after the occurrence of an explosion are the information related to the changes of gas concentrations (CO_2, CH_4, CO) and of air flow (Băltăreţu and Teodorescu, 1971; Cioclea, 2006; Crăciunescu, 1984; Gherghe, 2004; Patterson, 1992; Teodorescu et al., 1980).

In this regard, for establishing environmental conditions after the occurrence of an explosion, several steps are required to be performed:

- Simulation of explosive and or toxic gas dispersion, in normal exploitation conditions;
- Establishing the structure of the ventilation network after the occurrence of an explosion;
- Simulation of explosive or toxic gas dispersion after the occurrence of an explosion.

2.1 Simulation of Explosive and / or Toxic Gas Dispersion in Normal Exploitation Conditions

In order to perform the simulations a ventilation network has to be selected, in this case Vulcan mining unit ventilation network, network which is modelled and solved using a specialized software such as VENTSIM Visual Advanced (Figure 1).

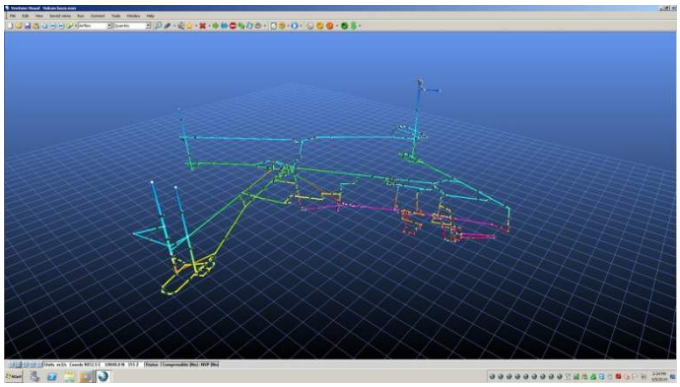

Figure 1. Ventilation network of Vulcan mine

For conducting the simulations in order to establish explosive or toxic gas dispersions (User Guide, 2012) the following steps have to be performed:

- Simulation of CH_4 dispersion at the level of the ventilation network;
- Simulation of CO_2 dispersion at the level of the ventilation network;
- Simulation of CO dispersion at the level of the ventilation network.

2.1.1 Simulation of gas dispersion at ventilation network level

For conducting the required simulations there has been used VENTSIM Visual Advanced software Figure 2, Figure 3 and Figure 4. The results of methane, carbon dioxide and carbon monoxide dispersion in normal exploitation conditions are the following:

- CH_4 is present in coal faces and has an average concentration of 0.3% vol.;
- CO_2 is present in coal faces and has an average concentration of 0.2 – 0.6 % vol.;
- CO is present in one coal face and has an average concentration of 220 ppm.

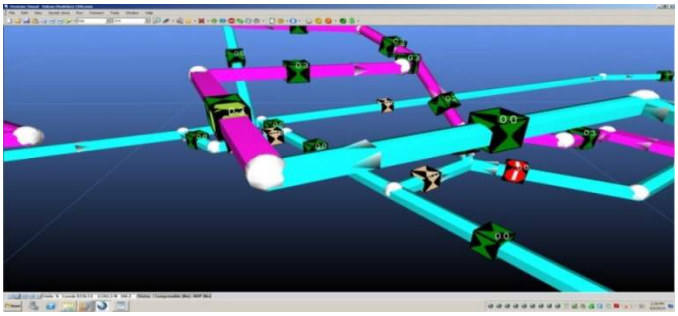

Figure 2. Simulation of CH_4 dispersion at the level of the ventilation network

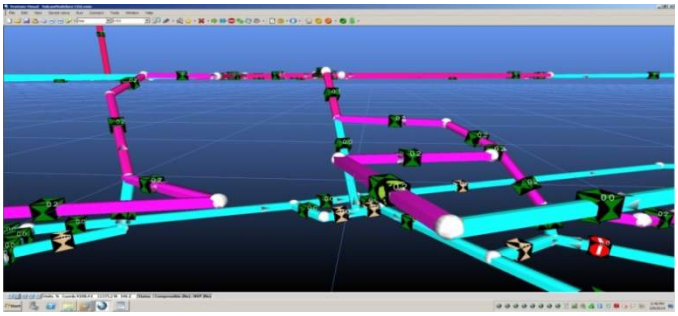

Figure 3. Simulation of CO_2 dispersion at the level of the ventilation network

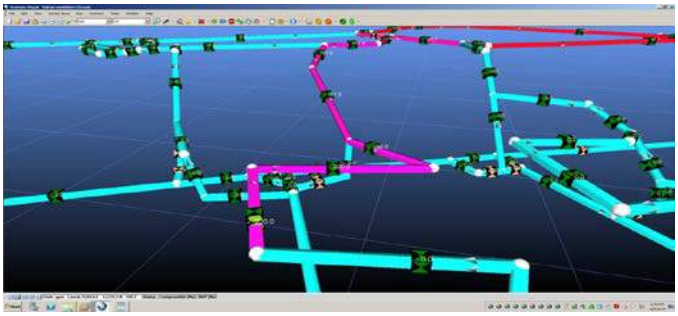

Figure 4. Simulation of CO dispersion at the level of the ventilation network

2.2 Establishing the Structure of the Ventilation Network After the Occurrence of an Explosion

In order to establish the structure of the ventilation network after the occurrence of an explosion (Bana, 1985; Bardocz, 1973; Barthnecht, 1981; Freytag, 1965; Hîndoreanu, 1972; Plasche, 1955) the following steps shall be performed:

- Establishing the influence of the explosion type phenomenon upon the ventilation network;
- Solving the ventilation network by taking into account the changes generated by the explosion

2.2.1 Establishing the influence of a high intensity explosion type phenomenon upon the ventilation network

In order to identify the effects of a high intensity explosion there shall be firstly established the following:

- The ventilation network on which the simulation is performed is the one of Vulcan mine;
- The chosen area for simulating the explosion is the coal face with undermined coal bed no. 1/3/VII;
- Length of the coal face: 54 m;
- Volume of the explosive mixture:375 m^3.
- Length of the face over which the methane accumulation occurs: 40 m;
- Section of the face: 9.375 m^2;
- Air-methane concentration 10 % vol.;
- Ignition source– spontaneous combustion phenomenon degenerated into an endogenous fire;
- Approximate explosion pressure: 10 bar.

2.2.1.1 Rate of pressure rise

The rate of the explosion pressure rise dP/dt_{max} is given by (Cleuet and Gros, 1994) the cubical law:

$$\frac{dP}{dt}\ \text{max} = K_g V^{-1/3} \quad \text{(bar/s)}$$

in which:

V – volume of the enclosure m^3;

K_g – gas characteristic constant, for turbulent mixture, having a value of 460;

$\frac{dP}{dt}$ max = 63,79 bar/s

2.2.1.2 Determination of the explosion pressure loss gradient

Taking into account the specialized literature and the experimental data developed in tunnels with relatively reduced lengths of 100 m, respectively 896 m ,(Bana, 1985; Bardocz, 1973; Cîrloganu, 1986; Hîndoreanu, 1972; Lei et al., 2012; Sochet, 2010; Zheng and Li, 2012) compared to the length of the mining works from within an underground mine which may add up to tens of km, with a high complexity degree from the structural point of view, there is

considered the maximum pressure loss gradient of dP/dx = 0.35 bar / 100 m.

Taking into account the explosion pressure of 10 bar, respectively the values of 0.07 bar and 0.15 bar for which ventilation doors, respectively insulation constructions structurally collapse (Technical expertise, 2014), it results that the dynamic wave generated by the explosion destroys the following ventilation doors belonging to the uniquely identified branches: 52; 63; 70; 103; 137; 147; 170; 171; 187; 197; 200; 202; 216; 258; 278; 286; 276; 285; 309 and 310, respectively the insulation constructions belonging to the uniquely identified branches: 226; 230.

3 SOLVING THE VENTILATION NETWORK WITH REGARD TO CHANGES GENERATED BY THE EXPLOSION

Figure 5 presents the spatial ventilation network of Vulcan mining unit in 3D solid format, modified with regard to the structural changes generated by the explosion (User Guide, 2012).

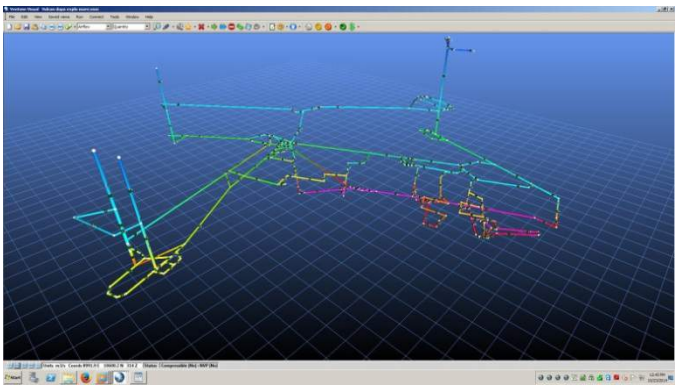

Figure 5. Vulcan mine ventilation network after the occurrence of the explosion

3.1 Simulation of Explosive or Toxic Gas Dispersion After the Occurrence of an Explosion

For conducting the simulation in order to establish the dispersion of explosive and or toxic gases after the occurrence of an explosion type phenomenon (Sochet, 2010), the following steps shall be performed:

- Simulation of CH_4 dispersion at the level of the ventilation network;
- Simulation of CO_2 dispersion at the level of the ventilation network;
- Simulation of CO dispersion at the level of the ventilation network.

Changes of the ventilation network's structure bring along the change of airflows at branch level and there occur major changes of gas concentrations in areas of influence.

3.1.1 Simulation of CH_4 dispersion at ventilation network level

Figure 6 provides the simulation of methane dispersion at the level of the ventilation network, representing the area of the active coal face no. 2/3/VI, no. 1/3/VII.

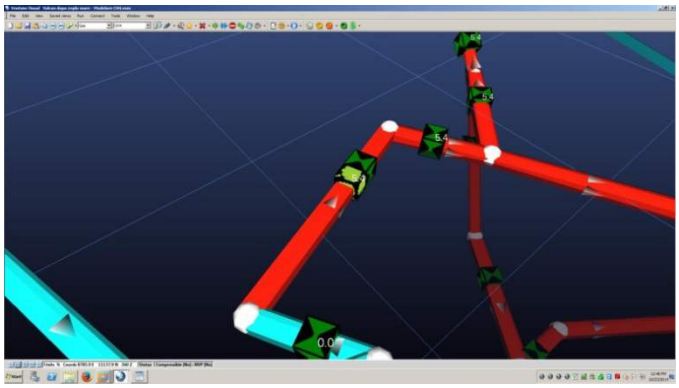

Figure 6. CH_4 dispersion in the undermined coal bed no. 2, layer no. 3, block VI

Following the simulation of methane dispersion at the level of the ventilation network, the following results have been obtained:

- CH_4 concentration at the level of the coal face with undermined coal bed no. 2, layer no. 3 bl. VI with unique no. 55, has a value of 5.4 % vol.;
- CH_4 concentration at the level of the face with undermined coal bed no. 1, layer no. 3 bl. VII with unique no. 191, has a value of 10.8 % vol.;
- CH_4 concentration at the level of the face with undermined coal bed no. 1, layer no. 3 bl. VIII with unique no. 214, has a value of 17.4 % vol.;
- CH_4 concentration at the level of the faces no. 1 – no. 4, layer no. 3 bl. VIII

with unique no. 223, has a value of 17.4 % vol.;
- On the ventilation shaft, branch with unique no. 274, CH_4 concentration is 0 % vol.

3.1.2 Simulation of CO_2 dispersion at ventilation network level

Figure 7 provides the simulation of carbon dioxide dispersion at the level of the ventilation network, representing the area of the active coal face no. 1/3/VIII.

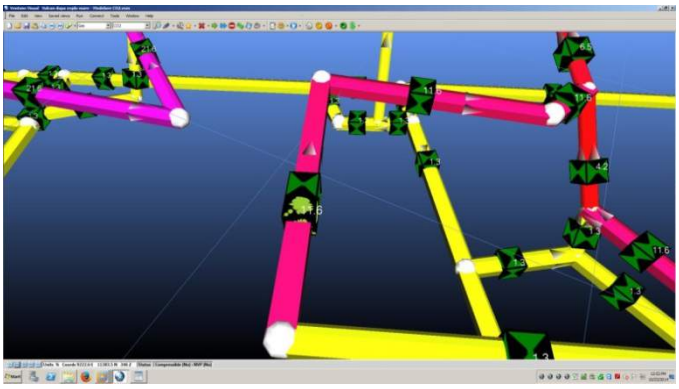

Figure 7. CO_2 dispersion in the undermined coal bed no. 1, layer no. 3, block VIII

Following the simulation of carbon dioxide dispersion at the level of the ventilation network, the following results have been obtained:
- CO_2 concentration at the level of the face with undermined coal bed no. 2, layer no. 3 bl. VI with unique no. 55, has a value of 3.6 % vol.;
- CO_2 concentration at the level of the face with undermined coal bed no. 1, layer no. 3 bl. VII with unique no. 191, has a value of 21.6 % vol.;
- CO_2 concentration at the level of the face with undermined coal bed no. 1, layer no. 3 bl. VIII with unique no. 214, has a value of 11.6 % vol.;
- CO_2 concentration at the level of the faces no. 1 – no. 4, layer no. 3 bl. VIII with unique no. 223, has a value of 11.6 % vol.;
- On the ventilation shaft, branch with unique no. 274, CO_2 concentration has a value of 1.5 % vol.
- At the level of the main ventilation station, branch no. 304, CO_2 concentration has a value of 0.1 % vol.

3.1.3 Simulation of CO dispersion at ventilation network level

Figure 8 presents a detail of the carbon oxide dispersion the level of Vulcan mine unit ventilation network, representing the area of the active coal face no. 1/3/VIII.

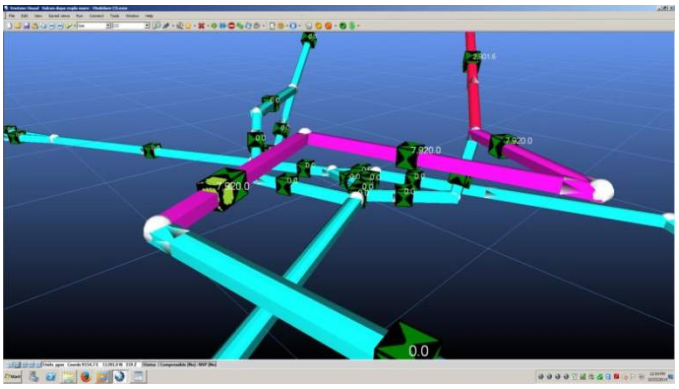

Figure 8. CO dispersion in the undermined coal bed no. 1, layer no. 3, block VII

Following the simulation of carbon oxide dispersion at the level of the ventilation network, the following results have been obtained:
- CO concentration at the level of the face with undermined coal bed no. 1, layer no. 3 bl. VII with unique no. 191, has a value of 7920.0 ppm;
- On the ventilation shaft, branch with unique no. 274, CO concentration has a value of 252.7 ppm;
- At the level of the main ventilation station, branch no. 304, CO concentration has a value of 5.7 ppm.

4 CONCLUSIONS

- Methane releases in areas of front faces is a complex phenomenon which depends in value and intensity on a series of natural-geological and technological factors.
- For establishing the methane, carbon dioxide and carbon monoxide concentration after the event there has been used the absolute gas flow method.

- Identifying environmental conditions after the occurrence of an explosion consists of the following phases:
- Simulation of explosive or toxic gases dispersion in normal exploitation conditions;
- Establishing the structure of the ventilation network after the occurrence of an explosion;
- Simulation of explosive or toxic gas dispersion after the occurrence of an explosion;
- Establishing explosive or toxic gas dispersion before and after the occurrence of an explosion, involves the following simulations at the level of Vulcan mine unit ventilation network:
  - CH_4 dispersion simulation;
  - CO_2 dispersion simulation;
  - CO dispersion simulation.
- Results on the dispersion of methane, carbon dioxide and carbon oxide after the occurrence of a high intensity explosion are the following:
  - CH_4 is present in coal faces and has concentrations of 5.4-1.4 % vol.;
  - CO_2 is present in coal faces and has concentrations of 3.6 – 21.6 % vol.;
  - CO is present only in one coal face and has a concentration of 7920.0 ppm.

Provenance of Organic Matter Preserved in the Chattanooga Shale at Hurricane Bridge, Tennessee, as Indicated by Organic Carbon Isotope

M. Musa and A. Swadan
Almergab University, Mesellata, Libya

J. Puckette
Oklahoma State University, Stillwater, Oklahoma, USA

ABSTRACT Stable isotopes of the organic carbon (δ13Corg) and organic carbon concentration in samples from the Upper Devonian -Chattanooga Shale were used to investigate sources of organic matter. Marine organic matter source that is characterized by more depleted δ13Corg is dominated in the Chattanooga Shale. Terrestrial organic matter was significantly contributed in the upper Dowelltown as indicated by some positive excursion of δ13Corg. These terrestrial spikes relatively have lower organic carbon contents. Most marine organic source (more negative organic δ13C) reflects good preservations of the organic carbon. A positive shift of δ13Corg at the base of the lower Gassaway member associated with high organic carbon contents (the highest in the entire formation) may reflect the global signature of the δ13Corg across the Frasnian-Famennian boundary. Variation in organic carbon content within the same level of marine organic source (same level of δ13Corg) may indicate variation in the intensity of organic matter productivity and or preservation conditions.

Keywords: Organic carbon, Chattanooga Shale, organic matter

1 INTRODUCTION

Organic carbon isotopes (δ13Corg) is reflected in the geologic timescales a reason that δ13Corg is used as a primary processes proxy (Philip, 1994). δ13Corg uses to distinguish between different sources of organic matter as a result of different CO2 sources using in their metabolisms (Alt-Epping et al., 2007; Lamb et al., 2006; Peters-Kottig et al., 2006; Philip, 1994, 2003; Tue et al., 2011). Phytoplankton favors utilizing lighter carbon isotope as a kinetics fractionation preferentially (Murphy et al., 2000). The fractionation of the δ13C is controlled by the rate of phytoplankton growth and the amount of dissolved CO2 (Bidigare et al., 1997; Laws et al., 1995). If the rate of growth increases or the reservoir of dissolved CO2 decreases, δ13C increases as a result of decreasing isotope fractionation between dissolved CO2 and photosynthesis (Murphy et al., 2000). In contrast decreasing the rate of growth or increasing in CO2 reservoir leads to increase carbon isotope fractionation resulting in depletion of δ13C (Murphy et al., 2000). Land plants are not largely influenced by surrounding CO2 as the phytoplanktons do because land plants use stomata to control CO2 diffusion (O'Leary, 1981). Consequently, carbon isotopes of land plants are not influenced by changes in the surrounding CO2 (gas) (Murphy et al., 2000).

Marine phytoplankton had tended to utilized lighter carbon isotopes compared to land plant during periods when the atmospheric CO2 was high compared to modern world (Arthur et al., 1988; Wenger et al., 1988). For instance, CO2 of the atmosphere was estimated as grater as six times from the present day at the end of Upper Devonian (McGhee, 2005). Consequentially, the concentrations of dissolved CO2 increased resulting high

isotope fractionation in marine organic matter that produced lighter (more negative) δ13Corg than land plants (Arthur et al., 1988). This pattern is opposite to what is observed in today marine and land organisms (Philip, 1994, 2003). (Maynard, 1981) illustrated that δ13Corg is strongly related to siliciclastic dispersal forms in the Catskill Delta of the Devonian Appellation Basin. These patterns show that the heavier δ13Corg is abundant at the shoreline area where coarse grain sediments (sandstone and siltstone) are dominated, while the lighter carbon isotope concentrates at the basin area that is characterized by mudstones rich (Maynard, 1981). This heavy and light δ13Corg distribution is opposite to what is observed in the present day shoreline and basin trends (e.g., (Kennicutt et al., 1987). Marine sources that are characterized by lighter δ13Corg than land plants have been observed in different locations and geological times. For instance, it is observed in Cretaceous rocks (Arthur et al., 1985; Dean et al., 1986), Devonian-Mississippian shales of Anadarko Basin (Sullivan, 1983) and Appalachian Basin (Maynard, 1981; Zielinski, 1977), and Jurassic shale in Germany (Küspert, 1982). The end-members of marine and land plant sources determined from Devonian Appalachian Basin have contributions of approximate -31‰ for marine plankton and -26‰ for land plants (Murphy et al., 2000). Contributions for marine and terrestrial sources were also estimated as -30.5 ‰ and -25 ‰ respectively (Maynard, 1981) in the upper Devonian at eastern United States. Therefore, the positive shifts of δ13Corg to the direction of -26 ‰ indicates increasing land plant influence, while a negative excursion to the direction of -31 ‰ indicates an increased influence in marine organic matter contributions.

The Chattanooga Shale formed from sediments deposited in the southwestern part of the Appalachian Basin (Figure 1), and is one of the a black shales that formed on the North America Craton during the Upper Devonian (de Witt et al., 1993). Economically, the Chatta=nooga Shale is considered an important hydrocarbon source rock (Charpentier et al., 1993; Comer and Hinch, 1987; Conant and Swanson, 1961; de Witt et al., 1993; Roen and Kepferle, 1993). The Chattanooga Shale was deposited in epicontinental shallow marine setting with low sedimentation rate on a low-relief shelf area (Breger and Brown, 1962; Conant and Swanson, 1961; Lobza and Schieber, 1999; Schieber, 1998b, 2001; Schieber and Riciputi, 2004). Sediments were carried from the east side of the basin and the perennial streams were dominate (Woodrow et al., 1988). Such environments may provide a significant amount of both terrestrial and marine organic matter. The mixing of land plant and marine organic matter in the Chattanooga Shale was remarked as indicated by kerogen analysis (Breger and Brown, 1962) and field observations (Conant and Swanson, 1961; Swanson et al., 1962). These studies were lacking to evaluate the variation of organic matter sources as they contribute in the entire Chattanooga Shale section. The objective of this study is to evaluate the contributions of marine and terrestrial organic matter sources in the Chattanooga Shale by using δ13Corg technique. Shale samples were collected from the Hurricane Bridge outcrop, DeKalb County, Tennessee, where the outcrop represents the reference section of the Chattanooga Shale (Kepferle and Roen, 1981).

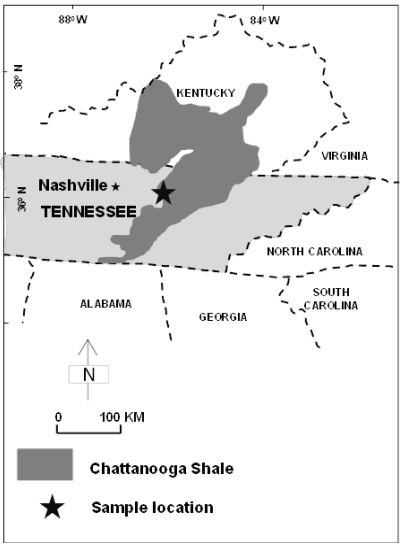

Figure 1. Sample location and geographic extent of the Chattanooga Shale [modify after de Witt, et al (1989).

2 THE EFFECT OF DIAGENESIS AND THERMAL MATURITY ON Δ13CORG IN THE STUDY SITE

Isotopic composition of organic matter could be affected by late diagenesis and metamorphic processes (Hoefs and Frey, 1976; Monin et al., 1981). The changing in the isotopes composition is estimated at about 1‰ as indicated by experiment carried out at 180 oC for several months (Schleser et al., 1999). Also the change recorded on wood material showed an increases by 0.5‰ at up to150 oC then decreasing about 1‰ up to 600 oC (Jones and Chaloner, 1991). With respect to δ13Corg alteration, no significant correlation between vitrinite reflectance and δ13Corg was observed (Strauss and Peters-Kottig, 2003). Other studies suggested that there is no systematic increase in carbon isotope concentration at temperatures below 250 oC or even approximate 350 oC (Schwarzkopf and Schoell, 1985; Watanabe et al., 1997; Whiticar, 1996). Generally, most studies suggest a common change of less than 1‰ (Peters-Kottig et al., 2006). Records show that δ13Corg keeps their original values even during organic matter transformation processes that include diagenesis, catagenesis, and metagenesis unless organic carbon and carbonate mineral isotopes exchange occur at high level of metamorphic processes (Schidlowski et al., 1983). It has been suggested that δ13Corg increases due to loss of lighter isotopes such as CH4 during organic matter transformation (Des Marais, 1992; Hayes, 1994; Hayes et al., 1983; Strauss et al., 1992). (Lewan, 1986) found that there is no significant changes in the carbon isotopes of the organic carbon in the Woodford Shale, the equivalent for the Chattanooga Shale, at different stages of thermal maturity a case that they could be used as a geochemical biomarker.

The estimated vitrinite reflectance of the Chattanooga Shale at the Hurricane Bridge outcrop and adjacent outcrops is less than 0.5% (Roberts, 1987). This low value (< 0.5%) is classified as immature source rock (Peters and Cassa, 1994; Wallace, 1977). Immature source organic rich shale has been affected by diagenesis processes without a significant influence of high temperature that is estimated between 60-80 oC (Peters and Cassa, 1994). As a result, the stable isotopes of the organic carbon in the Chattanooga Shale at the Hurricane Bridge outcrop should exhibit the original signature.starts immediately after a heading or a gap.

3 CHATTANOOGA SHALE GEOLOGY

The Upper Devonian-Chattanooga Shale was deposited in the Appalachian Basin as a part of hydrocarbon rich shales deposited in North America (de Witt et al., 1993). The name of the Chattanooga Shale was given by Hayes (1891) (Hayes, 1891). The thickness of the shale is approximately 10 m and thins westward. It represents deposition in a shallow marine setting with low sedimentation rate on a low-relief shelf area (Conant and Swanson, 1961; Schieber, 2001; Schieber and Riciputi, 2004). The study section of the Chattanooga Shale is located at the Hurricane Bridge outcrop, DeKalb County, Tennessee (Figure 1) where it is considered as a reference section of the Chattanooga Shale (Kepferle and Roen, 1981). The thickness of the Chattanooga shale in the Hurricane Bridge outcrop is approximately 10 m (Over, 2007; Schieber, 1998a; Schieber, 2001). The age of the Chattanooga Shale is Upper Devonian (Frasnian-Famennian) (Hass, 1956; Over, 2007). The shale is in regional disconformity with the underlying carbonate of the Liepers Formation and is subjacent to the Lower Carboniferous, Maury Formation, at the study section (Figure 2) (Conant and Swanson, 1961; Hass, 1956). The Chattanooga Shale is divided into three members; Hardian Sandstone (lower), Dowelltown (middle), and Gassaway (upper) (Conant and Swanson, 1961). The lowermost part (Hardian Sandstone) is only found in the southwestern Tennessee and it does not occur in the study area (Schieber, 1998a). The Dowelltown started at age of middle Frasnian as indicated by conodont biostratigraphy (Over, 2007) and it is divided further into lower and upper parts (Figure 2) (Conant and Swanson, 1961; Over, 2007;

Schieber, 1994a; Schieber, 1998a). The lower Dowelltown is about 2 m thick and consists of more resistant black shale interbeded with bioturbated gray shale (Conant and Swanson, 1961; Over, 2007; Schieber, 1994a; Schieber, 1998a). The upper Dowelltown is characterized by less resistant, more biotubated gray shale interbedded with black shale with a thickness of approximately 3 m (Conant and Swanson, 1961; Over, 2007; Schieber, 1994a; Schieber, 1998a). The Gassaway Member, Famennian (Ettensohn et al., 1989; Hass, 1956; Over, 2007) is also divided further into three parts (Figure 2) (Conant and Swanson, 1961; Over, 2007; Schieber, 1994a; Schieber, 1998a). The lower Gassaway is about 1.7 m and it consists of resistant dense black shale. The middle part of the Gassaway member consists of less resistant dark and light bioturbated gray shales with thickness about 1 m. The upper Gassaway member is about 2.5 m and it consists of black shales with interbedded lighter gray shale. The Frasnian-Famennian boundary in Chattanooga Shale is located at the base of the lower Gassaway Member as suggested by conodont stratigraphic study of the Chattanooga shale on different locations including the study site location (Over, 2002, 2007).

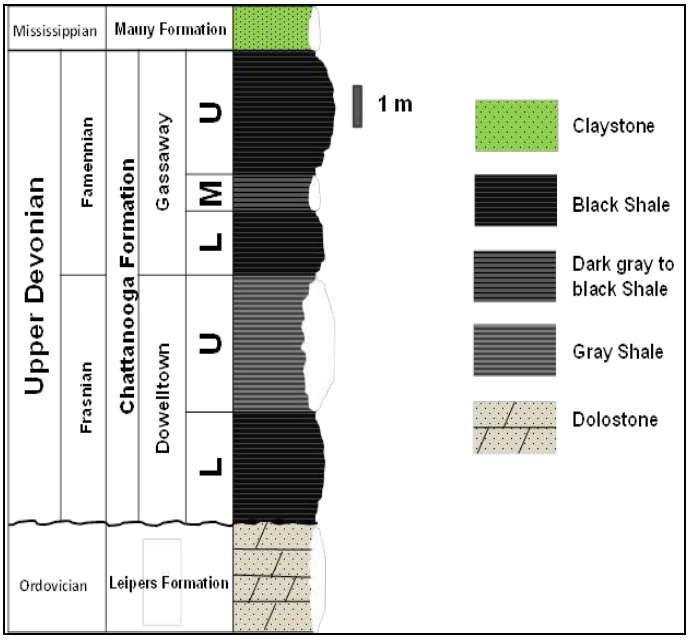

Figure 2. The stratigraphic profile of the Chattanooga Shale in the study area.

4 SAMPLING AND METHODS

Prior to collecting samples from the outcrop, weathered material was scraped away to access fresh, unweathered rock. Thirty three samples were collected at approximately 30 cm intervals from the Upper Devonian Chattanooga Shale at the Hurricane Bridge outcrop, TN. Samples were stored in plastic bags and labeled. Samples were powdered using a SPEX 8000 ball mill with alumina ceramic vial sets. Powdered samples were stored in labeled vials for further analyses. For stable isotopes of the organic carbon analysis, samples were acidified by applying 50 ml of hydrochloric acid (25%) to about 250 mg of powdered sample in centrifuge tubes for about 24 hours. All acid was removed by centrifuging the spent liquid first and then by adding ultrapure water three times and centrifuging. The residual samples were dried in an oven (60oC for 48 h) and stored in glass vials.

The concentrations of inorganic carbon (TIC) and total carbon (TC) were achieved by measuring the carbon through acidification with 2 N HCl and combustion at 950 oC under oxygen respectively. The mass for samples used in each run is about 50 mg. Pure calcite standards were reduplicate in both sides to calibrate the sample results. Finally, total organic carbon (TOC) for each sample was calculated by subtracting TIC from TC.

The concentrations of the δ13Corg in the samples were determined by processing acidified samples using a costech ECS 4010 combustion elemental analyzer that is connected to Thermo Finnigan Deltaplus XL mass spectrometer. Samples were folded in silver capsules in amounts ranges from 3 - 50 mg. the mass of samples was estimated based on a mass test done on different TOCs to give similar δ13C peak to that of the PDB. The USGS 40 (0.4 - 0.6 mg) and graphite (0.4 - 0.6 mg) standards were run after 10 sample sets to calibrate the results.

5 RESULTS AND DISCUSSION

The δ13Corg values varies across the Chattanooga Shale and it ranges from -28.4 ± 75 ‰ to -31.2 ± 0.75 ‰ with an average value of -30 ± 0.75 ‰ (Table 1; Figure 3). δ13Corg gradually decreases from the base of lower Dowelltown with a value of -29.35 ± 0.75 ‰ up to about half meter above the base of the Upper Dowelltown with value approximate -31.19 ± 0.75 ‰. Organic carbon content (TOC) in this interval increases from the base of the formation with value about 3 ± 5.7 wt. % until the middle of the lower Dowelltown at a height of 1 m where TOC is about 16 ± 5.7 wt. % then it gradually decreases to the base of the upper Gassaway with values of about 5 ± 5.7 wt. %. δ13Corg shows positive shift at the base of the upper Dowelltown from value about -31 ± 0.75 ‰ to about -28.5 ± 0.75 ‰. In the upper Dowelltown, δ13C generally shows enrichment/depletion fluctuations mostly with opposite directions to TOC (Table 1; Figure 3). For instance, at a height of 3.6 m δ13C is about -28.38 ± 0.75 ‰ and TOC is about 0.15 ± 5.7 wt. %, while at 4.6 m these values are about -30.8 ± 0.75 ‰ and 9.3 ± 5.7 wt. % respectively. A decreases in δ13Corg to values around -30 ‰ in the Devonian Appalachian Basin is interpreted as an increases in marine organic matter contributions, while increase around -26 ‰ indicates an increase in terrestrial organic matter sources (Maynard, 1981; Murphy et al., 2000; Zielinski, 1977). This depleted values in marine δ13Corg compared to land plants is related to the high fractionation between marine planktons and dissolved CO2 during periods when the atmospheric CO2 was high (Murphy et al., 2000). In the lower Dowelltown, decrease δ13Corg may indicate an increase in marine organic matter contributions that may lead to enhance organic matter preservation in this section especially in the lower part of the lower Dowelltown. A decline in TOC in the upper part of the lower Dowelltown may reflect a variation in organic matter productivity and/or preservation issues. Decrease δ13Corg to values of about -29 ‰ and less was interpreted as increasing marine organic matter sources (Strapoc et al., 2010). Strapoc et al (2010) showed that there is a strong relationship between more negative δ13C of the organic carbon (less than -29 ‰) and organic petrographic observations in the Upper Devonian-New Albany Shale. In contrast, an increase in δ13Corg in the upper Dwelltown may indicate increase in the contribution of the terrestrial organic matter. This may reflect that the area was in or very close to the shoreline that may have led to an increase in the oxygen concentrations that prohibited organic carbon preservation. This is consistent with the low TOC values that are associated with relative increase δ13Corg in the upper Dowelltown. Terrestrial organic source as indicated by δ13Corg is used as an indicator for the direction of the shoreline in Devonian shale at the Appellation Basin (Maynard, 1981) and in present day sediments (Kennicutt et al., 1987) by assuming that there is more terrestrial input near the shoreline than offshore. Sedimentology and stratigraphic studies have been done on the Chattanooga Shale at the same study section (Hurricane Bridge outcrop, TN) suggested that the dominate of the bioturbation gray shale and erosion surfaces in the upper Dowelltown represents periods where the water was more shallower than the interpreted black shale that was deposited in a more reduced environment (Schieber, 1994a; Schieber, 1998a).

At the base of the lower Gassaway Member, there is a sharp increase of δ13Corg from about -30.5 ± 0.75 ‰ at the top of the upper Dowelltown to -28.7 ± 0.75 ‰ at the base of the lower Gassaway. This is clearly indicting a positive excursion of δ13C in this interval that is also characterized by increasing TOC concentrations to about 20.7 ± 5.7 wt. % (Table 1; Figure 3). δ13Corg then gradually decreases throughout the top of the lower Gassaway. At the middle upper Gassaway δ13Corg remains semi constant with an average of -30 ± 0.1 ‰. In the upper Gassaway, δ13Corg is generally low with an approximate average of -30 ± 0.4 ‰ and it is slightly higher compared to the middle Gassaway. The organic carbon concentration in the lower, middle, and upper

Gassaway is generally high with averages of approximately 17 ± 2 wt. %, 8 ± 1 wt. %, and 15 ± 2 wt. % respectively. (Riquier et al., 2005)

A positive excursion at the base of the Gassaway Member is described by (Joachimski et al., 2002) as an unexpected shift through the Frasnian-Famennian boundary. This boundary is located at the study site (the Chattanooga Shale at Hurricane Bridge outcrop) at the base of the Gassaway member (Over, 2002, 2007). The shift in δ13Corg throughout Frasnian-Famennian boundary is interpreted as decreasing concentration of the dissolved CO2 that results in lower fractionation of carbon isotope during photosynthesis (Joachimski et al., 2002). The δ13Corg of marine algal biomarkers also exhibited identical trends to that of bulk organic carbon (Joachimski et al., 2002). Therefore, this positive shift of the δ13Corg may not reflect a change in the organic matter sources. We suggest that the marine organic matter may be dominate resulting high organic matter content due to increasing the sea level in that time that the depositional environment became more basinal areal. A major transgression during the begging of the Fammenian time when the Gassaway Member was deposited, was indicated by constraining the sea level curve (Johnson et al., 1985).

The relative decrease in δ13Corg through the top of the upper Gassaway to the end of the Gassaway Member may indicate an increase marine organic carbon contribution. May be some of the terrestrial organic matter sources caused the relative increase of δ13Corg at the top of the upper Gassaway. Increasing marine organic matter was interpreted as a shift from shoreline to more basinal environment (Kennicutt et al., 1987; Maynard, 1981). Thus, the dominance of marine organic sources in the Gassaway Member may indicate a shift of depositional environment from shoreline at upper Dowelltown to more basinal environment. This is consistent with the high organic carbon content in the Gassaway Member relative to the upper Dowelltown. Although the organic carbon concentrations are high in the Gassaway Member, the relative variation between member parts (e.g. TOC relatively low in middle Gassaway, Table 1; Figure 3) may indicate different organic matter productivity or preservation levels.

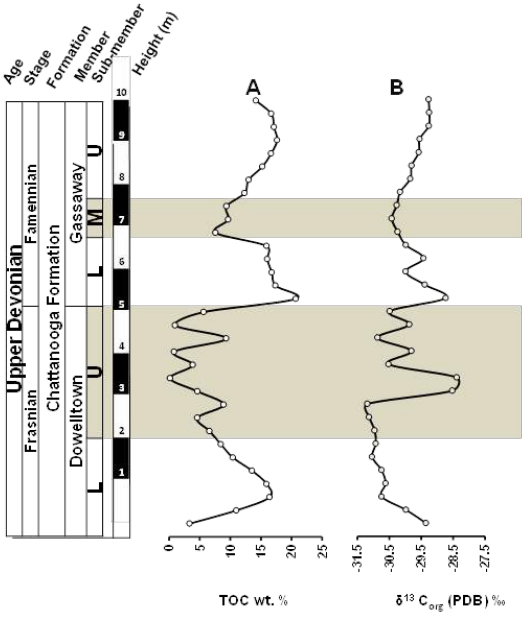

Figure 3. Total organic carbon (TOC) concentrations (A) and stable isotope of the organic carbon (δ13C) (B) in the Chattanooga Shale, Hurricane Bridge, Tennessee.

6 CONCLUSIONS

Organic matter preserved in the Chattanooga Shale appears to be mostly of marine origin, except where there was significant contribution of terrestrial origin in the upper Dowelltown. Marine and terrestrial organic matter resulted in different δ13Corg values where marine δ13Corg was more depleted than the terrestrial organic carbon. Marine organic matter in the most parts reflects high organic matter contents as indicated by organic carbon concentration (TOC). Variation in organic carbon content within levels of marine organic origin may reflect difference organic matter productivity/preservation levels. Most positive excursion reflects lower organic carbon contents, except the one at the base of the Gassaway member which may represent the unexpected spike of the Frasnian-Famennian boundary.

Estimation of Coal Gas Content Using Geostatistical Methods in GIS Environment: A Case Study From Tabas Coal Mine

V. Vaziri, J. Khademi Hamidi, A.R. Sayadi
Tarbiat Modares University, Tehran, Iran

ABSTRACT Coal gas content is one of the most effective parameters in safety and productivity of mechanized mining system. This gas can be explosive when it reaches a certain percentage of the mine air, i.e. lower explosive limit (LEL). Hence, knowledge about the coal gas content before exploitation operation is so necessary. This study uses geostatistical estimator to predict gas content of coal seams. First in this study, core data from 33 exploration boreholes in Tabas coal mine were gathered. Having preprocessed the quality of data and the absence of isotropy, Universal Kriging method was chosen as the best estimation method. Using estimation evaluation criteria, the best model among exponential, spherical and Gaussian model was selected. The map of gas content was plotted using of ArcGIS. Results showed that approximately 4% of total study area has the gas content less than 5 m^3/ton, and 7% between 5 and 10 m^3/ton. Meanwhile, in about 57% of total area, gas content more than 15 m^3/ton was predicted.

Keywords: Coal mining, Gas content, Geostatistical methods, ArcGIS

1 INTRODUCTION

Due to numerous advantages, such as coking and use in steel industry, coal has become a common energy carrier. However, coal mining, especially in underground mines, is one of the most dangerous industrial activities in each country. For example, according to the annual report of Social Security Organization (SSO) of Turkey in 2005, the coal industry in this country is in top of occupational diseases and disabilities, and also third and fifth places of fatal injuries and occupational injuries, respectively (US Bureau of Labor Statistics News, 2007). This type of disaster has been recognized worldwide as a potentially fatal and major hazard during the mining of gassy coal seams (Wold et al., 2008; Cao et al., 2001). Therefore, the most important task before coal extraction is to create a safe work environment. Hence, estimation of coal gas content before starting extraction in underground coal mines has a significant impact on safety and productivity.

There are various estimation methods for gas content among which Kriging is the most common. Almost half a century ago, kriging technique was used by Krig to estimate the distribution pattern of gold in South Africa mines. In this method, for choosing neighborhood radius, it is necessary to consider the maximum distance for which the data are spatially correlated. This work in kriging is done based on semivariogram, which is not involved in any other estimation techniques. In addition, data anisotropy detection and estimation error calculation and distribution are performed by using the same tool.

Geostatistical estimations have been widely used in mining engineering. Two dimensional kriging and co-kriging cross validation grade estimation results of the sample points were compared by using the data taken from Küre copper mine in Turkey and noted that the co-kriging technique estimates the variable with lower variance than the ordinary kriging. Moreover, the co-kriging estimation variance decreases as the block dimension increases (Yalcin, 2001). Kriging method was used to interpolate the content of feldspar in the entire granite deposit in order to characterize the saleable feldspar in a granite deposit, and they used

the same method to calculate the quantity of feldspar (Taboada, 2002).

A combination of geostatistical and GIS models has been used to estimate the amount of residual sulfur in coal beds (Watson et al., 2001). An example of integrated kriging technique and GIS is found in the work done by Diodato and Ceccarelli (2004). They used multivariate geostatistical technique of indicator kriging to detect and classify macro zones according to their tendency to soil degradation. Ahmed et al. (2007) used GIS to delineate the areas suited to soil degradation maps. A critical review of literature shows that integrated geostatistical and GIS have a good capability for estimation of quantitative parameters.

Because of long delays and significant down times across the extraction of w_1 panel in Tabas mechanized coal mine (i.e. due to high existing gas content of coal seam), the operation efficiency has been drastically decreased. It is expected that in deeper panels, due to high gas content gradient, the problems will be more than past. Hence, in this study, because of the ability of GIS in collecting, storing, analyzing spatial data, managing database, overlaying input parameters, validating output and providing the final model as a map, geostatistical estimation in GIS environment for estimating the gas content of coal seam in Tabas mine is used.

2 TABAS COAL MINE

Parvadeh-I is an underground coal mine located 85 kilometers south-east of Tabas city, southwest Khorasan province in east of Iran (Fig. 1). The total coal reserve is estimated 98 million ton (SKANSKA, IRASCO and IRITEC, 2002). The Tabas coal deposit includes five seams namely; C_1, B_1, B_2, C_2 and D. Currently, the seam C_1 is workable seam using mechanized longwall system. Within the mine, production started in 2007 using retreat system. The thickness and dip of seam mostly vary from 1.8 to 2 m and from 11 to 26°, respectively. The depth below surface changes between 100 and 680 m. Six main geological units including coal, mudstone, siltstone, sandy- siltstone and overburden are present in the mine area. A generalized stratigraphic column is shown in Fig. 2. Intermittently low strength sandstone and siltstone layers form the hanging wall of the coal seam. The footwall is formed by siltstone and mudstone seams, alternately. Totally, 27 longwall panels were planned for extraction by means of fully mechanized face. Up to date of this study, only three panels have been fully extracted. Panels' layout in Parvadeh-I of Tabas coal mine is shown in Fig. 1.

3 METHODOLOGY

Core data from 33 exploration boreholes in Tabas coal mine were gathered. Because of practical limitation and not being able to cover sampling in an area for gas content determination, interpolation method is utilized as a tool for analyzing and defining the amount of gas content in points where sampling was not performed. Therefore, Kriging technique is used for estimation of gas content of coal seam. The equation of Kriging is as following (Margaret, Carignan, 1997):

$$z^*(x_i) = \sum_{i=1}^{n} l_i z(x_i) \quad (1)$$

where; z^* is the estimated variable at x_i, l_i is the weight of i^{th} sample, $z(x_i)$ is the sample measured value and n is the number of samples. First, using histogram and QQ plot the normality of gas content data is evaluated. Having evaluated the normality in data distribution using histogram and semivariogram cloud, presence of global and local obvious outliers is studied. Meanwhile, using Statistical Package for the Social Sciences (SPSS) and ArcGIS, presence or absence of trend is determined. Finally, kriging method for gas content estimation was used. Considering the anisotropy in different steps, Semivariogram is plotted. Error evaluation criteria including MPE, RMSSPE, ASE and RMSPE are determined, accordingly the best model among exponential, spherical and Gaussian model is selected. Cross validation method to ensure the accuracy of estimation is used. Skochinsky & Komarov (1996) classification for classifying the amount of gas content of coal seam is presented. Finally, the map of gas content in Tabas coal mine is plotted. The proposed methodology is given as a flowchart in Fig.3.

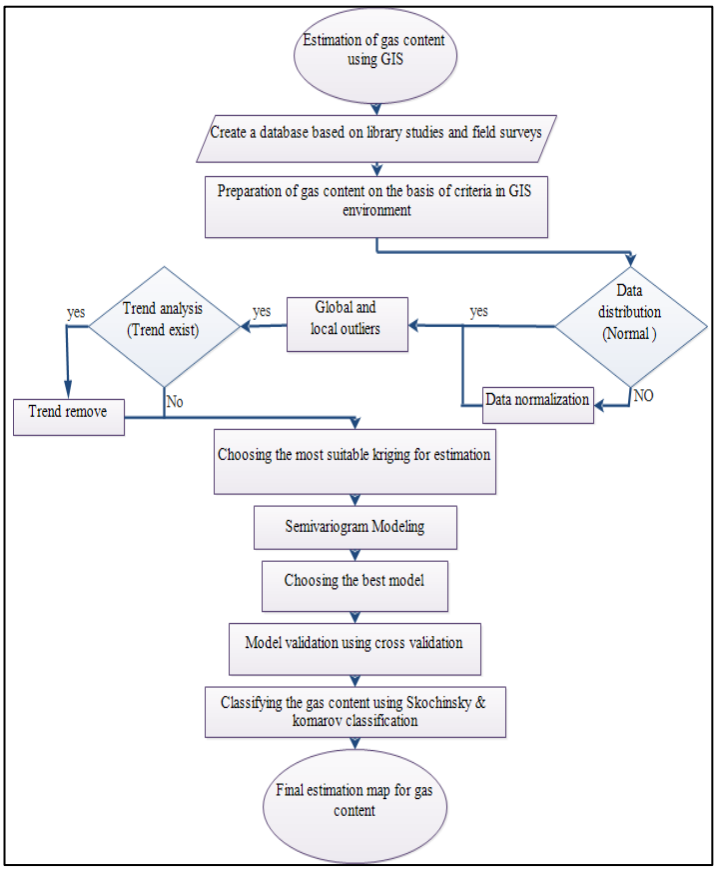

Figure 3. Flowchart of gas content estimation

4 EVALUATION OF GAS CONTENT CONDITION

4.1 Distribution of gas content data

Generally, the important features of the distribution are its central value, spread, and symmetry. (Johnston, K., et al., 2003). For normally distributed data, the mean and median should be similar, the skewness should be near zero, and the kurtosis should be near 3. If the data is highly skewed, then linear, box-cox or logarithmic techniques should be used to make a normal data distribution (Kamble and Aggrawal, 2011). Gas content data normalization survey was assessed with histogram and normal QQ plot. The results indicate that gas content data is not symmetric and don't have a normal distribution. So, the data redistribution is carried out by using logarithm method.

4.2 Global and local outliers

It is important to identify gas content outliers for two reasons: they may be real abnormalities in the phenomenon, or the value might have been measured or recorded

incorrectly. Global and local outliers were evaluated using histogram and semivariogram cloud. The analysis results reveal that there are neither global nor local outliers in gas content data in this study.

4.3 Trend analysis

Trend analysis for gas content data was performed using SPSS and ArcGIS as shown in Fig. 4. The points are projected onto the perpendicular planes, an east–west and a north–south plane. A best-fit line (a polynomial) is drawn through the projected points, which model trends in specific directions. If the line were flat, this would indicate that there would be no trend (Johnston, K., et al., 2003). As can be followed from Figs. 4a and 4b, the data seem to exhibit a strong trend in the north – south direction caused by increasing the depth (Z axis) and a weaker one in the east – west direction. So, before estimation, the trend of data was remedied.

4.4 Choosing the most appropriate kriging type for estimation

Because of trend existence in gas content data, universal kriging is used for estimation purpose. Once the trend is removed, the statistical analysis will be performed on the residuals or the short-range variation component of the surface. The trend will automatically be added back before the final surface is created so that the predictions produce meaningful results. By removing the trend, the analysis that is to follow will not be influenced by the trend, and once it is added back to the gas content, a more accurate surface will be produced. The semivariogram cloud allows one to examine the spatial autocorrelation between the measured sample points. In spatial autocorrelation, it is assumed that things that are close to one another are more alike (Johnston, K., et al., 2003). Variogram is calculated by the following equation (Margaret, Carignan, 1997):

$$\hat{\gamma}(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} \left[Z(x_i) - Z(x_i + h) \right]^2 \qquad (2)$$

where $Z(x_i)$ is the value of the examined variable at the position x_i, $Z(x_i+h)$ is the value of the examined variable at the position x_i+h and N is the number of pairs of sample points separated by distance h, called lag. To actually account for the directional influences on the semivariogram model, it is necessary to evaluate the anisotropy in different directions. Variography analyses of gas content in different directions show the maximum and minimum autocorrelation in 70° and 160° to the north direction, respectively. The semivariogram increases slowly in the north east – south west direction which represent the lowest violet line in the variography curve. Also, the semivariogram increases rapidly in south east - north west direction which is shown by the uppermost violet line in variography curve Fig.5.

So, the results show there is anisotropy in data and also, the major axis of the anisotropy ellipse is in NE-SW direction.

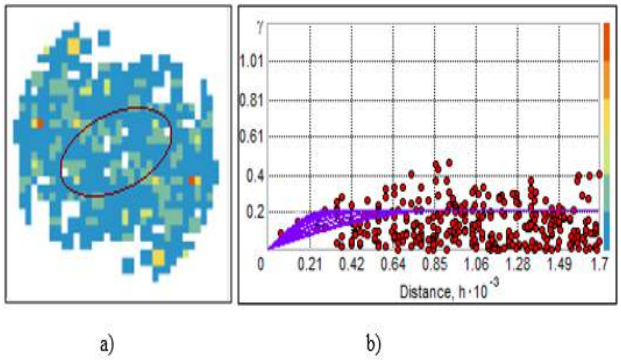

Fig.5. Gas content data evaluation; a) using semivariogram surface; b) using semivariogram plot.

4.4.1 Choosing the most appropriate model

ArcGIS have optimization functions to determine the best-fit parameters for a given variogram model. So, in cross validation, four statistics were evaluated for verification of the model outcomes. These statistics are standardized mean, root mean squared (RMS), root mean squared standardized (RMSS), average standard error and standardized mean. The most suitable model should have a standardized mean closest to 0, a smallest RMS value, an average standardized error that is close to the RMS prediction error and a RMS standardized value close to 1. Models that produce a RMS that is close to the average standard error is preferred more than the model that has a lower average standard error and a lower RMS (Burke, et al., 2013). Therefore, in this study, variography by Gaussian, spherical, and exponential models was performed. Based on these statistics, universal kriging seems to be the most suitable model as it has the smallest RMS value, a RMS standardized error close to 1 and an average standardized error that is close to the root mean square (Table. 1).

The values of other parameters showed in Table.2. The spherical semivariogram model fitted to gas content data is shown in Fig.6.

Table. 1. Calculated statistics of the cross validation

Model	Spherical	Exponential	Gaussian
MPE	0.0044	-0.0023	0.0015
RMSPE	0.4516	0.4478	0.4492
ASE	0.4737	0.4738	0.5071
MSPE	0.0044	-0.0054	-0.0013
RMSSPE	0.9525	0.9447	0.8871

Lag size	100
Number of Lags	17

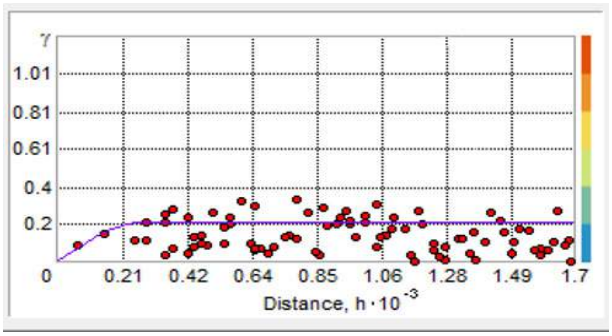

Fig.6. Spherical model of semivariogram for gas content data

4.4.2 Cross - validation

To check the suitability of model, cross validation is used. Cross-validation gives an idea of how well the model predicts the unknown values. For all points, cross validation sequentially omits a point, predicts its value using the rest of the data, and then

compares the measured with predicted values (Ahmed, et al., 2007). Results of cross validation for spherical model is shown in Fig.7. As seen in this figure, spherical model has an acceptable estimation accuracy.

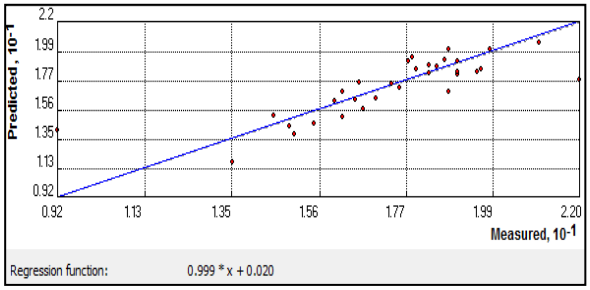

Fig.7. Cross – validation plot between predicted and measured data.

The term "prediction error" is used to check the difference between predicted and measured values of each borehole's gas content. The less the difference, the more accurate the model is. The measured and predicted values of seven boreholes along with prediction errors are given in Fig. 8. As seen in the figure, prediction error of each borehole is low, indicating the accuracy of the outcomes.

Source ID	Included	Measured	Predicted	Error
30	Yes	17.9	18.523	0.62301
0	Yes	18.6	18.139	-0.46061
21	Yes	18	18.227	0.22721
11	Yes	18.6	18.467	-0.13259

4.4.3 Gas content estimation map

With accurate geostatistical analysis on gas content data using classification showed in Table.3, the final prediction map of gas content using ArcGIS in Tabas coal mine was built. Areas with gas content of lower than 5 m^3/ton is shown with yellow color (first class), between 5-10 m^3/ton with yellow-brown (second class), between 10-15 m^3/ton with light brown and gas content of more than 15 m^3/ton is shown with dark brown.

Table.4. Coal gas content classification **(**Skochinsky and Komarov, 1996)

Gas content level (m^3/ton)	Definition	Color on map
0 - 5	First class	
5-10	Second class	
10 -15	Third class	
15 <	Over class	

Results of geostatistical analysis and gas content map in ArcGIS show that approximately 4% of total area has the gas content less than 5 m^3/ton and 7% between 5 and 10 m^3/ton. While, about 57% of total area has the gas content more than 15 m^3/ton which it seems a high gradient compared to world standards in similar depths. Hence, the risk of exploitation in this panels is very high (Fig.9).

The results of estimation map show high gas content for coal seams in Tabas coal mine. Experiences obtained during production in E_1, E_2 and W_1 panels show that the gas content is high.

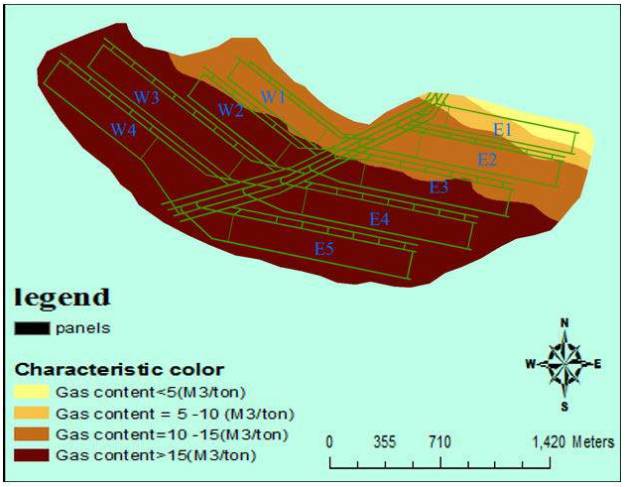

Fig.9. Gas content estimation map of Tabas mechanized coal mine

In Tabas coal mine, two methane gas detection systems are used: portable gas detector and fixed monitors. Portable detectors are designed to be hand-carried, so measurements can be made at any location. Fixed gas monitors are mounted at the ceiling, usually at the T-junction of tailgate and headgate and operate continuously.

The gas monitoring system includes a design that prevents the mining equipment from operating unless the gas monitoring system is functioning, an automatically controlling means that shut off power to the equipment when the gas concentration is 1.25 volume percent. This will provide a chance for mine crew to apply some emergency reactions such as adjustment of ventilation system or mine evacuation.

In Fig. 10, methane gas measurement for a period of one month (i.e. 21/04/2014 to 17/05/2014) during mining of panel W_1 is shown. The data were recorded by gas sensor installed in the tailgate. As seen in the figure, the methane gas concentration is generally high.

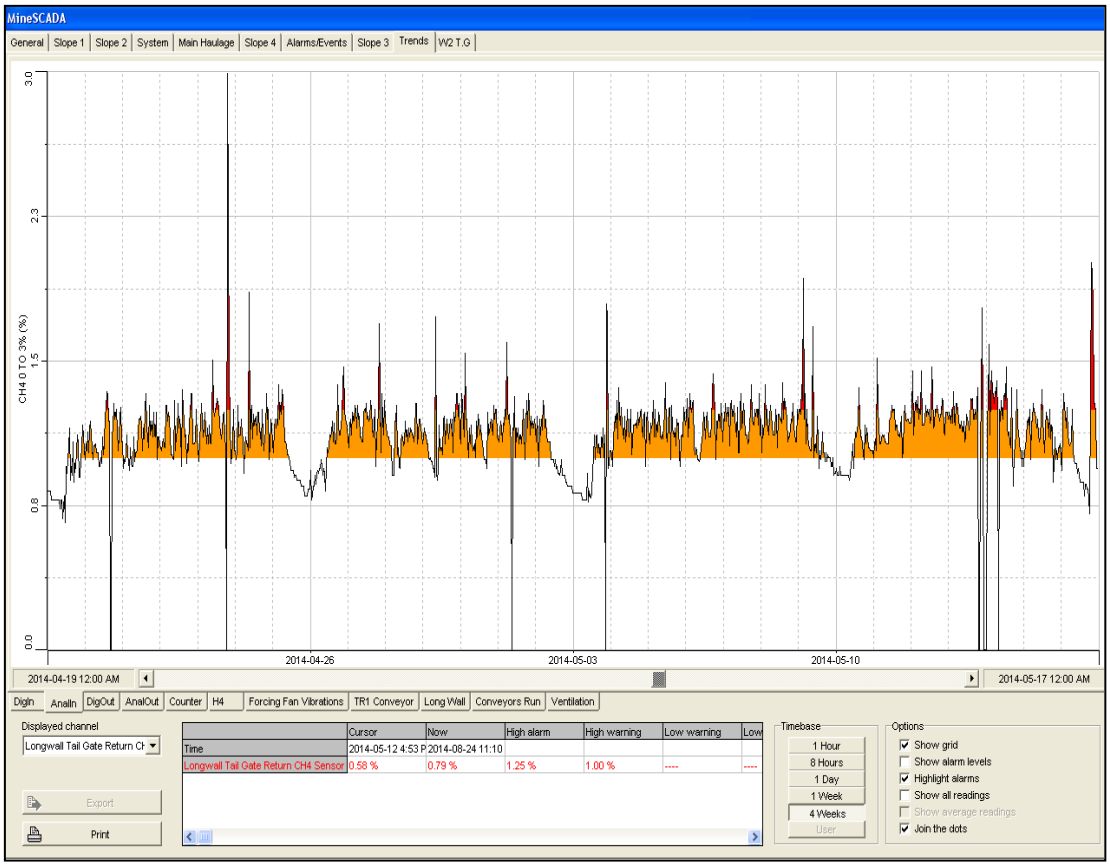

Fig.10. Methane gas concentration in W1 panel for the date; 21/04/14 to 17/05/14

Also, the gas concentration reached the maximum permissible value, i.e. 1.25%, several times a month, as shown in red colored areas in the figure. Meanwhile, the delays associated with the high gas concentration in W_1 panel for the same time period are given in Fig. 11. As can be followed from the figure, high gas concentration caused delays in mining operation, sometimes more than ten hours a day, which equals to more than a working shift.

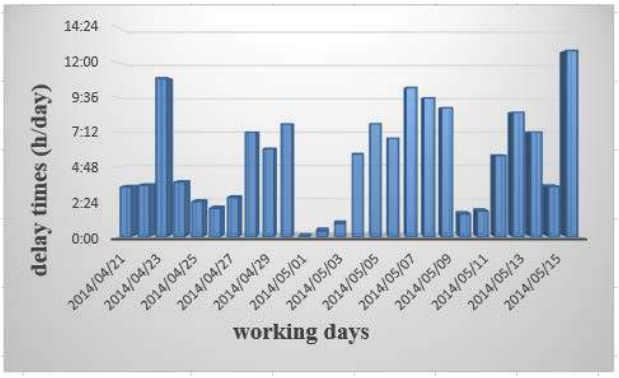

Fig.11. Delays associated with high gas concentration in W_1 panel for the date; 21/04/14 to 17/05/14

Figures 10 and 11 show that the coal gas content is generally high and expected to increase with the depth of coal seam, as

predicted and illustrated in ArcGIS map (Fig. 9). So, preventing or controlling the gas content of coal seam using methane gas drainage techniques is suggested for the panels that are under development or going to be worked in future in Tabas mechanized coal mine.

6 CONCLUSION

In this study, the gas content map of C_1 coal seam in Tabas coal mine was developed by using GIS. Having analyzed the normality distribution, global and local outliers and trend, the most appropriate method for estimation was selected. Due to existence of trend in gas content data, global kriging for interpolation was used. Accordingly, the variography was carried out on coal gas content data. Obtained results showed the anisotropy exists in data. The spherical semivariogram model was selected as offering the best fit to the estimated semivariance values. In order to check the estimation accuracy, cross validation was used. Totally, the results of estimation maps show high gas content of coal seams in Tabas coal mine. They show a high gas content even at shallow depths for which the gas content increases at 2 m^3/ton for every 100m in depth. This is a high gas gradient compared to World norms and standards. Also, estimation map shows that about 57% of total area has the gas content more than 15 cubic meter per ton of coal pertaining to over-class coal seams.

Uncertainty and Variability in Gas Desorption Measurements from Coal

J. Pope, A. Dutton & C. Nelson
CRL Energy Ltd, 97 Nazareth Ave, Christchurch, New Zealand.

ABSTRACT Total desorbed gas content of coal is used to estimate economic potential of coal bed methane resources and to identify hazards for underground mine operations. Total desorbed gas analysis of coal samples have several sources of uncertainty related to different approaches to sample collection, analysis equipment, data processing and calculation methods. The largest uncertainties that arise could cause up to about 25% variation in the measured total desorbed gas content when using methods that are compliant with published analytical standards.
Methods to minimize the uncertainties are well established, however are not always applied to data collection and analysis. In addition to analytical uncertainty, the total desorbed gas content of coal is variable between samples that are adjacent, even when robust and identical analytical methodologies are applied.
We present data on the scale of analytical uncertainties related to different aspects of data collection for total desorbed gas content of coal from data collected throughout New Zealand over the last 15 years.

Keywords: Gas desorption measurement, uncertainty minimization methods, variability

1 INTRODUCTION

Coal is a high surface area, micro-porous substrate that can store substantial quantities of gas as an adsorbed phase. Typically CH_4 and CO_2 are the most abundant gases adsorbed to *in-situ* coal and these are emplaced in coal either during coalification through thermogenic processes or after coal formation through biogenic processes (Butland and Moore, 2008). Gas content measurement of coal is commonly completed by desorption analysis and has two main applications;

1) to determine the size of coal bed methane resources for economic assessment,

2) to quantify gas that will be released when coal is disturbed by underground mining for hazard management.

In both of these applications the objective of gas content measurement is to determine the *in-situ* amount of gas stored in the coal recognizing that this value is often less than the total amount of gas that could be stored in the coal. The *in-situ* gas content of coal is dependent on many geological, geochemical, hydrogeological and biological processes.

The theory and approach to desorption analysis for both applications are identical and the same analytical standards apply. However the standard reference methods (ASTM, 2010) allow for quite variable, analysis methodologies, equipment, and data processing. The variability of results delivered by different methods is difficult to reconcile because duplicate samples cannot be collected and there is no standard reference material currently available for inter-laboratory comparison. In addition, there are uncertainties associated with quantification of gas in coal that are large and cannot easily be avoided.

As well as analytical uncertainty, coal is an inherently heterogeneous material and therefore has variable gas storage reservoir properties. There can be substantial variability in gas content spatially and stratigraphically in a coal deposit and also within samples from a single seam in a single drill hole.

We present examples of analytical uncertainty and variability from desorption data collected by CRL Energy Ltd over 15

years of service provision for coal bed methane exploration and coal mine methane gas measurement in New Zealand, Vietnam, Indonesia, China and Turkey. The method and data processing adopted by CRL evolved from a method developed by the US Bureau of Mines (Diamond and Levine, 1981) and currently operates within requirements of international standard reference methods (ASTM, 2010).

2 METHODS

Gas content measurement methods commonly measure or calculate three components of gas that can be desorbed from a coal core sample.

1) Gas that is desorbed between the time the sample is removed from its *in-situ* position by drilling operations and the time the sample is placed in a sealed vessel, commonly referred to as Lost Gas or Q1.
2) Gas that is desorbed from intact coal core in a sealed vessel, commonly referred to as Measured Gas or Q2.
3) Gas that is released by crushing coal, commonly referred to as Residual Gas or Q3.

In Australasia two approaches to gas content determination in coal have been applied and these are referred to as fast desorption and slow desorption (Australian Standard 1999). The difference in these approaches relates to the length of time that coal samples are stored in a sealed vessel while desorbed gas volumes are measured; this influences the ratio of the desorbed gas that is reported as Measured Gas (Q2) vs Residual Gas (Q3).

2.1 Lost Gas (Q1)

Lost Gas is calculated by extrapolation of data collected after the sample is sealed in the sample vessel. There are two main sources of uncertainty associated with lost gas calculations and these relate to assumptions regarding the point of time at which desorption of gas from the samples begins (time 0) and the method of extrapolation of measured data back to time 0.

We present a sensitivity analysis of the effect of assumptions related to time 0 and the use of different extrapolation methods for calculation of lost gas (Q1).

2.2 Measured Gas (Q2)

Measured gas is typically determined by either a falling head manometer or zero head manometer coupled to the air tight sample vessel (Figure 1). Gas volume measurements are accompanied by synchronous measurements of canister temperature and ambient pressure and all measured volumes are corrected to standard temperature and pressure (STP) conditions. Typically coal is desorbed at reservoir temperature with samples placed in a water bath or temperature controlled room to maintain constant temperature.

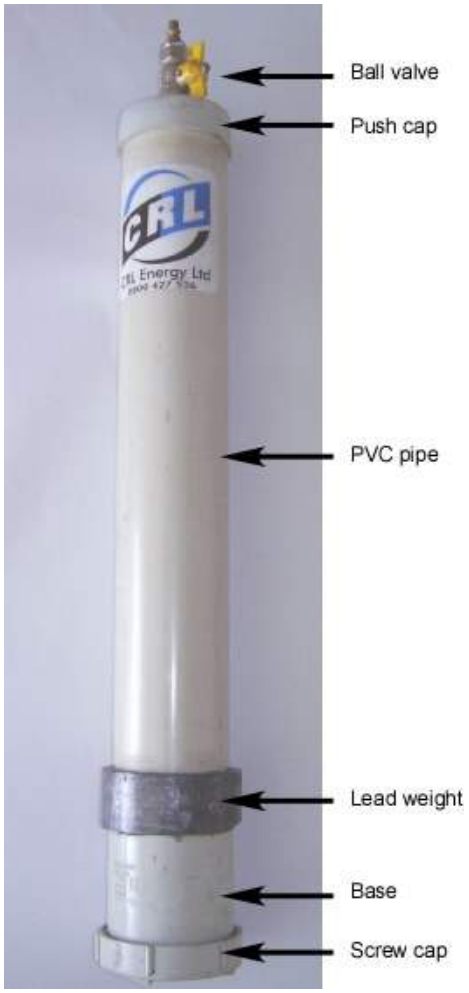

Figure 1. Sealed sample vessel for collection of measured gas. PVC construction is used for slow desorption only, similar stainless steel canisters are used for fast or slow desorption.

During data collection for slow desorption methods, gas volume measurements are commonly made until desorption diminishes to about 10mL/week for a ~1kg core sample. Volume measurements are made at regular intervals to ensure that the desorption rate from the coal is not influenced by pressure build up in the sample vessel.

During data collection for fast desorption gas volume measurements are made for between 1 and several days until the sample can be transported to a laboratory for Residual Gas determination.

There are several sources of uncertainty in Measured Gas data collection. These include operator bias, sensitivity differences between alternative equipment (including canisters with different headspace volumes and different types of manometer), gas solubility, partial pressure effects on gas desorption, oxidation of coal and differences in data processing.

In general, uncertainties related to Measured Gas are lower than those related to either Lost or Residual Gas. We present data that demonstrate oxygen depletion in headspace gas during desorption which increase analytical uncertainty if it is not corrected, and the influence of STP corrections on measured gas volumes.

2.3 Residual Gas (Q3)

Residual Gas analysis is completed by crushing one or more subsamples of core and use of similar manometer equipment to measure gas released during and immediately after the crush.

Uncertainty for Residual Gas analysis is mostly related to selection of representative subsample(s) and the number of subsamples that are analysed. In addition, there are differing crushing procedures and the potential for either re-adsorption of headspace gas by reactive surfaces exposed during crushing or overestimation of gas release due to heating of the sample and crushing apparatus.

Uncertainty related to Residual Gas calculation impacts fast desorption methods more than slow desorption methods because the proportion of residual gas compared to measured gas is higher in fast desorption samples. We present data showing the impact of subsample variability and crushing procedures on residual gas analysis.

3 RESULTS

Lost, Measured and Residual Gas are presented for samples collected from different coal fields in New Zealand using fast and slow desorption. Uncertainties associated with calculation of total gas are demonstrated through assessing the sensitivity of gas content to alternative interpretations related to desorption or alternative approaches to data processing.

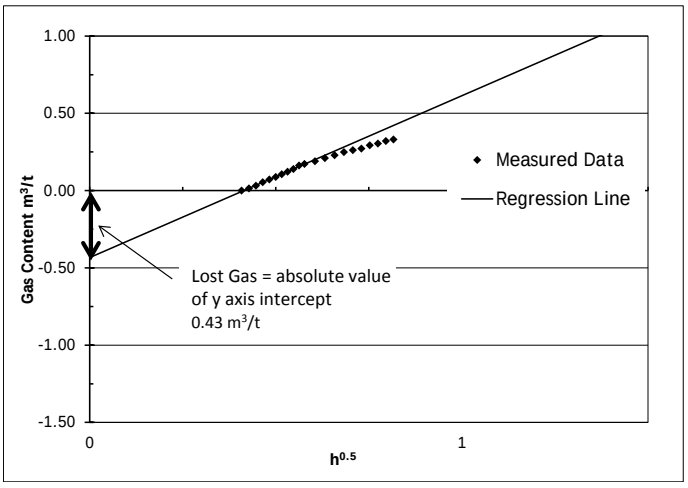
3.1 Uncertainties Related to Lost Gas

The largest potential source of uncertainty for lost gas analysis is poor interpretation or mistakes relating to selection of the onset of desorption (time 0). When coal samples are collected from surface drilling via wireline methods, the point at which desorption commences is the time at which drilling operations cause a reduction in pressure on the sample compared to the *in-situ* condition. For a sample where groundwater is saturated from topographic surface (or close to) the pressure reduction that initiates desorption occurs immediately the sample is removed from *in situ* during core retrieval. At this point in time, the pressure on the sample is not atmospheric pressure, instead the pressure reduces as the sample is winched upward by wireline. The most common approach in these circumstances is to assume time 0 is when the sample is at half of the *in situ* pressure when it is half way up the wireline and (and therefore has approximately half of the *in situ* groundwater head on it). This approach to identification of time 0 can be corrected for the density of drilling fluids if data is available (ASTM, 2010).

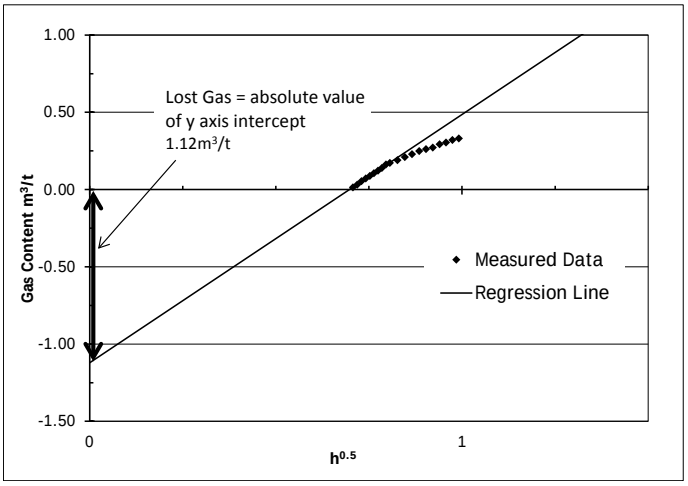
For samples that are collected from underground workings via inseam drilling, the onset of desorption is likely to be during the drilling operation when the low pressure

drilling fluid is in contact with the sample. Therefore it could be assumed that desorption starts during drilling of the sample. In these circumstances time 0 could be estimated as half way through the drilling process.

Inappropriate selection of time 0 strongly influences the lost gas calculations (Figure 2). Using exactly the same measured gas data from bituminous coal of the Greymouth Coalfield in New Zealand, lost gas varies between 0.43 and 1.12m^3/t by selecting time 0 during sample retrieval (appropriate for samples collected by surface sampling) or during drilling (for underground sampling).



(a)



(b)

Figure 2. a) Lost Gas extrapolation when time 0 is assumed to be half way through core retrieval by wireline. b) Lost Gas extrapolation when time 0 is assumed to be half way through coring of sample.

A second source of uncertainty for Lost Gas analysis arises from different approaches to extrapolating Measured Gas desorption data to time 0. The most common approach is to assume that early desorption data (less than 20 % of total desorbed gas) is released from the coal in a linear manner with respect to the square root of time (Bertard et al., 1970; Diamond and Schatzel, 1998) and to calculate lost gas from a linear regression. However, there are alternative interpretations and approaches to extrapolation of measured gas back to time 0 including a logarithmic approach (Chase, 1979) and an curve fit approach (Yee et al., 1993).

Differing approaches to correlation cause different values to be calculated for Lost Gas. Lost Gas varies between 0.25 and 0.35m^3/t using linear regression and a curve fit method respectively for identical measured gas data collected from sub-bituminous coal in the Huntly Coalfield in New Zealand (Figure 3).

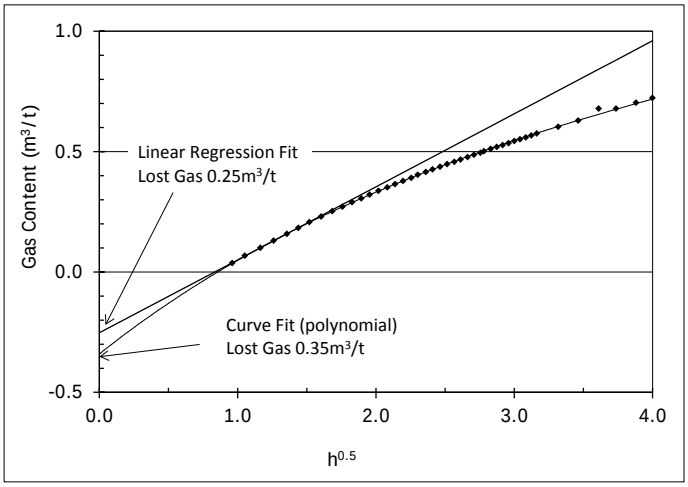


Figure 3. Lost Gas values calculated by linear regression compared to lost gas calculated by curve fit.

3.2 Uncertainties Related to Measured Gas

The main potential for uncertainty related to Measured Gas is caused by oxygen consumption in sample vessel headspace and corrections related to ambient pressure and temperature.

Gas composition analysis (Table 1) from air filled canister headspace using samples of sub-bituminous coal in New Zealand indicates that oxygen is consumed with time. Therefore the desorbed gas volumes that are measured are a mixture of gas released from the coal minus oxygen that is removed from the headspace volume by oxidation of coal (Jin et al., 2010). Inert gas (typically He or Ar) purging of headspace is commonly used to prevent oxidation especially for low rank coal. An alternative approach could be to complete multiple gas analyses of headspace gas over time and calculate a corrected desorbed volume that allows for oxygen consumption and dilution by desorbed gas.

Table 1: Example analyses gas samples showing O depletion. Methane has diluted the headspace by almost half of the total gas volume and the oxygen concentration had reduced by >75% indicating oxygen consumption as well as dilution.

Sample	CH_4	CO_2	N	O
Air	0	0.03	78	20.9
Gas from vessel	46.8	1.7	46.8	4.7

Correction of measured desorbed gas volumes for ambient pressure and temperature conditions at the time of measurement to STP (standard temperature and pressure) is critical for accurate analyses especially for long desorption datasets where many measurements are made over time with variable ambient conditions.

The Measured Gas from a sample of bituminous coal from the Pike River Coalfield in changes from 6.40 to 6.14m^3/t (Figure 4) if ambient pressures at the time of desorption are used instead of STP corrections, and from 6.40 to 6.52m^3/t if all volumes are assumed to be at STP during measurement (Figure 5).

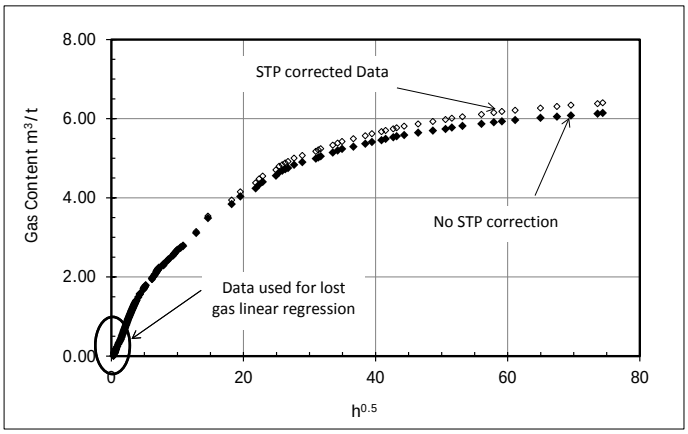

Figure 4. Example of the effect of STP correction to measured gas volumes. The size of this the difference between corrected data and non corrected data is proportional to the difference between measurement/ambient conditions and STP.

3.3 Uncertainties Related to Residual Gas

Subsample variability is the largest source of uncertainty related to Residual Gas measurement. This variability does not only reflect analytical uncertainty but indicates the heterogeneity of coal, which is variable at many different scales from microscopic to basin wide stratigraphy. Gas content varies with ash yield, coal type, maceral content (Masterlez et al., 2008; Moore et al., 2001) within the size of subsamples that can be collected for crushing.

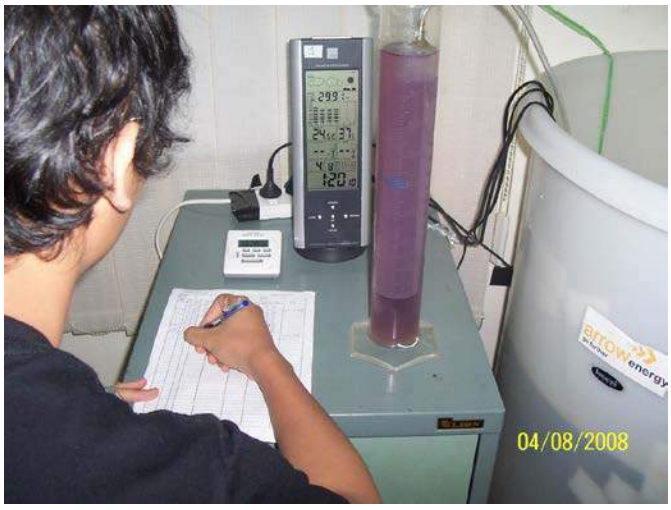

Figure 5. Collection of gas volume data using zero head manometer (nested measuring cylinders with pink die), ambient temperature and pressure measured with digital weather station and samples kept in water bath – (right hand side)

Residual gas content of samples of bituminous coal collected from the Greymouth Coalfield commonly vary by 30% and up to about 40% (Figure 6).

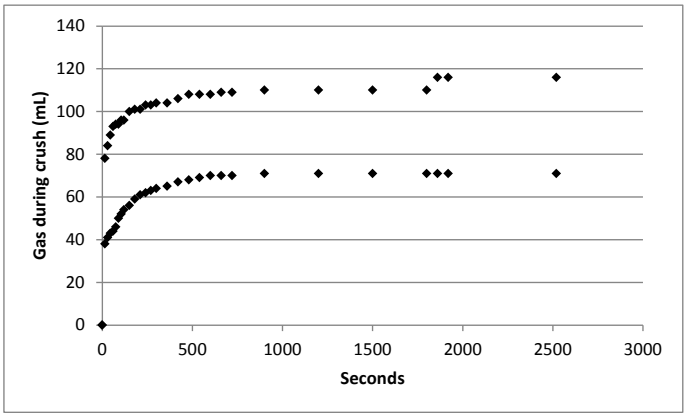

Figure 6. Gas released by different 100g residual gas sub-samples from bituminous coal samples collected in the Greymouth Coalfield. One sub-sample released 71mL and the other 116mL.

Crushing procedures also influence the residual gas content. Crushing requires 95% of the material passes through a 212µm sieve to ensure that all gas is removed from coal micro-pore spaces (ASTM, 2010). However, crushing for an extended period can cause the mill apparatus and sample to heat up and gas volumes can increase due to thermal expansion particularly in coals that is difficult to crush.

In addition, crushing procedures can lead to rapid oxidation of coal or readsorption of headspace gas causing the volume measured to be a mix gas released from pores and gas/oxygen depletion of the mill headspace. Argon purging of mill headspace prevents rapid oxidation or re-adsorption (Figure 7). In samples of lignite from the Mataura coalfield in New Zealand, up to half of the residual gas volume is lost by oxidation/re-adsorption if the mill is not purged with Ar.

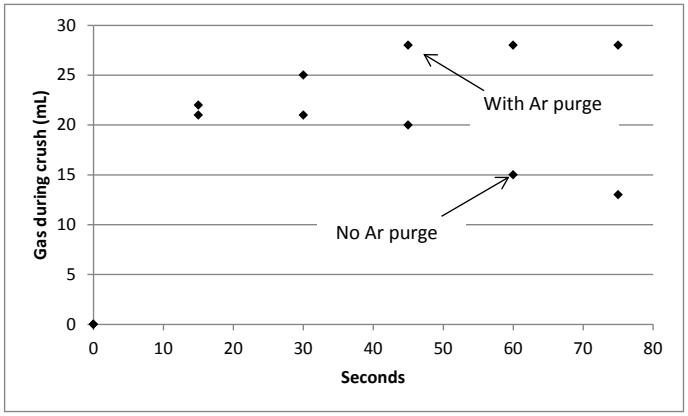

Figure 7. Residual Gas content during crushing of subsamples of lignite with and without Ar purge.

3.4 Gas Content Variability

Adjacent samples collected from the same seam and using identical desorption methodologies can be variable (Table 2). Samples collected from sub-bituminous coal in the Ohai Coalfield in New Zealand have greater than 25% variation over about 2m of continuous sampling. Adjustment of desorption data to a dry ash free basis can reduce variability of gas content, however variability of gas content commonly remains higher than variability of other analytical properties of coal.

Table 2. Selected slow desorption data from adjacent samples in the same drill hole. From and To depths in m and gas volumes in m^3/t (as received basis)

From	To	Lost	Measured	Residual	Total
464.2	464.7	0.39	5.54	0.26	6.19
464.7	465.2	0.39	5.24	0.26	5.89
465.2	465.6	0.15	5.16	0.26	5.57
465.6	466.0	0.21	4.3	0.26	4.78

Variability of desorption and adsorption analyses for coal seams have been researched (Mares et al., 2009) and in general multiple samples (at least 5) are required to obtain a robust value for gas content for a seam.

4 DISCUSSION

Uncertainties within gas content measurement can be large because of different approaches, assumptions and methodologies that are compliant with standardized methodologies.

Uncertainty related to lost gas can be significant if time 0 selection is inappropriate. The Lost Gas values derived can vary by more than 100% if this selection is inaccurate. Commonly, lost gas is 5 to 20% of the total desorbed gas content and therefore this uncertainty can cause up to about 20% variation in the total desorbed gas content. Smaller uncertainty in Lost Gas values also arise from selection of the correlation method used to extrapolate measured gas data to time 0.

Uncertainty related to Measured Gas content is generally low. However, variations in the application of STP correction could cause an uncertainty of up to about 5% of total desorbed gas. Oxygen consumption within sample vessel headspace can be measured especially in sub-bituminous coal and lignite and could be corrected with gas composition analysis if available. More commonly, inert gas purging of sample vessel headspace is used to prevent this uncertainty.

Sub sample selection for Residual Gas analysis can cause a 30-40% variation in the gas released on crushing. Where quick crush analytical methods are employed and Residual Gas can account for 50-70% of the total desorbed gas, this uncertainty can cause an analytical uncertainty of more than 25% of the total desorbed gas.

Natural variability in gas content is high with adjacent samples commonly varying by greater than 10% when analysed by the same method and assumptions. Statistical analysis of variability indicates multiple samples are required to adequately quantify the gas content of coal seams.

4.1 Minimizing Uncertainties

The uncertainties and variabilities in analysis methods for total desorbed gas content of a coal sample are large but they can be minimized. Uncertainties related to Lost Gas can be minimized by ensuring that Lost Gas is kept to a minimum as a proportion of total desorbed gas. This means that samples must be placed in sample desorption vessels as quickly as practical for collection of Measured Gas data. In addition, the assumptions related to time 0 for samples should be examined by a technical expert to ensure they are appropriate.

Uncertainties related to Measured Gas content are minimized by good data collection of ambient pressure and temperature and correction to STP conditions. Typically oxidation or re-adsorption headspace gas is minimized by inert gas purging of sample vessel headspace. However, in older datasets before publication of current standards (ASTM, 2010) oxidation or gas readsorption might remain an issue, especially for sub-bituminous coal or lignite.

Uncertainty related to Lost Gas analysis can be minimised by completing replicate analysis on 2 or 3 subsamples from each desorption sample. In addition, proximate analysis on the sub samples compared to the whole desorption sample could be used ensure that representative sub samples are collected. Uncertainty related to crushing is reduced if curves of Residual Gas release during crush are plotted (Figures 4 & 5) so that readsorption or thermal effects on the crushing apparatus are identified.

5 SUMMMARY AND CONCLUSION

Desorbed gas content of coal seams is commonly measured to examine the economic potential of coal bed methane or identify gas hazards for underground mining. We present data on several sources of uncertainty for the measurement of total desorbed gas content. These uncertainties can be large, causing up to about 25% uncertainty in the total measured gas content using analysis techniques that are compliant with standardized methods.

These uncertainties can be minimized by good analytical practice including:

- Robust assessment of time 0 by a technical specialist
- Purging desorption equipment with inert gas
- Sub-sample repetition for Residual Gas analysis with supporting proximate analysis

With the analytical uncertainties minimized the gas content of coal is spatially variable, even within adjacent samples in the same coal seam. Therefore, most accurate assessment of desorbed gas content of coal horizon requires assessment of multiple samples.

ACKNOWLEDGEMENTS

Data collected for this study is related to coal seam gas exploration and mining projects in New Zealand. We acknowledge the contribution of the anonymous New Zealand mining and exploration companies to collection of this data. Dr Jane Shearer (Resoultionz) provided robust review of this paper.

Study of Porosity and Permeability of Coal and Coal Measure Rocks from Raniganj Coalfield of India

B. K. Prusty, S. K. Pal, J. H. Kumar
Indian Institute of Technology, Kharagpur, India-721302.

ABSTRACT Porosity and permeability are critical reservoir properties that affect the flow behavior of methane in coal and coal measure rocks. The field-scale permeability is significantly different than the value determined in the laboratory. However, permeability is usually determined in the laboratory since it is less expensive. Porosity and permeability measurements were carried out in the laboratory using coal and coal measure rocks such as sandstone and shales from the Raniganj coalfields of India. The gas permeability was measured using the inert gas argon. Permeability of shale, coal and sandstone were found to be 0.022, 1.97, and 32.38 mD respectively. Porosity of the rocks was measured using the buoyancy method. Effective porosity values for coal, shale and sandstone were found to be 1.8, 12.38 and 17.31 % respectively. It was observed that the flow of gas deviated from the Darcy's law. An exponential relation between permeability and porosity was observed for coal and sandstone.

Keywords: Coal, coal measure rocks, porosity, permeability

1 INTRODUCTION

Permeability and porosity are the most important reservoir parameters which control the flow of fluid in porous rocks. Porosity is the measure of voids in the rock and is calculated as the ratio of volume of voids to the total rock volume. Porosity is generally measured in percentage. Effective porosity is the inter-connected voids in the rock that contributes to fluid flow. Permeability is the measure of the inter connectivity among the pores and is a measure of ease of flow of fluid in the porous medium through the connected pores. Permeability plays an important role incontrolling the economic viability of coal bed methane (CBM) reservoir. Permeability is a dynamic property and changes through the active life of reservoir.

Coal consists of cleats and fractures which contributes to the permeability of the CBM reservoir. The cleats are of two types, namely, face cleats which are continuous and butt cleats which are discontinuous; butt cleats terminate against face cleats. In general, face cleats contribute more to the permeability than the butt cleats. In addition to face cleats and butt cleats, there may be fractures and fissures present in the coal contributing to the permeability of the coal reservoir. The study of permeability and porosity of the coal and coal measure rocks are very important to quantify methane emissions in the mine as well as recovery of coal mine methane (CMM).

2 THEORETICAL BACKGROUND

In general, coal reservoirs are in equilibrium until some external processes like CBM recovery or enhanced CBM recovery are initiated. To recover CBM, the reservoir is depressurized by pumping off large volumes of formation water which leads to desorption of methane from the coal pores (Puri and Yee, 1990). Primary recovery method usually yields not more than 50% of gas in-place reserves (Murray, 1996). CBM recovery is enhanced by injecting a second gas such as CO_2into the coal. The recovery can go up to 90% of gas in-place while simultaneously a large quantity of CO_2can be sequestered (Stevens et al, 1999). Study

of porosity and permeability is very important both from the recovery of CBM and also to ascertain the CO_2 sequestration potential of the CBM reservoir.

When primary recovery starts, the fluid pressure starts to decrease and subsequently the effective stress increases. The increase in effective stress results incompaction of cleat/fracture leading to decrease in permeability (Gray, 1987). With lowering of fluid pressure below the equivalent sorption pressure, methane starts desorbing from the coal and this results in 'shrinkage' of coal matrix. The shrinkage associated with desorption opens up the cleats, and results in an increase in the permeability of coal. The increase of permeability depends on the initial in situ stress conditions and the shrinkage characteristics of the coal. The shrinkage of coal matrix with desorption may not only widen the cleats, but also reduce the effective horizontal stress. In fact, a very large shrinkage may even lead to a complete loss of horizontal stress. Overall, matrix shrinkage can have a significant impact on long-term gas production from coalbed methane reservoirs (Gray, 1987). Somerton et al (1975) conducted a series of permeability experiments on bituminous coals by flowing methane gas axially through a cylindrical coal specimen under specific stress conditions, and observed that the permeability is highly stress dependent. Hence, for CO_2 sequestration and enhanced coal bed methane recovery, it is very important to understand the impact of injection of CO_2 on the microstructure of coal and the resultant change in porosity and permeability.

The mechanisms of storage and transport of gas and water in coal differ from that of conventional gas reservoirs. Figure 1 illustrates the mechanism of transportation of gas in coal, which occurs in two steps: flow in cleat and fractures, and flow in coal matrix. Flow in the cleat system is pressure-driven and is described using Darcy's law, whereas flow through the matrix is by diffusion. The basic law governing the flow of fluids through the fractures and cleats is the Darcy's law which is given below.

$$q \propto \frac{\Delta P}{L} \tag{1}$$

The proportionality constant is found to be dependent on the viscosity property of the flowing fluid and Equation 1 can be re-written as;

$$q = \frac{Q}{A} = k\frac{(P_1 - P_2)}{\mu L} \tag{2}$$

q = flux rate or pore velocity m/s.
Q = Total discharge rate, m^3/s.
A = Cross sectional area to the flow, m^2.
k = Permeability of the rock, milliDarcy.
P_1, P_2= Pressures across the fluid flow in a porous medium, N/m^2.
μ = Viscosity of the fluid, kg/m.s
L =Length of the sample, m.

Darcy's law does not hold good for flow of compressible fluids like gas at higher pressures and has been modified as below:

$$Q = k_c \frac{A\{P_1^{(1+m_1)} - P_2^{(1+m_1)}\}}{(1+m_1)P_2^{m_1}} \tag{3}$$

where k_c is the permeability coefficient for compressible fluid.

m_1 = constant determined by thermodynamic character of flow (m_1=1 for isothermal flow).

$$Q = k_c \frac{A\,(P_1^2 - P_2^2)}{2\mu L P_2} \tag{4}$$

$$k_c = \frac{Q\mu L P_2}{A P_m (P_1 - P_2)} \tag{5}$$

Where $P_m$is the mean pressure across the sample and may be assumed to be the average of P_1 and P_2.The Equation 4 may be re-written as:

$$k_c = \frac{2Q\mu L}{A}\frac{P_2}{P_1^2 - P_2^2} \quad \text{(in Darcy)} \tag{6}$$

$$k_c = \frac{2000Q\mu L}{A}\frac{P_2}{P_1^2 - P_2^2} \quad \text{(in milliDarcy)} \tag{7}$$

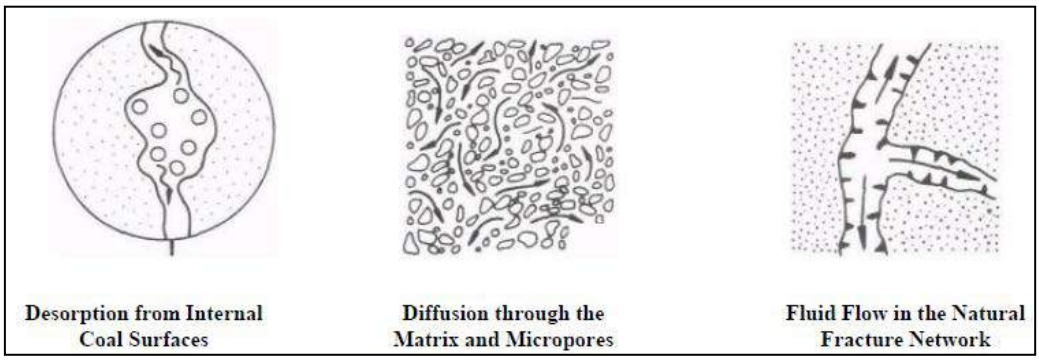

Figure 1. Methane transport mechanism in coal (Law and Rice, 1993).

2.1 Klinkenberg Effect

It has been observed that there is deviation from Darcy's law for flow of gas in porous medium. The permeability of rocks for gas is different from that for water. Permeability of porous rocks to gases is approximately a linear function of pressure under steady state and laminar flow. Klinkenberg observed that the permeability of air (gas) is more than the water (liquid) in porous medium. Liquid (water) generally possess zero velocity at the sand grain surface and gases possess some finite velocity. This is due to the gas slippage or the Klinkenberg effect. (Jones and Owens, 1980). The amount of slippage is directly proportional to the frequency of molecular collisions or the mean free path of the flowing gas. The Klinkenberg effect is more in rocks of low permeability. Considering the Klinkenberg effect, the coefficient of gas permeability is given by Ohle (1951) as:

$$k_g = -\frac{Q_m \mu L}{A(P_1 - P_2)} + \frac{4C}{P_m r_{av}} \quad (8)$$

where, P_m=mean pressure
Q_m= mean flow rate
k_g = coefficient of gas permeability
C= ratio of mean free path to the reciprocal of mean pressure
P_1=gas inlet pressure
P_2 =gas outlet pressure
r_{av}= average capillary radius for slip correction

2.2 Permeability and Pore Structure

Permeability of any porous medium is dependent upon whether the pores are interconnected or not and on the size of pores. Porosity of rocks is of two types: total porosity and effective porosity. In most rocks, many pores are blind at one end and these pores do not allow any flow across them. Thus rocks having same porosity may have different permeability depending upon the degree of interconnection between pores in the direction of flow. Further, the size of the pores has effect on the permeability. For example, shales usually have large porosity; however most of the pores of shales are of very small size of the order of nanometer and many of the pores are closed pores. These small pores offer high resistance to flow resulting in very less permeability of shales. For the flow of gas in rocks, the effective porosity is more important rather than the total porosity.

3 LITERATURE SURVEY

Gensterblum et al. (2014) studied the interaction between the coupling of slip-flow of gases and the cleat volume compressibility of coals using two Australian samples from Surat Basin, Queensland. Permeability measurements were performed using inert(helium and argon) and sorbing gases (nitrogen, methane and carbon dioxide) as the permeating fluid and at varying effective stress. Apparent permeability coefficients decreased in the order: helium >argon>nitrogen > methane>carbon dioxide. It was suggested that the Darcy equation, which is derived using the ideal gas law has a reduced validity for non-ideal gases like N_2, CH_4 and CO_2.

Adeboye and Bustin (2013) investigated the flow properties (permeability and diffusivity) of sub-bituminous to high

volatile bituminous coals from the Horseshoe Canyon and Mannville formations of the Western Canada Sedimentary Basin using both solid coal plugs and crushed samples (20–30mesh). Permeability of crushed coal ranged from 1.46E−5 mD to 7.6E−3 mDand that for coal plug ranged between 0.01 to 0.38 mD. This difference of up to four orders of magnitude between crushed and coal plug permeability is attributed to different stress conditions during sample testing and the influence of cleats and fractures on coal plug permeability. Increasing effective stress, with all other factors kept constant, leads to a decrease in coal plug permeability. Coal plug permeability declines exponentially with increasing effective stress which is attributed to the closure of permeability pathways due to compaction of coal at high effective stress levels. Probe gas type influences plug permeability. Helium permeability measurements are higher than permeability measured with methane or nitrogen. Permeability difference with probe gas is attributed to a combination of different probe gas molecule size, relative swelling effects of probe gas on coal and associated changes at in-situ stress during tests.

Letham (2011) studied the matrix permeability of low permeable gas shale. At pressures less than 4 MPa, matrix permeability of gas shales show a strong dependence upon the pore pressure. In case of gas flow in porous media in the low pressure regime, the Darcy's Law breaks down and gas slippage dominates. In gas shales, the range of pore pressures where gas slippage is recognizable is larger than in conventional reservoir rocks. This is due to smaller pore sizes in the gas shales. The molecular size of the probing/permeating gas will also influence the matrix permeability. Thus, matrix permeability determined using helium as a probing gas will be different than when methane is used.

Cui et al. (2009) measured permeability in gas shales, coal, and tight gas sands using gases with larger adsorption potentials than He, such as N_2. This study measured permeability using the pulse-decay measurement technique and considering the effect of gas adsorption. They explained that this new approach of permeability measurement is more reliable and theoretically accurate.

4 MATERIALS AND METHODS

4.1 Sample Description

Coal, sandstone and shale blocks from Raniganj coalfields were collected to study porosity and permeability. For porosity measurement, cylindrical core samples of 22 mm diameter and nearly 25 mm long are used. For gas permeability measurement core samples of 54 mm diameter and 57-59 mm in length are cut using the Bosch2000 model rotary drill in the laboratory. The two ends of the cylindrical core sample are smoothened to remove irregularities. Care is taken to ensure that the two circular ends of the core are perpendicular to the axis of the cylindrical specimen.

4.2 Experimental Setup to Measure Porosity

The effective porosity of the rock samples are measured using a setup based on the buoyancy method. The schematic of the setup is shown in Figure 2. The experimental setup consists of a vacuum pump connected to a vacuum desiccator containing samples through two 3-way stop cocks A and B. One end of stop cock A is connected to a vacuum gauge having minimum graduation of 1 torr and one end of the stop cock B is connected to a bottle filled with deaerated water. All connections are made permanent and leak-proof using araldite. The total system is checked for leakage. Stop cocks A and B are turned such that vacuum pump is directly connected to the vacuum desiccator and the pump is switched on to evacuate the desiccator. The pump continues to evacuate till the vacuum gauge shows 5 torr. At a vacuum gauge reading of 5 torr, the stop cock A is turned to connect the desiccator and the vacuum gauge, thereby isolating the pump from the system. Now the system is kept in vacuum for 24 hours. Then the stop cock B is turned slowly to connect vacuum

desiccator and the water bottle. Water is sucked into the desiccator and when the samples are completely submerged under water, stop cock B is turned off to stop further water inflow. Another 24 hours are allowed for samples to be submerged under water at normal atmospheric pressure. Samples are then transferred to a beaker containing deaerated water. Each sample is tied to a string and hung from the hook of a balance and weighed while the sample is still immersed in the water. Then the sample is removed from water and string is untied and surface-water is quickly absorbed on a blotting paper and the weight of the saturated sample in air is measured. The sample is then dried for 24 hours at 110 °C in an oven and transferred to a desiccator. After cooling, the sample is weighed again. The step-wise experimental and computational procedures are given as below:

1. Clean and dry the rock.
2. Fully saturate the rock in de-aerated water as explained above.
3. Weigh the saturated sample suspended in the water bath to give its submerged weight, W_{sub} as shown in Figure 3.
4. Remove the surface water from the sample by mopping with a blotting paper and measure the weight of the saturated sample in air (W_{sat}).
5. Dry the sample in the oven for 24 hours at 110 °C in a hot-air oven and take the dry weight (W_{dry}).
6. The effective porosity($\emptyset_e$) is calculated using the formulae:

$$\emptyset_e = \frac{W_{sat}-W_{dry}}{W_{sat}-W_{sub}} * 100 \text{ (in \%)} \qquad (9)$$

4.3 Experimental Setup and Procedure to Measure Permeability

The setup used to measure permeability is shown in Figure 4. It consists of rock sample holder, leveling bottle, burette, pressure transducer and transparent water bath. The sample holder contains stainless steel sleeve in which the sample core is cast using araldite. The steel sleeve is held at the center of the sample holder by two flanges on either side. A pressure transducer is connected to the 3-way inlet valve and a digital display shows the inlet pressure. The setup is first

tested for leakage under the highest working pressure. Permeability of the core sample is measured by flowing a fluid of known viscosity while maintaining a set pressure difference across the core. The fluid used is usually an inert gas. In this study, Argon gas has been used. The Argon gas cylinder is connected to one end of the sample holder by high pressure tubes. The other end of the sample holder is connected to a graduated 50 cm^3 glass burette through a flexible polyethylene tube. One end of the burette is fitted with a 3-way stop cock which allows bleeding of the gas when the measurements are not taken. The other end of the burette is connected to a leveling bottle through a flexible polyethylene tube for measuring gas flow rate under atmospheric pressure condition. The barometric pressure and room temperature are recorded while conducting the experiment. The following steps are performed sequentially to determine permeability.

1. The core sample is kept in the steel casing and araldite is applied. It is ensured that there is no gas leakage along the walls of the casing.
2. The two ends of the rock sample are smoothened to remove the irregularities.
3. The core casing is placed in the setup and the bolts are tightened.
4. After connecting the inlet and outlet valves, the setup is again checked for leakage.
5. The inlet pressure is set to the desired constant value.
6. Under the set pressure difference, the time required for 25 ml of gas to flow through the sample is measured by a stop watch.
7. The atmospheric pressure and temperature are noted.
8. The above procedure is repeated for different set pressure differences.

5 RESULTS AND DISCUSSIONS

The permeability and effective porosity values of the studied samples are shown in Table 1.It can be seen that sandstone sample-2 has high effective porosity and permeability of 17.31% and 32.38 mD respectively. Shale has 12.38% of effective porosity and very low permeability value of 0.022 mD respectively.

Table 1. Effective porosity and permeability of the coal measure rocks.

Sl. No.	Sample	Effective Porosity (%)	Permeability (mD)
1	Coal	1.825	1.975
2	Sandstone-1	6.34	1.632
3	Sandstone-2	17.31	32.38
5	Shale	12.38	0.022

The relationship between the applied pressure gradient, $(\Delta P/L)$, and the resulting flow rate per unit cross-sectional area of gas through different rock and coal samples are plotted in Figures 5-7.

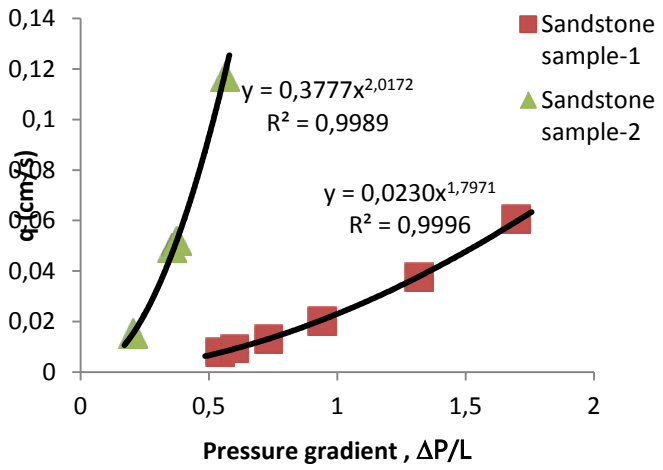

Figure 5. Flux rate versus pressure gradient for sandstone samples.

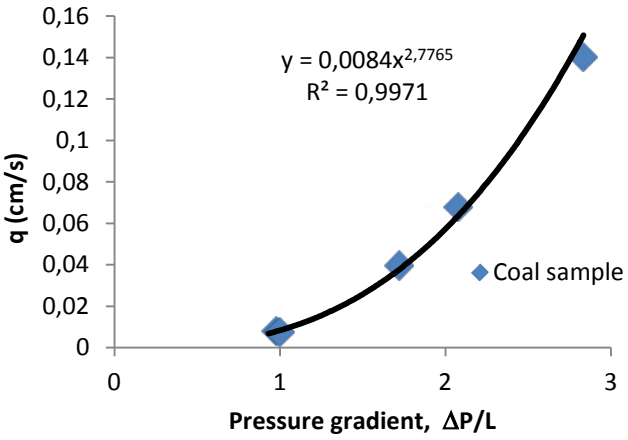

Figure 6. Flux rate versus pressure gradient for coal sample.

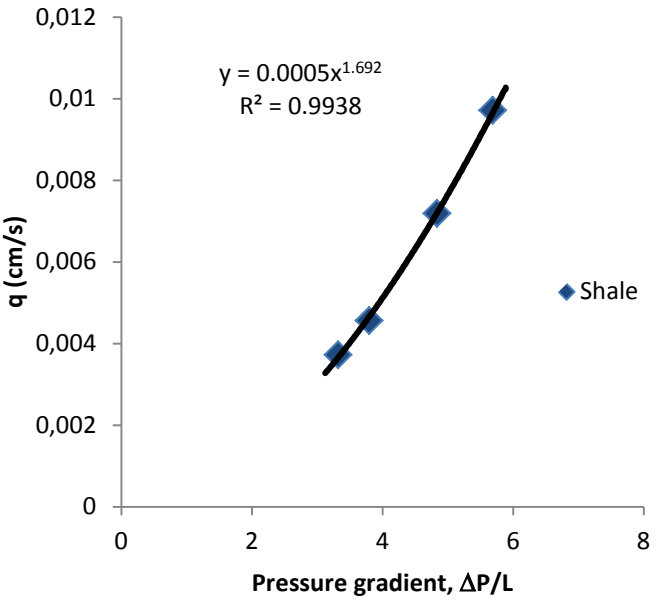

Figure 7. Flux rate versus pressure gradient for shale sample.

The relationship between the flow rate and pressure gradient has been observed in the form of Equation 10.

$$q = a\left(\frac{\Delta P}{L}\right)^{m} \quad (10)$$

Where a and m are constants. The values of a, m and the coefficient of correlation (R^2) values are given in Table 2.

Table 2. a, m and R^2 for the flow equation.

Sl. No.	Sample	a	m	R^2
1	Coal	0.0084	2.776	0.99
2	Sandstone-1	0.023	1.797	0.99
3	Sandstone-2	0.377	2.017	0.99
5	Shale	0.0005	1.692	0.99

The above data indicate that the gas flow equation is non-Darcy. The value of index m is greater than one, and it suggests that a large increase in flow rate corresponds to a small increment in pressure rise. This is possible when the total cross-sectional area of flow increases with increase in inlet pressure. The increase in cross-sectional area of inter-connected pores can occur due to elastic compression of isolated pores in rocks owing to higher static fluid pressure acting normal to the pore-walls. In the experiment, enlargement of inter-connected pores occur during continued step-wise pressure increment of the flowing gas, through gradual compression of isolated pores. The rock samples are capable of accommodating this temporary elastic deformation of the pores. The gas permeability co-efficient is calculated from Equation 6 and are presented in Table 3.

Table 3.Gas permeability experimental results.

		31.1	1.018	0.256	0.0248	

The Equation 6 can be re-written as:

$$\frac{1000QP_2}{P_1-P_2} = k_c \frac{AP_m}{\mu L} \quad (11)$$

The *permeability plot*, i.e., plot between $\frac{1000QP_2}{P_1-P_2}$ and $\frac{AP_m}{\mu L}$, should be a straight line passing through the origin. The permeability plots are shown in Figures 8-10. It can be seen that the plots are linear but not passing through the origin. The plots not passing through the origin may be due to:

1. The thermodynamic character of flow may not be isothermal where index m_1 is considered as one.
2. Elastic expansion of inter-connected flow path at higher pressures.
3. The molecular effect due to slip flow of gas. This effect is important in the case of pore diameter compared to or less than the mean free path of the flowing gas.
4. The wall effect in sample holder of the permeability set-up.

The phenomenon of slip flow in coal is very important from the CBM recovery point of view. The occurrence of slip-flow in coals, may lead to a significant increase in productivity of coalbed methane reservoirs near the abandonment pressure.

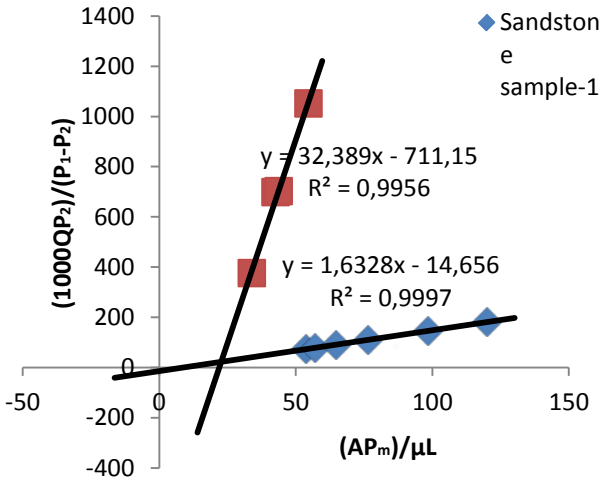

Figure 8.Permeability plot for sandstone samples.

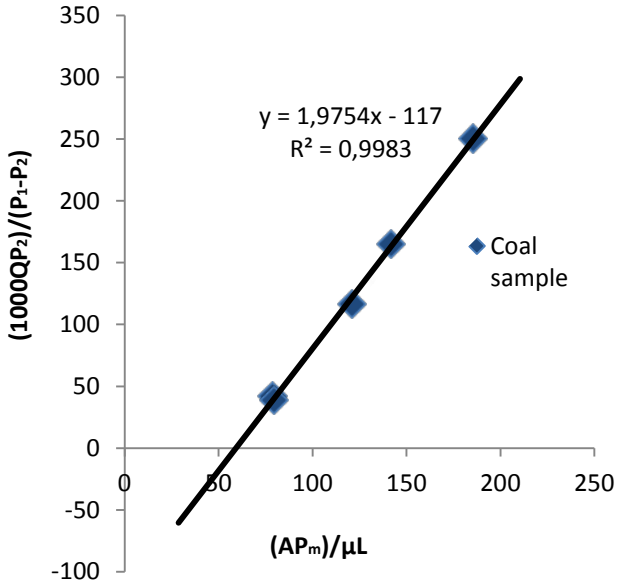

Figure 9.Permeability plot for coal sample.

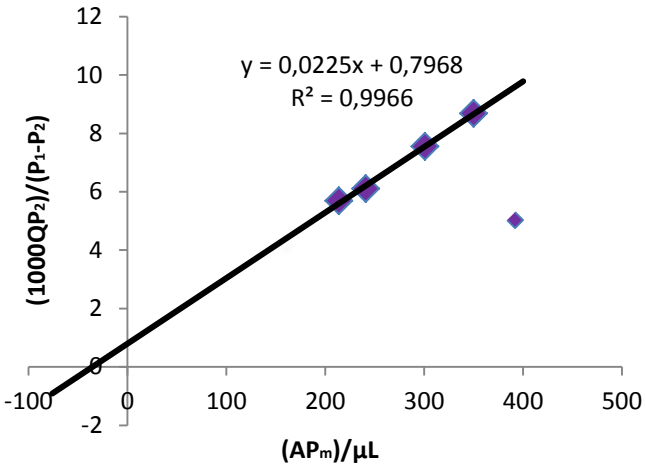

Figure 10.Permeability plot for shale.

The relation between$\emptyset_e$and k_c depends on the pore space configuration. As per Aschenbrenner and Chillingar (1960), for rocks with $\emptyset_e < 12\%$, k_c is given as:

$$k_c = 2.0\, e^{0.316\emptyset_e} \qquad (mD) \qquad (12)$$

The relation between permeability and effective porosity for the studied four samples are plotted in Figure 10. It can be seen that for coal and two sandstone samples, the relation is exponential as given by Equation 13. However, the same equation is not holding good for the shale sample. This may be due to the fact that shale has very fine grain sizes and have different pore space configuration. For the coal and sandstone samples, the permeability and effective porosity are related as:

$$k_c = 0.878\, e^{0.197\emptyset_e} \qquad mD \qquad (13)$$

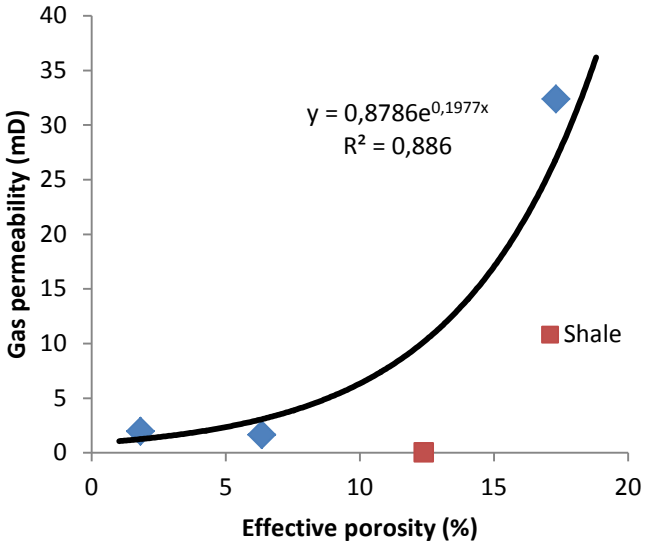

Figure 11.Relation between effective porosity and permeability.

6 SUMMARY

1. The pressure gradient $\frac{\Delta P}{L}$ and flow rate per unit cross-sectional area 'q'are related as$q = a\left(\frac{\Delta P}{L}\right)^m$. The value of a varies from 0.0005 to 0.377 and m varies from 1.692 to 2.776.
2. The value of m more than unity indicates that there is greater increase in flow rate against a smaller increase in pressure gradient. It may be due to increase in flow path area on account

of higher static pressure on walls of inter-connected pores.

3. The permeability co-efficient of coal sample is 1.018 mD, and for sandstone it varied from 1.499 mD to 21.27mD. The fine grained shale sample has the lowest permeability of 0.017 mD because of its extremely small size pores.
4. All samples exhibit deviation from the Darcy's Law. Deviations are attributed to: (a) Non-isothermal gas flow condition, (b) Expansion of flow path area at higher pressures, (c) Molecular effect arising from slip flow and (d) Wall effect during permeability measurement.
5. The relationship between gas permeability co-efficient and effective porosity for the coal and coal measure rocks under study except shale is given by: $k_c = 0.878\, e^{0.197\emptyset_e}$ (mD)

Gas Content and Spontaneous Combustion Investigations for Uckardesler Asphaltite Vein

Üçkardeşler Asfaltit Filonunun Gaz İçeriğinin ve Kendiliğinden Yanma Eğiliminin Tayini

Istanbul Technical University, Mining Engineering Department, Istanbul

ABSTRACT Asphaltite with its high calorific value is important raw material for energy and thermal power plant. Southern eastern part of Turkey is also a good deposit for asphaltite. The increasing amount of demand from energy sector will cause in the production of asphaltite from deeper levels. Therefore, production of asphaltite from underground mining methods will be interested in mining sector. Gas content and risk classification of spontaneous combustion are the important factors to understand the applicability of underground mining methods for asphaltite. These investigations are used to select the underground mining method not only for economic reasons but also for safety concerns. This study contains the results of these investigations specified for Uckardesler asphaltite vein located in Silopi, Sirnak, Turkey. The results of this study shall be discussed among designers and planners specialized in mining for the possibility of underground mining applications for asphaltite production.

Keywords: Uckardesler Asphaltite Vein, gas content, spontaneous combustion

ÖZET Yüksek kalori değeri ile asfaltit önemli bir enerji ve termik santral hammaddesidir. Türkiye'nin güneydoğusu ise iyi bir asfaltit maden yatağıdır. Enerji sektöründeki artan talep, asfaltitin daha derin seviyelerden üretilmesine sebebiyet verecektir. Bu durumun bir sonucu olarak, asfaltitin yeraltı üretim teknikleri üretilmesi, maden sektörünün ilgi alanları içerine girecektir. Asfaltitte, gaz içeriği ve kendiliğinden yanma risk sınıflaması, yeraltı üretim yöntemlerinin uygulanabilirliklerinin anlaşılması için önemli faktörlerdendir. Bu araştırmalar yeraltı üretim yönteminin seçiminde sadece ekonomik değil iş güvenliği ile ilgili sebeplerden dolayı da yapılır. Bu çalışma, Silopi İli Şırnak İlçesinde bulunan Üçkardeşler asfaltit filonu özelinde yapılan araştırmaların sonuçlarını içermektedir. Bu çalışma, madencilik alanında çalışan tasarım ve planlamacıların, asfaltitin yeraltı madencilik uygulamaları ile üretilebilme ihtimallerini tartışabileceği sonuçları içermektedir.

Anahtar Kelimeler: Üçkardeşler asfaltit filonu, gaz içeriği, kendiliğinden yanma

1 INTRODUCTION

Asphaltite is a hard and black solid fuel formed in geological time by oxidation of crude oil and losing volatile matter with influence of bacteria and temperature. Although it is an oil-based, it is used a solid fuel like coal and is included to coal group in assessments (Ünalan, 2010).

The coalification process is defined as the transformation of plant material to anthracite and graphite passing through the stages of peat, lignite and bituminous coals (Gürdal, 1998). It is well known that large amount of gas is formed during the coalification process and significant amount of this gas is stored in coal and rock. The storage gas in coal contain a mixture of gases in which methane makes up 90-95 % Minor amounts of carbon dioxide, nitrogen, hydrogen sulphide, and sulphur dioxide make up the other

components of storage gas in coal (Flores, 1998).

A large part of the gas in coal is stored as free and adsorbed gas with equilibrium pressure in coal seams and layers. Due to disturbed of pressure equilibrium by mining methods, methane gas storage in coal fractures and pores is released in various ways resulting from bursting, firing and strangulation. Furthermore in some underground mines, the storage gas in coal seams under pressure is spontaneously exceeding the strength of face that results high amounts of gas is emitted. It can be defined as a sudden outburst of gas and coal and is the most important problem of the underground mining safety (Ökten, 1983).

In underground coal mines, the management of methane is controlled by "Ventilation and Methane Drainage". In working places, methane emission should be estimated previously. There are various techniques developed for methane emission prediction. The gas contents of coal seams are the more important parameter for methane emission prediction (Noack, 1998).

The amount of carbon monoxide gas which is formed in coalification process decreases with time due to the solution in water. A large part of methane gas is released to atmosphere when the coal seams are closer to the surface. The gas is commonly stored in pores when the coal seams is bedded at deep and covered with compact rocks.

The methane gas exists in coal and rock as free and adsorbed gas (Figure 1). The amount of free gas found in fractures, micro fractures and pores of coal and rock is very low than adsorbed gas in micro fractures and pores of coals. The ratio of free gas in total gas is given by 5-10% (Didari ve Ökten, 1994).

On the other hand, spontaneous combustion is described as the event that starts with adsorption of oxygen with connection between air and coal and continues with oxidation, and then it can be converted to open fire by the storage of the heat which is occurred in the working place, (Ramlu, 1991; Banerjee, 1985; McPherson, 1993; Durucan and Guyaguler, 1987).

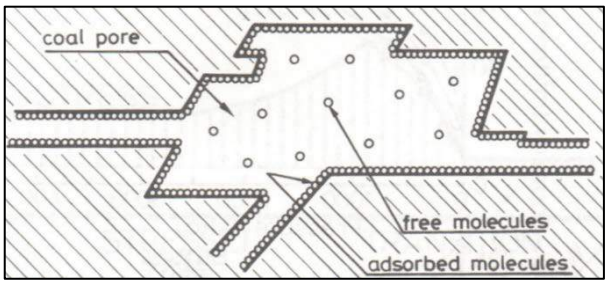

Figure 1. Existence of gas molecules in coal pores (Didari ve Ökten, 1994)

Oxidation is an exothermic reaction. In normal circumstances, the heat which is a result of reaction is transported with air flow and the event continues without causing dangerous heating. However in some cases, produced heat never leaves the medium and then temperature starts increasing. If this continuous reaction isn't prevented, the spontaneous combustion is converted to open fire when the heat reaches the ignition temperature. Because of this, the ramble openings, gobs, fractured pillars, fault zones, silos etc. are suitable for spontaneous combustion (Ayvazoglu, 1984).

Each coal has spontaneous combustion risk in appropriate environmental conditions. In addition each coal type reacts different because of different structural features even they exist in same environmental conditions. For the spontaneous combustion of coal, the following three important conditions must be occurred:

- A coal source able to oxidize in normal conditions,
- Sufficient oxygen source for oxidation,
- A storage feature of heat (unreleased from working place).

The oxygen is adsorbed by coal when contacts with oxygen because of its structure even in low degrees. This adsorption process increases the temperature of the environment by turning to an exothermic reaction at temperatures over 40°C. If this temperature couldn't be reduced, the CO and CO_2 gas concentrates become increasing after the temperatures approximately 70°C or higher and the water steam (H_2O) is occurred at 125°C. When the increased temperature of the working place reaches the ignition degree, coal starts to ignite. The first level of

the coal oxidation is adsorbing of the oxygen to coal by physical ways. As the result of chemical reaction, generated by this physical adsorption, the coal-oxygen complexes are occurred and then this complexes are decomposed to CO, CO_2 and H_2O (Ramlu, 1991; Banerjee, 1985).

The aim of this study is to investigate gas content as well as spontaneous combustion of an asphaltite vein called as Uckardesler located in Silopi. The results are participated in this study for design and planning studies especially for the research of underground mining production of asphaltite.

2 STUDY AREA INFORMATION

Study area is located in the City of Sirnak, Silopi region where is in the southern eastern part of Turkey,

Uckardesler asphaltite vein with its approximately 22.5 million ton reserve capacity is an important energy raw material for a thermal power plant planned to construct in this region.

The vein is formed in between Gercus and Midyat formations that are consists of mostly clay stone and limestone, respectively. A geological cross-section is given in Figure 2 to show a brief geological aspect of the study area. A study of Karpuz et.al. (1986) was the first application for the site.

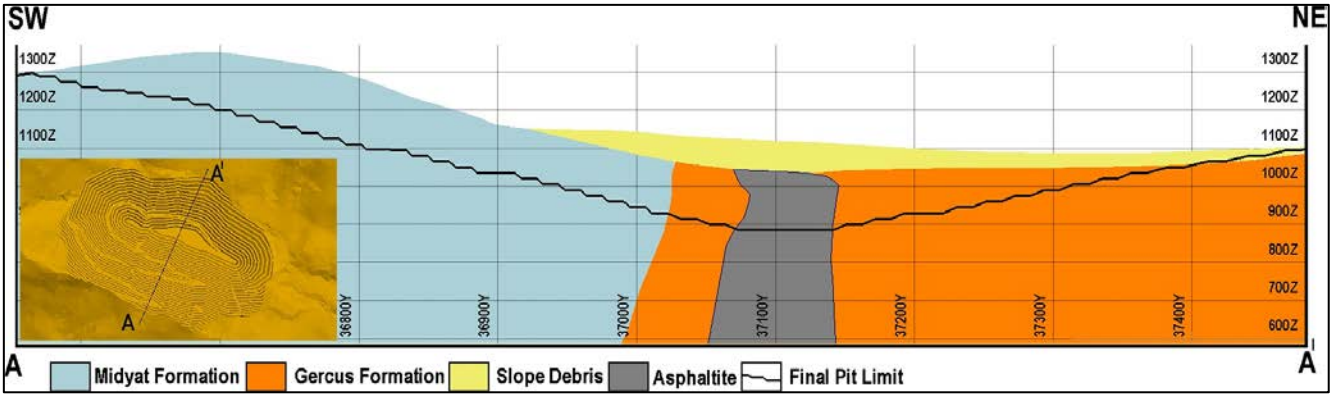

Figure 2. Geological cross-section of Uckardesler asphaltite vein (Ozturk, 2013)

3 GAS CONTENT DETERMINATION OF ASPHALTITE SAMPLES

The gas content of the coal seams is required to know in the designing of preventive measures for the gas emissions during the coal production in underground coal mines. The measurement of gas content of the coal seams can be determined by direct or indirect methods. In addition it can be calculated by empirical methods which were developed by different researcher (Diamond ve Schatzel, 1998).

There are a lot of direct methods to determine the gas content of the coal. The most commonly used gas content determination methods subdivide the total gas content of a coal sample into three parts: lost, desorbed and residual gas. Each of these parts is generally measured or estimated by a different procedure, and then combined to yield the total gas content of the sample. The US Bureau of Mines direct method (USBM) was used to measure the gas content of Uckardesler asphaltite vein. The schematic view of gas content measurement apparatus is given in Figure 3.

In the direct methods, immediately after drilling, the sample is collected. It is sealed in a specially designed canister, which allows measuring the volume of gas with high accuracy. The actual release (desorption) of the total volume of gas is determined in three stages: measurement of desorbed gas, determination of residual gas and estimation of lost gas. For the first few hours, the volume of desorbed gas released from the sample is regularly measured at short intervals. This data is later used to estimate the lost gas released during retrieval and handling at the surface. The volume of released gas is measured over increasingly longer intervals until the volume decreases to 0.05 ml/g/day for several days.

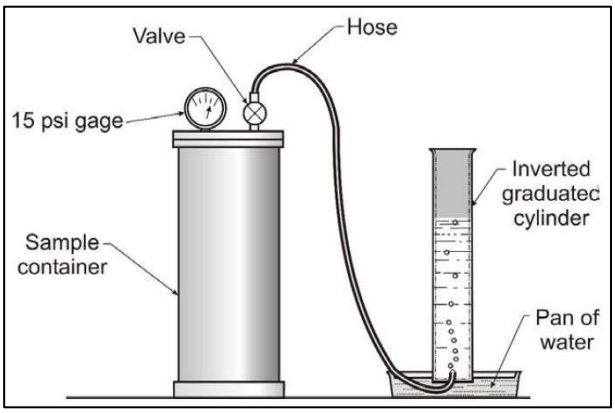

Figure 3. Gas content measurement apparatus (Kissell, 2006)

Once the sample effectively stops releasing gas, weighs and prepare the sample for the determination of residual gas. Core samples are crushed and the volume of residual gas measured through water displacement. Finally, the volume of lost gas is calculated graphically. Data for a number of variables including drilling medium, drilling times, times for reaching the surface and time sealed in the canister are applied to reach an accurate volume of lost gas. The actual gas content of the sample is calculated by adding the volumes of desorbed gas, residual gas and lost gas.

3.1 Site Study and Results

Measuring the gas content of Uckardesler asphaltite vein, a vertical drilling was made by The Company "Sirnak Enerji Inc". This drilling was cut the seam at least 80 m from the surface and the samples were taken the depths from 97, 143, 180 and 340 meters.

USBM method was used to determine the gas content of samples which are taken on the Uckardesler asphaltite vein. During the drilling, samples were taken in the canisters. In order to determine the lost gas, the time was measured during since the bits cut the seam and the samples were taken in the canisters. The desorbed gas was measured till the end of releasing of gas in canister using the apparatus given in Figure 3. The lost gas was determined by a graphical technique. The desorbed gas data are plotted on a graph of cumulative desorbed gas versus the square root of desorption time. The residual gas is determined with grinding of the samples in laboratory.

The lost gas is that portion of the total gas that escapes from the sample during its collection and retrieval prior to being sealed into an airtight desorption canister. Lost gas volumes cannot be directly measured and therefore must be estimated from the subsequently measured gas volume data. Since the lost gas is an estimated quantity, it is generally considered to be the least reliable component of the total gas content. Desorption gas volume data of the Uckardesler asphaltite vein and the estimation of their lost gas data are given in Figure 4, 5,6 and 7.

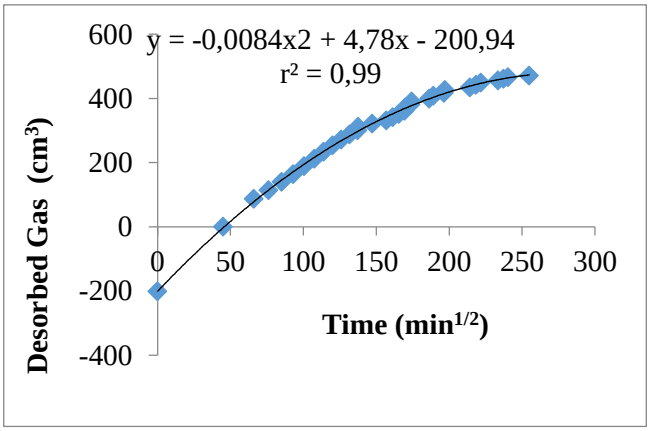

Figure 4. The desorbed and lost gas of the first sample (97 m)

The results of the determined gas content of the Uckardesler asphaltite vein was given in the Table 1. The gas content of the samples varied from 1.34 m^3/ton and 2.33 m^3/ton.

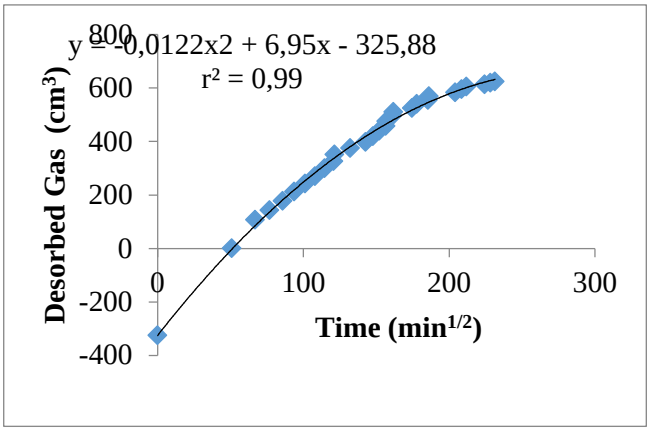

Figure 5. The desorbed and lost gas of the first sample (143 m).

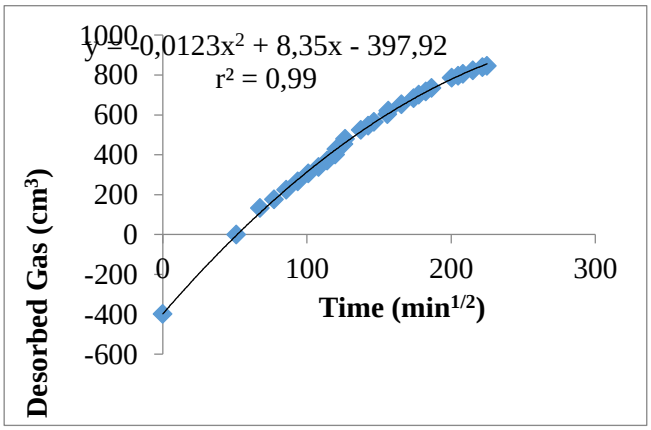

Figure 6. The desorbed and lost gas of the first sample (180 m).

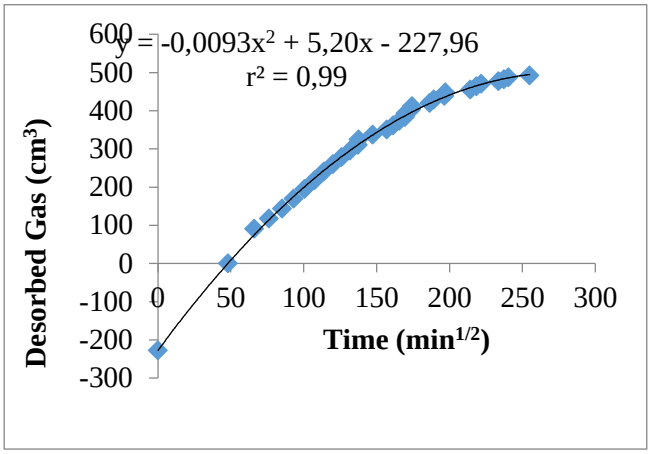

Figure 7. The desorbed and lost gas of the first sample (340 m).

It can be seen from the results that the gas content of Uckardesler asphaltite vein determined with direct method increase with the increasing of depth. The gas content of the Uckardesler asphaltite vein are lower than the gas content of coal seams.

Table 1. Gas content of samples from Uckardesler asphaltite vein.

Depth (m)	Gas Emission (m³/ton)			Gas Content (m³/ton)
	Desorbed	Lost	Residual	
97	0.84	0.36	0.14	1.34
143	1.06	0.56	0.20	1.82
180	1.33	0.63	0.16	2.12
340	1.41	0.65	0.27	2.33

4 LIABILITY INDEX FOR SPONTANEOUS COMBUSTION RISK CLASSIFICATION

The aim of this section's study is the determination of liability index for spontaneous combustion of Uckardesler asphaltite vein which will be mined by Sirnak Enerji Inc. with underground mining methods.

Table 2 is prepared to explain the important factors called as inner and outer effecting spontaneous combustion.

The structure of coal and geological features are defined as inner factors because they are unchangeable; changeable features like mining applications are defined as outer factors.

Further information can be determined from the studies of Banerjee, 1985; Ramlu, 1991; McPherson, 1993; Ayvazoglu, 1984; Durcan ve Guyaguler, 1987.

4.1 Liability Index for Spontaneous Combustion

Two different methods are used for determination of Liability Index of Spontaneous Combustion and they called "Laboratory Techniques" and "Practical Methods" (Kaymakcı, 1998). Practical methods are based on the classifications that acquired experiences, environmental conditions and frequency of heating events. Laboratory techniques are depended on observing the changes on coal as a result of airflow passing over coal

Table 2. The Factors influencing the spontaneous combustion (Kaymakcı, 1998).

Inner (Natural) Factors		Outer Factors
Coal		Environmental
Structure of Coal	Geological Factors	Structure of Coal
Coalification (Rank)	Seam Thickness	Coalification (Rank)
Petrography	Seam Dip	Petrography
Grain Size	Roof Collapsing Skills	Grain Size
Dry Content	Faults and Joints	Dry Content
Pyrite Content	Depth of Coal Bed	Pyrite Content
Physical Features	Geothermic Gradient	Physical Features
Ash Content	Seismic Movings	Ash Content
Volatile Matter	Roof-Hanging Conditions	Volatile Matter Content
Content	Gassiness of Coal Seam	Oxygen Content
Oxygen Content	Layered Seams	
	Methane Emissions	

The basis of the intersection point method is; passing the air over coal sample in a reactor placed in a directly heated furnace and monitoring the time - temperature relations. The heats of both the furnace and the sample are recorded and the point that sample's heat reaches the furnace's heat or intersects is called the "intersection point" (Kaymakcı ve Didari, 1992). The coals which have high liability index have lower intersection temperature points (Didari et.al., 1993). A typical intersection point graph is given in Figure 8 (Kaymakcı,1998).

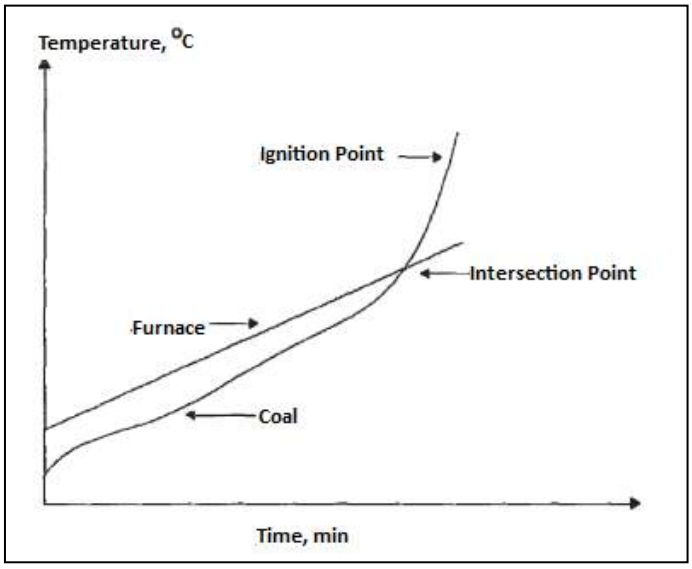

Figure 8. A typical intersection point graph.

In the experiments based on intersection point are made by Feng et.al. (1973), 100 grams of coal samples are placed into a reactor, and it placed into a furnace which has temperature increasing linearly 0.5 °C/min of acceleration. Also 40 ml/min air are passed over coal samples and make them oxidized. Coal temperature which is lower than furnace temperature in the beginning becomes higher with the effect of oxidation and starts passing it. The point that sample temperature surpasses the furnace temperature 1°C is accepted as the intersection point.

"FCC (Feng, Chakravorty, Cochrane) index" is used for determining the liability index of coal as given in Equation 1, which is developed by Feng et.al. (1973).

$$FCC\ (\text{min}^{-1}) = \frac{\text{Average temperature increase (°C/min)}}{\text{temperature of igniton point (°C)}}\ x\ 1000 \quad [1]$$

When the Heating Risk Index is found from the Formula above, this value is compared with the data in Table 3 and the risk classification is made for the coal.

Table 3. The liability to heating according to FCC Index.

FCC Value (min^{-1})	Prone to Spontaneous Combustion
0 - 5	Low
5 -10	Medium
> 10	High

Under these circumstances, high heating rate and low combustion temperature of coals would be more obvious liable to spontaneous combustion.

4.2 Experimental Studies

Experimental test were carried out in Bulent Ecevit University, Mining Engineering Department Laboratory. The Intersection Point Method is used to determine the "Spontaneous Combustion Risk Index" of Uckardesler Asphaltite vein. In this method, passing the air over asphaltite sample in a reactor placed in a directly heated furnace and therefore asphaltite is oxidized. During the experiment the furnace and the sample's temperature are recorded at regular ranges. The experiment equipment is shown at Figure 9.

Figure 9. The intersection point method's experiment equipment.

The representative asphaltite are taken from core samples and they are crushed in conic and jaw crushers. Finally, the samples are grinded and the grain sizes of samples are decreased under 200 mesh. Two samples are packed about 35 grams as they would be used in spontaneous combustion.

The conditions for spontaneous combustion experiments are given below.

Amount of sample: 35±0.1 g
Air flow : 100±0.5 ml/min
Furnace temperature: 0.5°C/min
Getting data frequency: 1 min

The results for spontaneous combustion experiment are given in Figure 10.

The temperature of the sample was increased 30°C in 1 hour, during 313 minute in heating bed, it was heated to the ignition temperature and above this degree. The reaction between oxygen and asphaltite was accelerated with increasing of the temperature and after 277 minute in 165°C the sample was reached and went beyond the degree of the heating bed temperature (Figure 10).

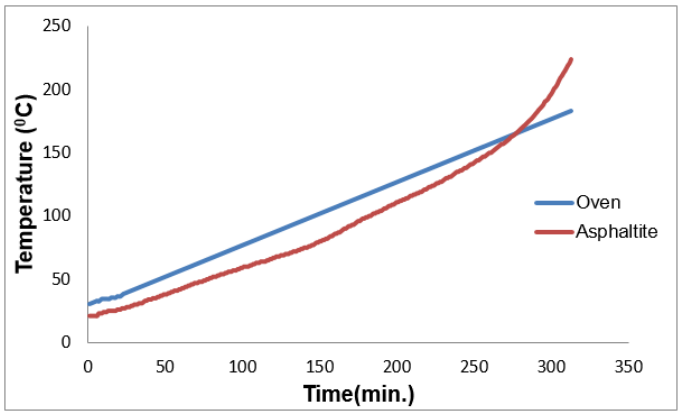

Figure 10. The temperature-time graph for the results of spontaneous combustion test.

The average increased temperature and the FCC Index value which is calculated by intersection point and the ignition degrees according to the spontaneous combustion test data are given in Table 4.

According to FCC index value (5.96 min^{-1}) as it is shown in Table 4; the liability index of Uckardesler asphaltite sample is determined as "Medium".

Table 4. The spontaneous risk classification of Uckardesler Asphaltite.

Asphaltite Vein	Intersection Point Temp. (°C)	Igniton Point Temp. (°C)	Average Increased Temp. (°C/min)	FCC index (min^{-1})	Risk
Uckardesler	164.9	165.9	0.98	5.96	MEDIUM

5 CONCLUSION

Gas content and spontaneous combustion risk classification is investigated in this study for Uckardesler asphaltite vein located in Silopi, Turkey. The results are especially important for the use of planning and design studies carried out for underground mine production project.

Gas content investigations were carried out at site, and measurements were initiated in the drill studies including laboratory investigations. Average gas content of the vein is 1.90 m^3/ton while the content increases with depth. 2.33 m^3/ton gas content is the maximum determined from the laboratory investigations however the amount should be more for deeper depth.

The vein is classified as medium for the risk of spontaneous combustion based on the outcomes determined from laboratory works.

ACKNOWLEDGEMENTS

This paper contains some of the outputs from the project titled as “Uckardesler Asphaltite Vein Prefeasibility Project” completed by Istanbul Technical University Mining Engineering Department. The Authors would like to appreciate the contributions of Sirnak Enerji Inc. for their support to the research.

Coal and Coal Technology

Geology and Mineralogy Investigation of Pb-Zn Mineralization in El Abed Deposit, Algeria.

H. Chaa, A .Boutaleb
LMMA-FSTGAT-USTHB, Algiers, Algeria

ABSTRACT The Aaleno-Bajocien formation of El Abed deposit is situated in northwestern of Algeria, hosted the most important Mississippi Valley Type (MVT) of Pb, Zn mineralization. This area is characterized by horst and graben system. The bodies of ore include: (i) Stratabound" epigenetic mineralization is hosted dolomie.(ii) Mineralization hosted in dissolution cavities (karsts) filling. Such the karst was control most economic bodies of zinc ores.

The mineralization that related to karst cavity is dominantly detritic (DIS: Detrital Internal Sediment), formed by the galena, sphalerite, pyrite, organic matter, dolomie, clay (kaolinite), and the silica.

The ore have mechanical and chemical reworked redesigning in the cavities of dolomites, caused by the action of hot acid and reducing fluids.

Keywords: El Abed, karst, lead and zinc mineralization, detritic, reworked, mechanical, chemical.

1 INTRODUCTION

The Touissit, Bou Beker, El Abed metallogenic province of eastern Morocco and western Algeria is the most important Mississippi Valley Type (MVT) district of Northern Africa, extending from the Oued Mekta deposit eastward to Bou Beker (Morocco) and to El Abed in Algeria (Fig. 1). In all deposits of economic interest, the stratiformand and karst sulfide-bearing ore bodies are found exclusively within a dolomitic Aaleno-Bajocien condensed series.

This sedimentary cover overlies unconformably a Paleozoic basement made up of igneous rocks (granodiorite and rhyodacite) and low-grade schists (Makhoukhi, 2003).

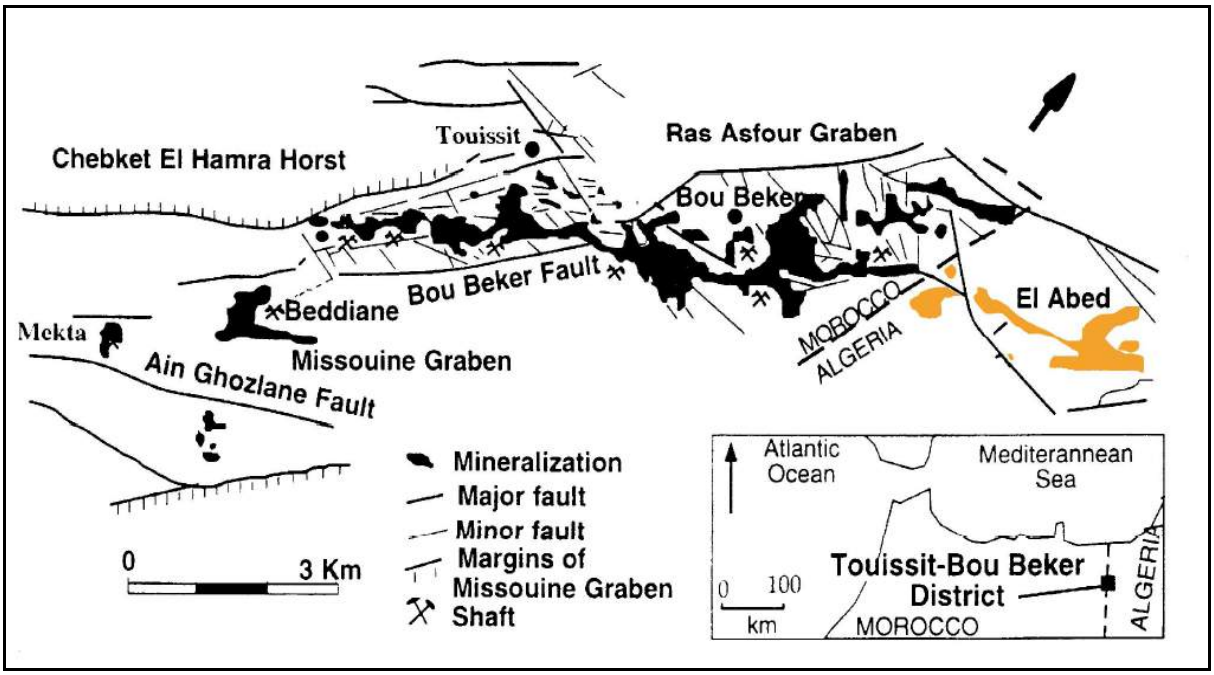

Figure 1. Structural map of Touissit, Bou Beker, El Abed (Boutaleb,1996)

2 GEOLOGICAL SETTING

In the El Abed deposits, mineralization are essentially lead –zinc bearing, rarely with copper. They form stratiform and karst ore bodies in the upper part of dolomitic series and are overlain by a thick sedimentary cover. They form a small number of steeply dipping veins along tensional faults (Touahri, 1987; Makhoukhi, 1994). Two main types of ore bodies have been distinguished in the El Abed deposit. Type I correspond to powdery and reworked mineralization with a karst formation. The ascending fluids were chemically aggressive to the dolomitic host rock which has been strongly dissolved. Type II corresponds to stratiform ore bodies where mineralization has almost replaced the carbonate host rock without destroying sedimentary structures.

3 PETROGRAPHY SETTING

Karst products are rich in organic matter (Fig.2) and sulfide ore, silica, clays and carbonates (Fig.3). Mineralization consists essentially of pyrite, sphalerite (Fig.4) and galena; incidentally; barite, kaolinite and chalcopyrite. Petrographic study show that the mineralization related to karst level is detrital dominant (clastic internal sediments), originated from the mobilization and transformation of mineralization hosted in stratabound dolomies.

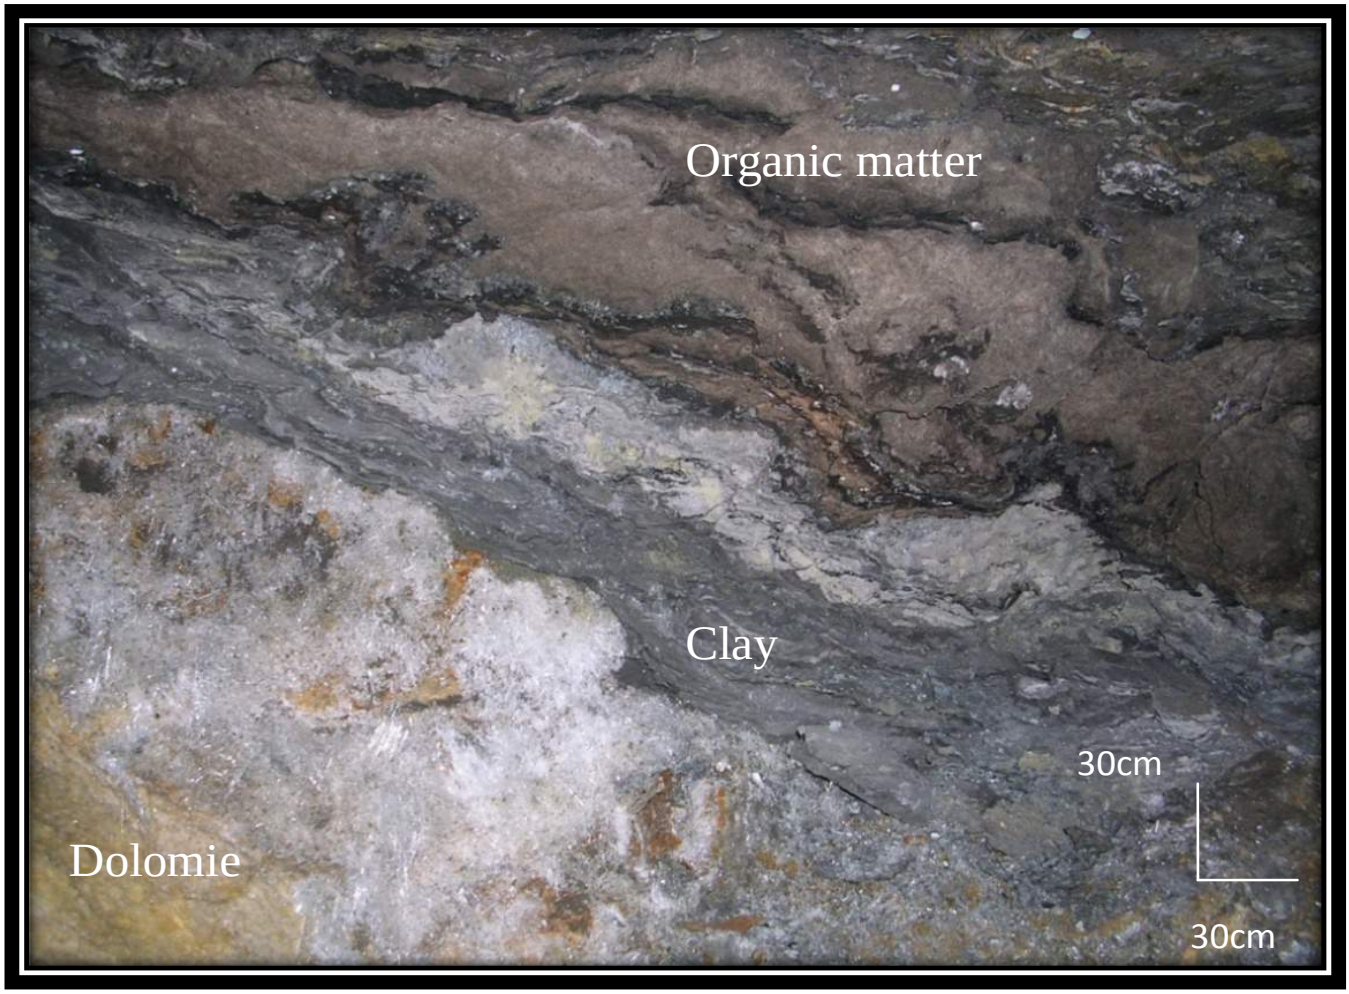

Figure 2. Photograph show detritic karst morphology

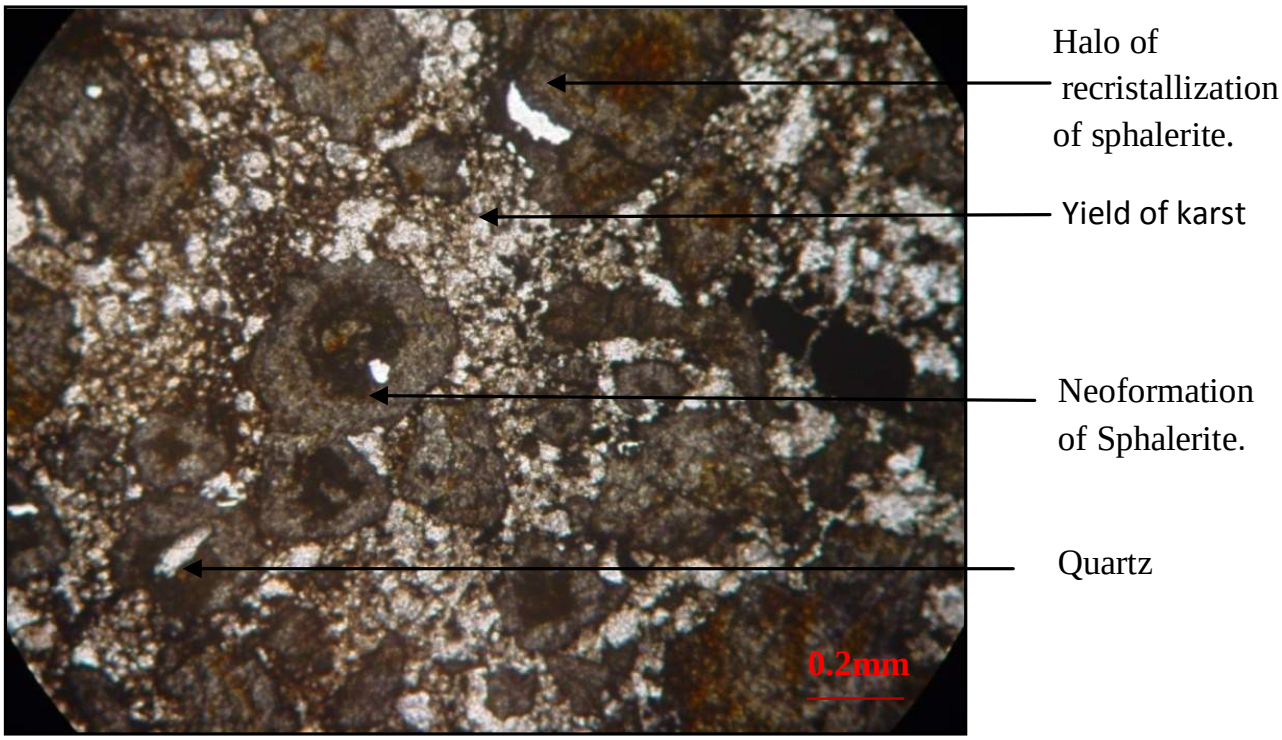

Figure 3. Microphotograph of karst product (Reflected light, crossed polars) (Gx5).

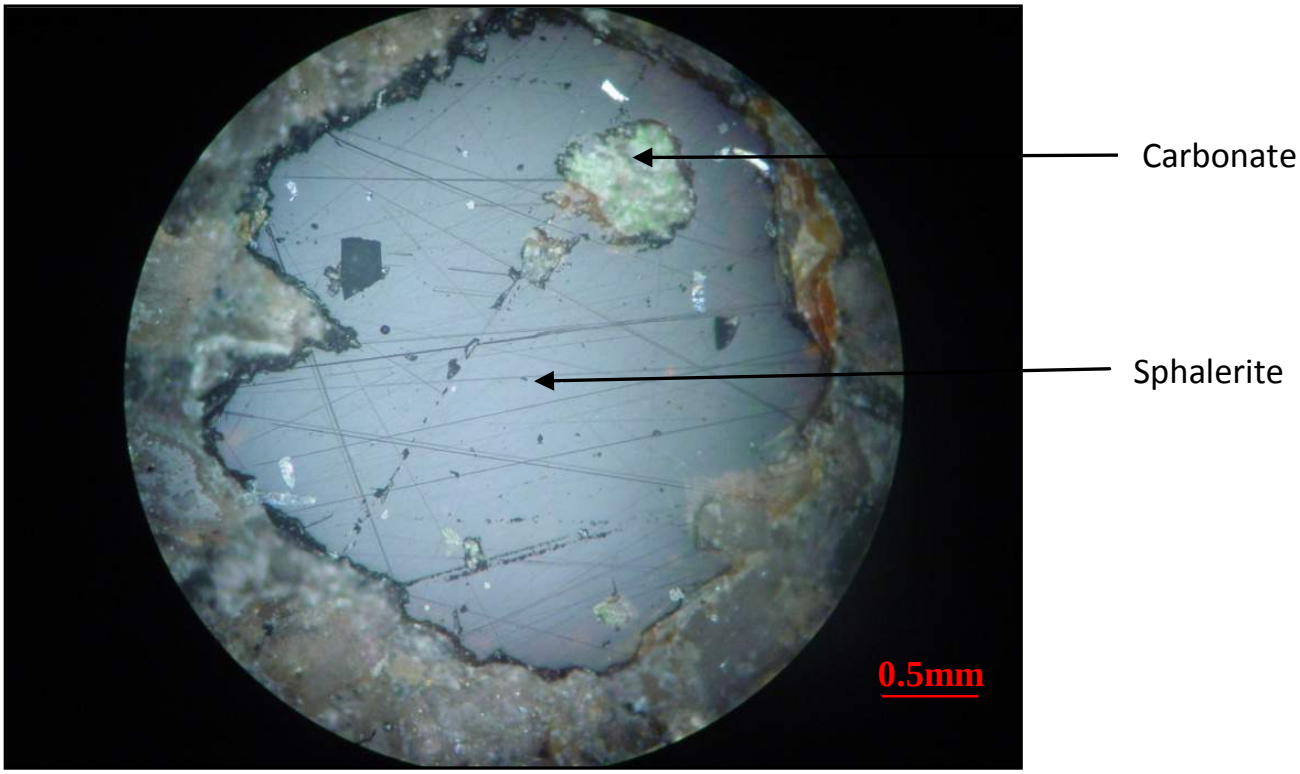

Figure 4. Sphalerite with carbonate inclusion (Reflected light, crossed polars) (Gx10).

4 CONCLUSION:

From the metallogenic study of karst and with the comparison to the stratabound mineralization, we can reconstruct the chronological sequence of events that have prevailed in this deposit as follows:

In Eocene movements, there is the expulsion of hot and salty fluids from subsidence areas to paleohorst (Bouabdellah, 1996 Boutaleb, 2003) giving the stratabound mineralization.

Later; another hot fluid, acid reducer and "sterile" karstified dolomites, reworked

mechanically and chemically, transported over short distances and redeposited clastic products in karst cavities.

Chemical Inhibitors – Scope for Using Control and Combating Surface Mine Fire as Clean Coal Technology

R. V. K. Singh
Mine Fire Division, CSIR-Central Institute of Mining & Fuel Research, Dhanbad, 826015, Jharkhand, India

ABSTRACT The problem of spontaneous heating/mine fire not only endangers the lives of men in mines, but also causes considerable economic losses to the nation and damage the environment. Surface fire in coal mines directly affects the atmosphere with respect to clean coal technology. Due to fire in coal mines, huge quantity of CO, CO_2 and methane, noxious gases are liberated and evolved to the atmosphere. Presently, In Indian coal mines about 70 to 75 % coal is being extracted by surface mines. Besides this, most of the fires in different coalfields originated from many decades ago in collapsed workings of thick seams, at shallow depth. Where the workings were at shallow depths and the extracted seam thickness were high subsidence cracks appeared on the surface providing a path of the air flow to the fire zone. In this way many underground fires turned to surface fires at a later stage. The problem of spontaneous heating/fire in coal mines is very serious and needs immediate attention. There are two important aspects of mine fire- one is prevention and other is control and combat. Presently only water is being used for control of fire in coal mines, but it is not properly suitable for fire of high intensity (temperature). Previously identified chemical inhibitors are mainly suitable for preventing spontaneous heating in coal mines. Presently, there is urgent need for identification and application of chemical inhibitors for controlling and combating surface coal mine fire of high intensity (blazing fire). After carrying out literature survey work, some of the different chemical inhibitors have been identified and analysed in Differential Scanning Calorimeter (DSC) equipment and other techniques for development of suitable composition for use in surface coal mines to control and combat spontaneous heating/fire. This objective of the paper is to describe the scope for use of chemical inhibitors for controlling and combating surface coal mine fire as clean coal technology.

Keywords: Mine fires, clean coal technology

1 INTRODUCTION

Searching for the suitable chemical inhibitors for control and combating surface fires in coal mines is the dream of researchers. Some of the inhibitors have been identified to prevent spontaneous fires by hindering the process of oxidative heating of coal, perhaps by blocking the formation of free radicals, or otherwise. Besides this, work is being continued to develop suitable chemical inhibitors/additives for control and combating high intensity fire in coal mines.

Coal can interact with oxygen in the air at ambient temperature liberating heat. If the heat is allowed to accumulate the interaction rate increases and may ultimately lead to fires – known as spontaneous fires. The exact mechanism of the reaction of oxygen with coal is not completely understood as the chemical nature of coal is not yet fully established. But most of the workers agree that the reaction of oxygen with coal is a surface phenomena and proceeds through a loosely bound coal-oxygen-water complex with subsequent steps being breakdown of the complex to simpler molecules such as

CO, CO_2 and H_2O etc. Most popular hypothesis is that the overall reaction proceeds through a chain mechanism with moisture facilitating the formation of free radicals that act as chain carrier.

2 LITERATURE SURVEY

Tarpagosova (1) tested the oxidation inhibiting action of various reagents over coal and found petroleum products and theiremulsions to be fairly effective, while fatty acids and a few other agents showed only minor improvements. Nakano and Yamski claimed to have obtained encourasing result by applying a thick coat of asphalt emulsion over the coal surface (2).

Banerjee et al (3) corroborated the observation of Nakano and Yamski running a trial with a coat of tar and burnt mobile emulsion, in the ratio 1:3 over a quarry bench wall in Jhingurda seam MP, India). They claimed to have increased the incubation period considerably. But the chief drawback of such agents is that they induce greater risk from contact fire (exogenous fire) and cannot be used in a hot spot/fire nereby. These agents have however been improved upon making them fire resistant, which offers good promise as a protective agent (4).

Accordingly, Singh et al of Central Institute of Mining & Fuel Research, Dhanbad, India developed a cationic bitumen emulsion based fire protective coating material (under S&T project, funded by Ministry of Coal, Govt. of India) for preventing spontaneous heating in coal mines. It would, therefore help not only in saving a huge amount of coal lost every year due to fire in coal mines but also in minimising environmental pollution.

The efficacy of the coating has been well proved by rigorous laboratory scale studies as well as field trials in coal benches at Karkatta opencast project, Dakra (CCL), Jagannath opencast project, Talcher (MCL) and Jhingurdah opencast project, Singrauli (NCL) having coal of high susceptibility of spontaneous heating. These studies have confirmed that a fire protective coating material has following advantages : (i) offers good fire resistance (ii) prevents air permeation and (iii) does not washed down by water/rain (iv) it forms no cracks, remains intact for a long period of time (more than one year) and does not create the problem of scaling-off the material. Moreover, it is easy to spray and is very much compatible with coal. A patent application has been filed for the fire protective coating and the technology has been commercialised to M/s Signum Fire Protection (India) Pvt. Ltd., Nagpur, India for manufacturing and marketing. The said firm is manufacturing & marketing this product under the trade name SIGNUM-CMRI Fire Protective Coating/Sealant (5).

Polish workers claim to have achieved encourasing results using plastic/PVC sheet layering over vulnerable patches and hot spots on coal stacks, thereby preventing ingress of fire. Among the two groups, CaCl2 used by Enterbrink and Lewer (6) and NH3 suggested by Kroger and Beier (7) have showed promise as oxidation heating inhibitors. Chinese workers claim to have achieved good results by infusing inhibiting agent such as 10-15% CaCl2/MgCl2.6H2O in the goaf (8). Czechoslovakian and Hungarian researchers have confirmed 10% calcium chloride to be suitable for reducing the incidence of spontaneous combustion in pits. Australian researchers have suggested use of ammonium hydrogen tetraborate for preventing spontaneous heating. In Japan Diapon T (Na-N methyl-N olieltuarte) is claimed to be surface active agent (9).

The search for suitable Chemical inhibitors to spontaneous heating is in progress in many countries, but a foolproof solution has not yet to be achieved. There are two important aspects of mine fire- one is prevention and other is control and combat. Presently only water is being used for control of fire in coal mines, but it is not properly suitable for fire of high intensity (temperature). Previously identified chemical inhibitors are mainly suitable for preventing

spontaneous heating in coal mines. Presently, there is urgent need for identification and application of chemical inhibitors for controlling and combating surface coal mine fire of high intensity (blazing fire). This objective of the paper is to describe the scope for use of chemical inhibitors for controlling and combating surface coal mine fire as clean coal technology.

3 CHEMICAL INHIBITORS

The endothermic characteristics of chemicals have been determined for prevention & control of coal mine fire using Differential Scanning Calorimeter (DSC) equipment. Chemical inhibitors like NH_4Cl, $CaCl_2$ and NaCl – when mixed with coal show varied degree of endothermicity on heating at Different temperature regions. NH_4Cl shows pronounced endothermicity at 250^0C; $CaCl_2$ indicates minor endothermicity at 50^0C and $150\text{-}170^0C$; and NaCl shows at around 400 to 450^0C. NH_4Cl may find use for preventing goaf fires because of liberation of NH_3 as its endothermic effect at the onset of heating.

3. 1 Differential Scanning Calorimeter (DSC)

Differential Scanning calorimeter (DSC) is a technique in which the difference in energy inputs into a substance and reference materials is measured as a function of temperature while the substance and reference materials are subjected to a controlled temperature programme.

In Differential Thermal Analysis (DTA) equipment, a thermogram of coal can be divided into three segments or stages. In the initial stage of heating (stage I), the endothermic reaction predominates, probably due to the release of inherent moisture in coal. In the second stage (stage II), the exothermic reaction becomes significant but the rate of heat release is not steady all through, as it changes with temperature. A steep rise in heat evolution is observed in the third stage (stage III).

But in the DSC technique, the ordinate value of an output curve at any given temperature is directly proportional to the differential heat flow between a sample and reference material in which the area under the measured curve is directly proportional to the total differential calorific input. By this technique, coal samples can be studied under experimental conditions that simulate spontaneous heating process of materials (10). Author used DSC equipment named METTLER TOLEDO DSC 821^e and LINSEIS L 62 H 1550. The temperature range of the METTLER TOLEDO DSC 821^e equipment is 0 (room temperature) to 600^0C and LINSEIS L 62 H 1550 is 0 to 1450^0C.

In Mettler Toledo $STAR^e$ system, the DSC 821e module is designed in modular concept (basic module with the facility of later extension. The basic module consists of:

- DSC 821e measuring cell with ceramic sensor,
- Module electronics
- Manual furnace lid
- Operating status indicator
- Air cooling (cooling at room temperature by ventilator).

The DSC measurement in the instrument is based on the heat flux principle. It can only be operated in conjuction with the personal computer. LINSEIS DSC equipment comprising a programme for higher temperature range data evaluation to display a large amount of data in a very short time on a screen. Any energy difference in the independent supplies to the sample and the reference is then recorded against the programme temperature. Thermal events in the sample in DSC equipment shows endothermic or exothermic direction (downward and upward peak), depending upon whether more or less energy has to be supplied to the sample relative to the reference material. Downward peak represent the endothermic and upward peak represent the exothermic behavior of the chemical inhibitors. Presently, we are

analyzing the chemical inhibitors using High temperature Differential scanning calorimeter DSC 404F3A01 Pegasus equipment supplied by NETZSCH Geratebau GmbH, Germany.

3.2 Analysis of Results from DSC Thermogram

The thermogram represents the various reactions occurring during oxidation process. It was followed by endothermic and exothermic reaction took place in the sample during analysis. Particularly in the coal sample, the temperature of initiation of exothermic reaction can be considered as an indicator of spontaneous heating susceptibility of coal sample, which is known as the onset temperature. The onset temperature obtained from differential scanning calorimetry may be the better indication for determining spontaneous heating susceptibility. Similarly, different composition of identified chemical inhibitors has been analysed in the DSC equipment. The degree of endothermicity represents the absorbing capacity of the chemical inhibitor at different temperature. After that some of the composition has been identified and selected after laboratory scale study and applied successfully in the field application for controlling and combating fire. The results of the field application are excellent.

4 FIELD APPLICATION

Author is presenting a case studies of fire at Giddi colliery, Argada Area, CCL. The project Giddi 'A' is accessible from Ramgarh Ranchi Road and Patratu railway station which lies on the National Highway No. 33. The project was started in June 1958 for operation of both underground mine and mechanised opencast mine. Mining activities were started in both underground and opencast mines in Argada, Argada-A, Sirka, Bansgarha, Hatidari and Semana seam. Underground mine working was stopped by March 1984 whereas coal production is limited to opencast mine only. Fire was noticed in the year 1997 near Giddi workshop and surface was subsided from the quarry side. The colliery authority tried to control the fire using overburden material. But after some time, filled up overburden material was also heated and fire reached very near to Workshop and Sub-station (11).

4.1 Location

The Karanpura coalfields in Jharkhand forms the western most patch of the lower Gondwana of the Damoder Valley situated within latitude $23^0$28' and $23^0$56' North and longitude $84^0$46' and $85^0$28' east. This coalfield is extended over an area of 550 sq. miles (1424.50 Km^2). An elongated patch of the Lower Gondwana rocks, covering an area of 75 sq. miles (194.25 Km^2). Giddi-A block comprising almost a rectangular patch 1.75 sq. miles (4.50 Km^2) situated in the district Hazaribagh, Jharkhand. The Damoder River which forms the western and southern block boundaries takes 'Z' blende here. The southern margin is also marked by the confluence of Damoder River and Nakri Nallah. In the north east the mine is bounded by the mining lease of Religara colliery (Giddi- B block). To the north lies "Kurkutta Block", on the west the sub leases of Khas Karanpura & the Associated Karanpura collieries are situated. To the south west and south Sounda block-B and working mines of Bhurkunda collieries of CCL are lying.

4.2 Geology of the Seam

The coal seam occurring in Giddi – A block belongs to Barakar formation. Thirty two coal seams have been proved varying in thickness from 0.76M to 24.28M. Out of 32 seams the Sirka, Argada, Argada-A and Argada –B is considered as working seams due to their thickness and persistence. Argada seam varies from 15.85m to 24.28m. Parting between Sirka seam and Argada seam varies from 43.28m to 62.33m. Argada –A seam varies in thickness 7.92 to 13.89m

and parting between Argada and Argada –A seam varies from 18.6m to 45.90m. The seam wise thickness, gradient, grade and present status are given below.

Particulars	**Name of Seam**			
	Sirka	**Argada**	**Argada-A**	**Argada- B**
Average Thickness (m)	12.0	18.0-20.0	10.0	6.0
Gradient	1:3.54	1:2.96	1:2.75	1:2.75
Direction	$N70^0$29'W	$N82^0$40'W	$S85^0$30'W	$S80^0$15'W
Grade	B	C-D	C-D	C-D
Present status	Standing on Pillar	Standing on Pillar	Standing on Pillar	Virgin
Estimated reserve below Washery (million ton)	Nil	1.600	1.320	0.125

5 SCIENTIFIC INVESTIGATION

Fire site of Giddi-A colliery near by Giddi workhop, sub-station and Giddi Washery was visited and it was observed that Argada and Argada –A seam are developed on pillar lying below the Giddi workshop whereas Argada A seam lying below Giddi washery and sub-station also. Both the seam partially quarried by opencast mining method. Argada - B seam is virgin and lying below the Giddi workshop and Giddi Sub-station at a depth of 54m. Argada seam quarried before March, 1986 whereas Argada-A seam quarried before 1976. Fire observed in September 1997 near Giddi workshop from the quarry mouth edge due to the presence of loose coal (Fig. 1). The area is subsided near road and workshop which is creating several cracks and passage for ingress of oxygen leads to spontaneous heating/fire. The blazing flame is coming out through the mouth due to further progress of spontaneous heating and chemical chain reaction. Mine authorities tried to control the fire by filling the overburden material but it was not controlled, the problem became more serious when filling material was heated near the Mining Workshop.

Temperature was measured with the help of Heat Spy Infra-red Thermometer at different locations near the Giddi workshop, sub-station, washery, mine road and the quarry edge (Figure 2). The maximum temperature was observed as 492^0C near washery boundry and road side. Fire fighting chemicals/inhibitors, have been applied which reduced the flame and extract the heat near mining workshop. Different chemical inhibitors were mixed with water in different proportion and applied on blazing flame as per intensity of the fire and site specific condition. Continuous fire fighting operation was carried out for five to six months and after that the combated portion was covered with binding material and top soil (Figure 3).

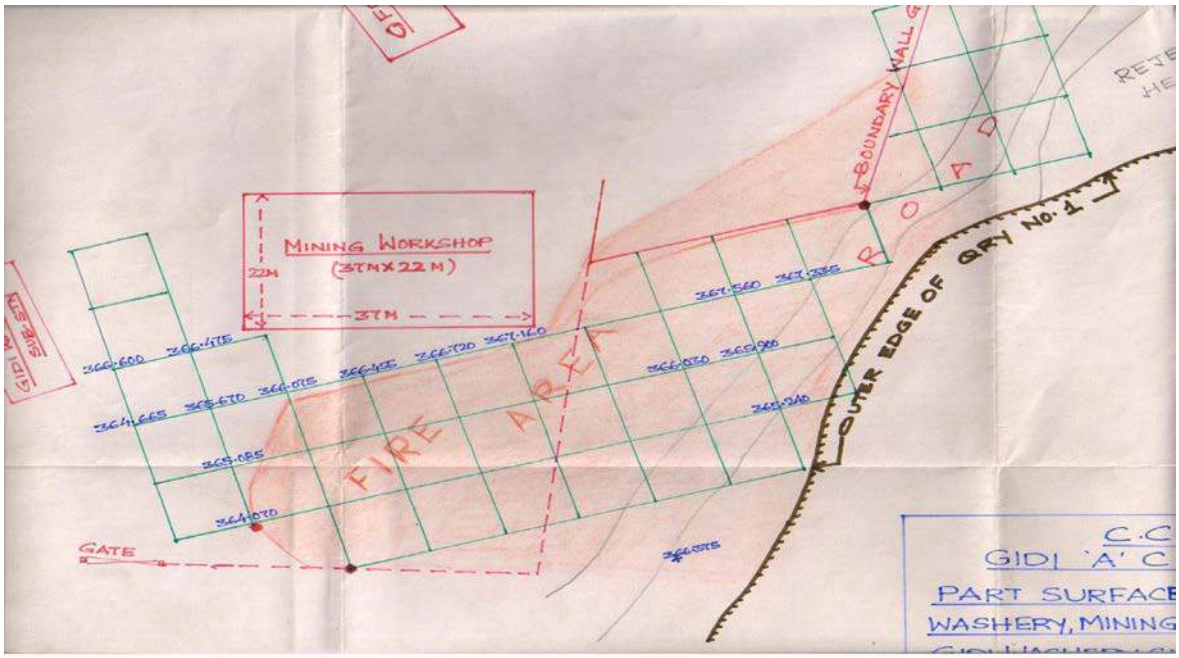

Figure 1. An overview of fire area near substation workshop and Giddi Washery, CCL.

Figure 2. Thermal investigation using Heat spy Infra-red Thermometer near Giddi Sub-station and Mining workshop, CCL.

Figure 3. Fire combated portion treated with binding material with top soil near Mining workshop and Giddi power sub- station, CCL.

6 RESULTS AND DISCUSSION

During thermal investigation, it was found that fire was present in most of the portion near by area of roadways, sub-station and fire was under blazing condition near Giddi workshop. Temperature was in the range of 265 to 307^{0}C at workshop and 492^{0}C observed near the washery boundry towards road side (Fig. 4). After application of fire fighting Chemical inhibitors/additives temperature reduced to 35 to 46^{0}C (Fig. 5). Then combated fire surface was treated with different binding material and finally to minimise the ingress of air an area of 3750 sq.m was sealed on surface using 7250m^3

topsoil. Detailed thermal profile was marked on surface lay out before application of fire fighting chemicals to the final surface sealing operation as per requirement. Finally, temperature was found near about ambient after surface sealing. Mine authorities were trained for application of fire fighting chemicals. Suggestion was also given for making two benches using top soil in quarry side for checking the penetration of air from the mouth of gallery and blanketed area should be compacted time to time. Early implementation of the control and combating technology has given successful result for control of fire near Giddi workshop and sub-station. After control of fire, the valuable national property like Giddi Sub-station and washery have been saved and environment was also protected from the release of noxious gases (11).

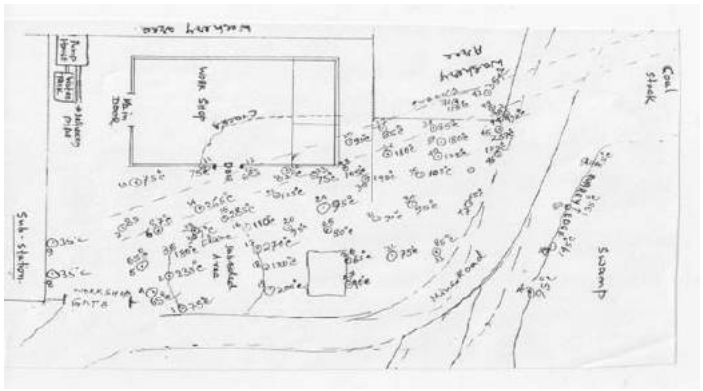

Figure 4. Thermal mapping using Infra red-Gun nearby fire affected area at Giddi Sub-station and Washery, CCL (Not to scale).

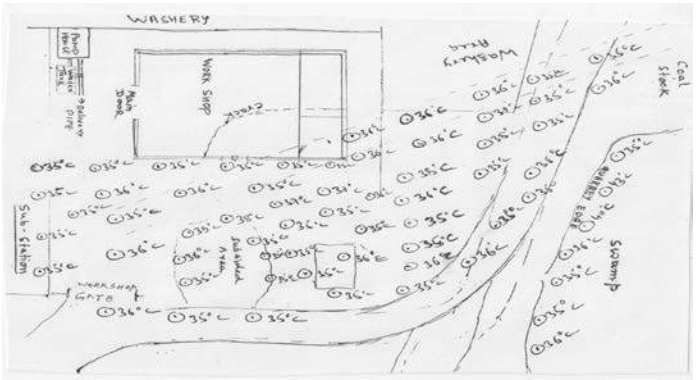

Figure 5. Thermal mapping after application of combating and preventive measures nearby fire affected area at Giddi Sub-station and Washery, CCL (Not to scale).

7 SUGGESTIONS

As per the studies carried out during the project work and site specific fire condition, the following preventive and control measures are suggested: -

1. Thermal monitoring should be carried out using Heat spy Infra red thermometer regularly for detection of fire, so that immediate control measures can be planned as per site situation.
2. Fire should be combated by application of fire fighting chemical inhibitors for suppressing the fire and extracting the heat and it should be continued till the temperature reduces to ambient level.
3. Dozing/compaction is very much essential in the compacted area after some interval to minimise the air ingress.
4. Minimum two benches should be formed from bottom to top using top soil in quarry side for checking the ingress of air from the mouth of gallery to save the mine roadways, washery and sub-station.

8 CONCLUSIONS

After carrying out scientific investigation for control of fire near Mining workshop and sub-station, it is concluded that speedy implementation of the control and combating technology has given successful result. After control of fire, the valuable national property has been saved. Environment was also protected from the release of noxious gases. Under these circumstances, direct application of fire fighting chemical inhibitors will be much effective for suppression of flame, extraction of heat and cooling the hot mass. Author has taken a new R&D Project under 12th Five Year plan from Planning Commission, Government of India for development of suitable chemical Inhibitor for control and combating high intensity surface fire in coal mines under Clean Coal Technology. Research work of this project is being continued and rigorous laboratory work is going on.

ACKNOWLEDGMENTS

Author is grateful to Dr. A. Sinha, Director, CSIR-Central Institute of Mining & Fuel Research, Dhanbad for giving permission to present the paper. Author is also grateful to the management and officials of Giddi–A colliery for providing all facilities and full co-operation for carrying out the project work. Thanks are due to the staff of Mine Fire Division of CSIR-CIMFR for their assistance in various stages during laboratory & field work. Views expressed in this paper are of author and not necessarily of CIMFR.

Effective Approaches for the Fast Liquidation of Locked Up Coal in Standing Pillars in Indian Underground Coal Mines

A. Kushwaha, R. Bhattacharjee, S. Tewari and A. Sinha
CSIR-Central Institute of Mining and Fuel Research, Dhanbad, India

ABSTRACT Ensuring energy security for the growing population with rising per-capita energy demand has emerged as one of the greatest challenges before India. The developing nation like India will continue to rely heavily on thermal power plants for meeting energy demands against restricted access to nuclear technology and mixed success of non-conventional energy sources. Since inception of mining industry till now, Bord and Pillar (Room and Pillar) method of mining is still the predominant method of working in India. In most cases only the development workings have been done due to various complex mining conditions. As a result, huge amount of coal reserves are locked as Standing on Pillar (SOP) in these mines. Therefore, the adoption of effective mining technologies for the fast liquidation of these standing pillars is the need of the time to meet energy demands of India up to some extent. This paper presents a brief review and successes of different mass production technologies like continuous miner technology, shortwall mining and blasting gallery method of mining adopted for fast liquidation of SOP reserves in some of the Indian coal mines.

Keywords: Fast liquidation, coal, Indian coal mines

1 INTRODUCTION

Ensuring energy security for the growing population with rising per-capita energy demand has emerged as one of the greatest challenges before India. The developing nation like India will continue to rely heavily on thermal power plants for meeting energy demands against restricted access to nuclear technology and mixed success of non-conventional energy sources. Since inception of mining industry till now, Bord and Pillar (Room and Pillar) method of mining is still the predominant method of working in India. In most cases only the development workings have been done due to various complex mining conditions. As a result, huge amount of coal reserves are locked as Standing on Pillar (SOP) in these mines. Conventional depillaring using SDL's/LHD's of these standing pillars is slow and uneconomical. With widening gap in production and demand of coal, production has to be ramped up from existing mines to keep the shortfall within limit. Hence, the coal pillars in underground need to be rightly exploited to meet the country's present coal requirement. Under such circumstances, the only option is to innovate and improve the available technological scenario. Therefore, the adoption of effective mining technologies for the fast liquidation of these standing pillars is the need of the time to meet energy demands of India up to some extent.

This paper presents a brief review and successes of different mass production technologies like continuous miner technology, shortwall mining and blasting gallery method of mining adopted for fast liquidation of SOP reserves in some of the Indian coal mines. The paper deals with basic design parameters, support assessment, strata monitoring, safety issues, improving methods of operation, reducing machine downtime, manpower effectiveness and others covering macro and micro level management for planning and execution of pillar extraction/depillaring. Adoption of these technologies in other mines will ensure higher production, improved productivity and enhanced safety standard.

2 MASS PRODUCTION TECHNOLGY FOR UNDERGROUND DEVELOPED COAL PILLARS

Underground production has remained stagnant over the decade in Indian coal mining industry in spite of large area of the coal seam has been developed and standing on coal pillars. The main reason is that there is a lack of suitable underground fast liquidation mining technology for these developed pillars, although the overall coal production has considerably increased. The increase in overall production contributed mainly due to opencast mines. The coal production in India during 2013-14 was 565.64 Million tonnes as published in Annual Report 2013-2014from Ministry of Coal, Govt. of India. Out of which only 9% of the coal produced was from the underground mines.

Due to increasing demand of coal world-wide and the fast depletion of open castable reserves at shallow depth cover, the mining of coal by underground methods in mass scale is inevitable. The main bottleneck in this endeavour is that the adoptability of the mass production technology for developed coal pillars from underground in Indian coal mining sector is very slow. Fortunately, Coal India Limited (CIL) and Singareni Collieries Company Limited (SCCL) both are now realizing to adopt mass production technology in their underground coal mines at large scale to cope up with coal demand and future necessity. To initiate in this direction, the following mass production technologies are being introduced in some of the Indian coal mines:

1. Continuous Miner Technology
2. Short Wall Mining Technology
3. Blasting Gallery Method of Mining

3 BASIC PARAMETERS OF ROOF ROCK STRATA REQUIRED FOR SUCCESS OF THE MASS PRODUCTION TECHNOLOGY

All the above described technology are new to India and is vastly different from other mechanized Bord & Pillar mining methods, mainly due to extraction of developed pillars at high rate. This resulted quick variation in stress re-distribution pattern at the face and in surrounding rocks in the working areas. For achieving successful implementation of these technologies in any mining field, the following strata characteristics, have to be studied properly:

3.1 Cavability Characteristics of the Roof Rock Strata

CSIR-CIMFR Dhanbad has developed its own method for assessing the cavability of roof rocks strata. The following empirical relationship expresses the relation between caving index ‘I’ (Sarkar, S.K. and Singh, B., 1985) with the influencing factors as mentioned below:

$$I = \sigma_c \frac{t^{0.5}}{5} L^n \qquad (1)$$

where, I = Cavability index; σ_c = Intact rock compressive strength(kg/cm^2); t =Bed thickness(m); L= Average core length(cm); n=1.0 for RQD<80 and 1.2 for RQD > 80.

For estimating the Cavability Index of the roof rock strata of any seam, rock samples of at least two bore hole sections of the proposed area have to be studied properly in the laboratory. The measuring parameters are length of the core samples, its thickness and RQD. Putting these values in above Eq. 1, cavability index of the roof rock strata can be estimated. Based on field observations and caving behaviour, the roof rock has been categorized as given in below Table 1.

Table 1. CSIR-CIMFR Characterization of Roof Rock Strata

Sl. No.	Category of the roof	Range of Cavability Index	Roof Rock Strata Characteristics
1	Category – I	Up to 2000	Easily cavable
2	Category – II	2000 to 5000	Moderate cavable roof
3	Category – III	5000 to 10000	Roof strata cavable with difficulties
4	Category – IV	10000 to 14000	Cavable with substantial difficulty
5	Category – V	>14000	Cavable with extreme difficulty

3.2 Possibility of Air Blast During Caving

The chances of air blast during extraction of any seam are dependent on roof rock strata characteristics. If the cavability index of the majority of the roof rock strata is less than 5000, chances of air blast will be minimal and the roof rock failure in the goaf will be in periodic manner. If this index is between 5000-10000, the roof rock failure in the goaf will delay, but there is a little chance of air blast at the face. In case of Cavability Index more than 10,000, chances of air blast at the face will always be there if area of exposure will increase more than a certain limit. CSIR-CIMFR Dhanbad has developed a correlation between the equivalent face advances or ultimate stable span a_{eq} with RQD as given below:

$$a_{eq} = 0.59\ RQD + 5.2m \quad (2)$$

Expected area of main fall

$$= (1.55 \times a_{eq})^2\ m^2 \quad (3)$$

In case of depillaring of developed pillars from any mine, if the area of expected main fall increased more than the calculated value using above Eq. 2 & 3, the chances of the air blast cannot be ruled out. Under such condition, blasting of hard overhanging strata at the goaf edge can be one of the alternatives to avoid air blasts. In this technique it is by no means intended to bring down the entire overhanging strata. It is only meant to cause a blockage with broken rock so that air cannot escape outbye in the event of an air blast. It can also be used as a regular measure during extraction. The method is more amenable to application in those mines where long hole rock drills (Jumbo drills) are available.

3.3 Design of Method of Extraction and Support System

To design a suitable method of extraction and support system in and around the face a well established numerical modelling technique has to be used to assess the stability of the surrounding rock strata and required support density at the face. For the modelling purposes, the following rock properties (Floor rock, Coal and Roof rock) have to be estimated in the laboratory as per ISRM Standard given below:
(1)Young's Modulus, (2)Poisson's Ratio, (3)Compressive strength, (4)Tensile Strength and (5)Rock Density.

Rock mass ratings (RMR) of the roof rock strata along with RQD of the borehole rock samples are also needed at the time of designing of method of extraction, support system and induced caving pattern to achieve successful extraction of developed pillars with high production and productivity with Mass Production Technology.

4 CASE STUDIES

4.1 Continuous Miner Technology: VK7 Incline, SCCL Mine (India)

This is a case study of VK7 Incline of Singareni Colliery Company Limited (SCCL), where CM technology (with a combination of Continuous Miner i.e. Coal Cutting machine + Quad bolter i.e. Bolting machine + Shuttle car i.e. Coal Loading machine) was deployed for the extraction of 6.5m thick King Seam. This seam has already been developed with a height of about 3m along the roof, almost 20 years back. CSIR-CIMFR Dhanbad has conducted

detailed scientific study for its first two caving panels such as CMP-5A and 5B to design the extraction pattern. The cavability index of the proposed seam was determined which came to category I & II of the Table 1. Therefore, chances of air blast during extraction of King seam with caving is very less as the overlying strata are not very difficult to cave. However, it has been tried to quantify the extent of the area of roof exposure after which the induced blasting is required to initiate the roof fall in the goaf areas of King seam using CIMFR formula Eq. (2) & (3). The average RQD up to 23m for the immediate roof was found to be 72. Putting this value into above equation (2), the ultimate stable span can be calculated as: $\mathbf{a_{eq}}$ = 0.59 x 72 + 5.2m = 48m approximately and the expected first main fall will be around = $(1.55 \times 48)^2 = (74.4)^2$ = 5535 sq.m

Considering the maximum 3 pillars wide extraction at VK-7 incline, this area will be achieved just within 1st row of pillar extraction. Regular controlled caving of overlying roof rocks of King Seam will obviate the risk of air-blast, stress abutments in working areas and goaf encroachment. Therefore, seeing the characteristics of roof rock strata of King seam, it has been decided that the proposed panel CMP-5 (Fig. 1) can be extracted with CM Technology with full caving using "Split & Slices" method of mining as described below:

Geometrical parameters of the development workings of CMP-5 Panel at VK-7 Incline were as follows:

Pillars size:	45m x 45m (centre to centre)
Development roadways:	4m along the roof
Roadway height:	2.8m to 3.0m
Depth of cover:	325m to 425m

To minimize the effect of adjacent worked out panel on this new panel, two rows of barrier pillars between this panel CMP-5 and already extracted panels were left. In the first step, all the developed roadways have been widened up to 6.5m from both sides of the pillars and height was left 3m only, so that shuttle car can move smoothly. Total widened roadways had been supported with resin encapsulated rock bolts of length 1.8m at an interval of 1.5m. For depillaring of these pillars, a single split of 6.5m wide and 3m height had been driven along level in such a way that it divided pillar in two stooks with dimension of one stook was 38.5m x 18.5m and of other stook was 38.5m x 13.5m. Similarly, one more experiment was done with double split of 5.5m over a pillar so that three stooks of size 38.5m x 9m can be formed. To estimate load coming over the stooks in both the cases, 3D numerical modelling using FLAC^{3D} software (Itasca Consulting Group Inc, FLAC3D, 1997) was performed against the goaf. Isometric view of model is shown in Fig. 2.

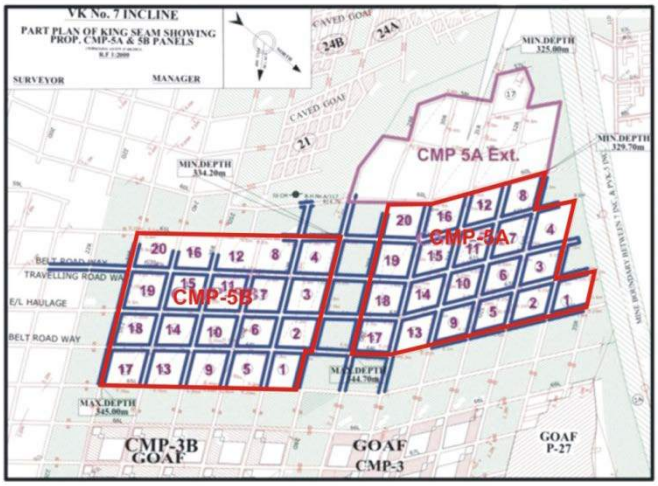

Figure 1. Part plan of CMP-5A and 5B panels with sequence of extraction of pillars

The safety factor of stook with single split was found to be 1.35 and 1.04 for 18.5m wide and 13.5m wide stooks respectively. With double split it was 0.84. This study concludes that the safety factor of the stook with double split was less than 1, therefore; single split option with stook width of 18.5m and 13.5m was followed in panel CMP-5 during depillaring at VK-7 Incline Mine of SCCL during application of CM Technology.

4.1.1 Support system used in CMP-5

For supporting the widened roadways and split level, resin encapsulated rock bolt of 1.8m length and 22mm dia was used as shown in Fig.3a. These support patterns

have been designed based on the modelling results. For side support, wire mesh with cuttable GRP bolts has been used to check the spalling of the pillar during depillaring process as shown in Fig. 3a. In case of slips and fault intersecting the roadways, 2.4m long resin encapsulated rock bolts was used as shown in Fig. 3b.

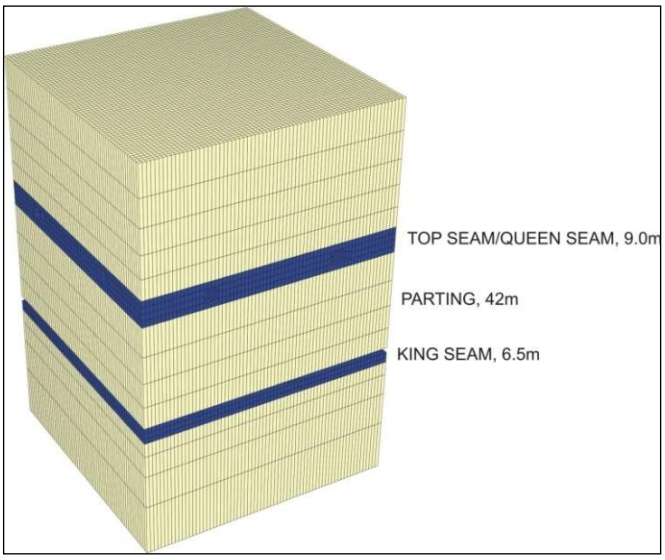

Figure 2. Isometric view of the model showing grid pattern used

Figure 3b. Support design for the area intersected with slips and faults

Figure 3b. Support design for the area intersected with slips and faults

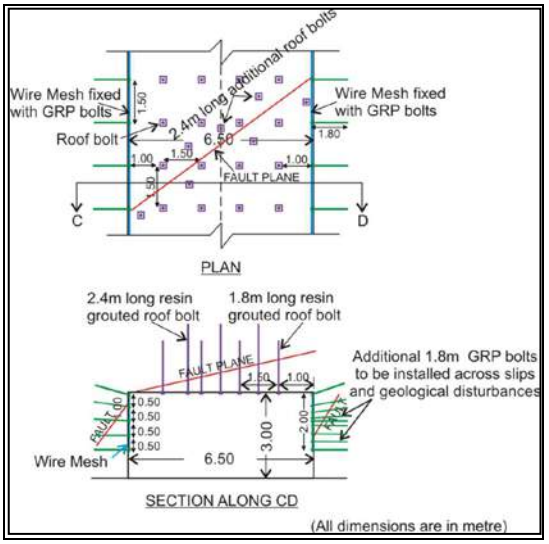

Figure 3b. Support design for the area intersected with slips and faults

4.1.2 Pattern of extraction of pillars with CM technology in CMP-5

In CM Technology during pillar splitting, two pillars are attacked at a time as shown in Fig. 4. The sequence of splitting and slicing of a pillar with CM technology in CMP-5 panel of VK-7 Incline was as follows:

- Two dip-rise pillars were splitted simultaneously by driving level split galleries of 3.0m height along the roof and 6.5m wide, from stages 1 to 6 (Fig. 4) forming two stooks in respective pillars of the dimension 38.5m x13.5m (1/3rd, dip side Fender-A) and 38.5m x 18.5 (2/3rd, rise side Fender-B).
- Roof bolting with resin grouted rock bolts, side supports with wire meshing and GRP bolts were completed in splits along with the installation of breaker lines as shown in Fig. 4.
- A ramp of 1 in 7 gradient was made along dip gallery from the rise side junction of the same pillar as shown in Fig. 4 (stage 7D) and deepened to 4.6m height by floor dinting.
- The split of first pillar was deepened up to 4.6m by dinting (stage 8D).
- Slicing operation from no. 9 to 11 by slicing 5m in upper side (upper stook) and 13.5m in lower stook (Fender-A) (Fig. 4); up to 4.6m height was completed leaving 3m thick ribs after each slicing till it reaches against last snook.

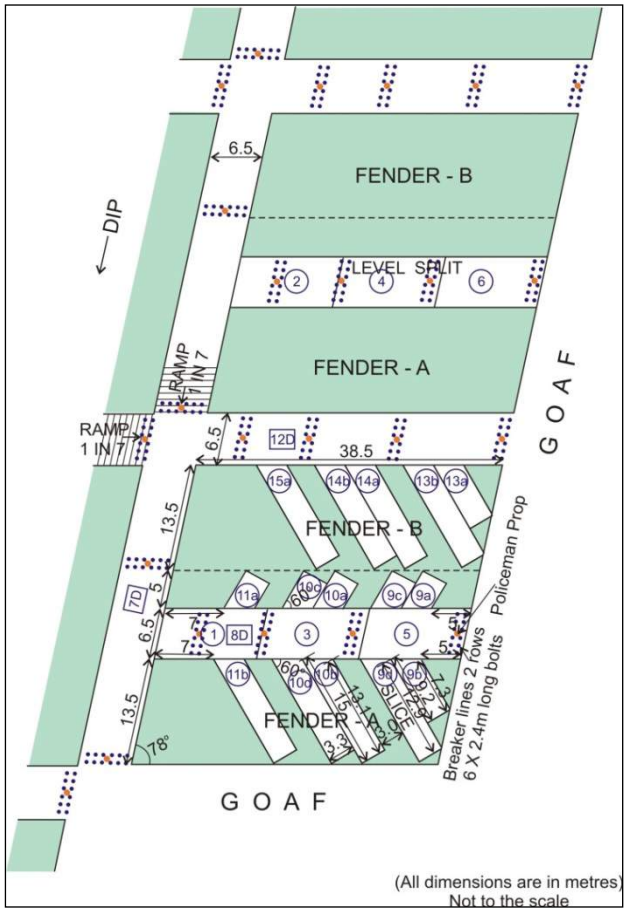

Figure 4. Extraction sequence during splitting, slicing and dinting for CMP-5 panel along with breaker line supports

- The dimension of the last snook was kept 7m x 13.5m x 15m x 14m. The estimated safety factor of this snook was 0.27, which can stand for few hours to withdraw the men and machine from face.
- Sometimes, this snook was not crushing, in that condition one slice of 3.3m was taken from this snook to weaken this snook, so that it fails and it allows the roof to come down.
- Lastly, level gallery (between pillar first and second) shown as 12D was dinted and slicing stages from number 13 to15 were completed with full height of 4.6m leaving 3m ribs in between. A snook of size 7m x 13.5m (Fig. 4) was left against four way junction for judicious extraction.
- If the caving in the goaf got delayed, goaf-edge induced blasting at the roof of the level junction was adopted. Before going for induced blasting over the junction of splits and level galleries after extraction of each fender, the snooks/ribs were further reduced or knocked down to facilitate the roof caving in the extracted area.

4.1.3 Findings

Average production with CM technology in CMP-5 panel at VK-7 incline was around 2000 tpd and coal recovery within the panel was around 72%. Due to this technology, VK-7 Incline underground mine was running in profit.

4.2 Shortwall Mining

The shortwall mining technology is the method of extraction suitable for developed bord and pillar workings is similar to longwall mining but with shorter face lengths, ranging between 40 and 90m, with the aim of controlling the caving nature of the overlying upper strata, the load on support and the overall operation of the supports applied at the face. In shortwall mining technology, face is generally inclined 9^0 to 11^0 from pillar edge so that stability problem at the face can be maintained (Fig. 5). This technology was firstly introduced in Balrampur Mine of SECL (Kushwaha, A. and Banerjee, G., 2005) with following mining geometry:

Depth of cover : 50m;
Developed pillar size : 20m x 20m
Roadway width : 4.2m
Seam Thickness : 2.4m
Development height : 2.4m

4.2.1 Mining pattern in shortwall mining

Orientation of the short longwall face was kept as oblique to avoid the formation of a thin long rib which could collapse suddenly. To overcome this problem, obliquity of the face minimized the exposed area and provides easier access to cross the advance gallery, from one end of the face to the other. Obliquity for Balrampur mine was kept as 9^0 to cross one advance gallery at a time.

With an oblique face crossing the advance gallery, a triangular rib was formed at last in every junction of the extracted pillar. In order to estimate the safety factor of the

triangular rib, its strength was estimated using CIMFR strength formula and the load by using FLAC 3D numerical models. Factor of safety of ribs was ≥ 0.6 which stand stable for few days. Therefore, two travelling power support of 4.5m length was used in the advance gallery against rib which travelled from one end to other as the face progressed.

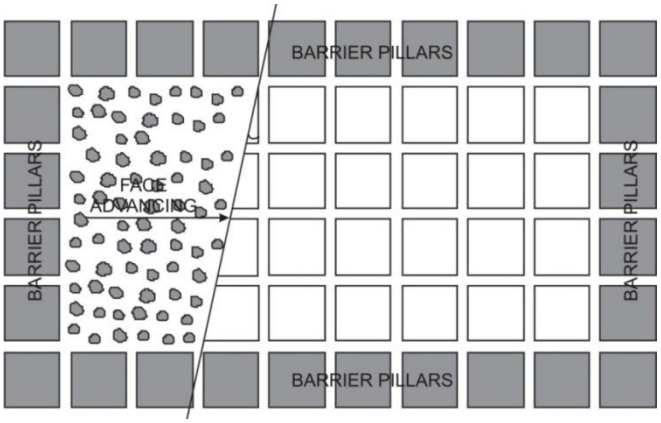

Figure 5. Face Obliquity during Short Wall mining

4.2.2 Support Requirement at the Face and in the Advance Gallery

The similar equipment used in Longwall is utilized here too and open galleries ahead the face are well supported with longer roof bolts and cable bolts. Additionally, breaker line supports which are of normal power supports set in the open galleries with remote operation. Self advancing, crawler mounted supports are also used as breaker line supports. Numerical models using FLAC 2D software was used for estimation of support requirement at the face and in the advance gallery. Support resistance on the powered support applied at the face was adequate to prevent failure of the immediate roof as the face approaches the advance gallery. This support system was designed with the safety factor more than 2.0.

4.2.3 Findings

Average production with shortwall mining technology at Balrampur Mine of SCCL was around 1500 tpd and coal recovery within the panel was around 95%. With Shortwall mining technology, about 8 developed panels of was extracted successfully.

4.3 Blasting Gallery (BG) Method of Mining

Extraction of seams thicker than 4.8 meters has always been a technical problem for the mining industry. The problem is further aggravated by the presence of already developed pillars that are estimated to be of several million tons. Several methods had been tried in India for the extraction of thick coal seam but Blasting Gallery method of mining is considered to be the only economical and viable technology for thick seam extraction and it can be treated as Mass production Technology.

At Vakilpalli Mine of RG-II area of Singareni Collieries Company Limited (SCCL), there are four seams viz., seam 1, 2, 3 and 4 in descending order which are dipping at an average gradient of 1 in 8.5. The upper most Seam 1 at a parting of 92m above 3 Seam was already extracted with longwall caving method and Seam 2 was not workable due to poor quality of the coal. Keeping in view of low gradient and seam thickness more than 9m of seam 3, Blasting Gallery method of mining was adopted in the south side property at Vakilpalli Mine. Parting between Seam 3 and Seam 4 is 8m. 4 Seam was being worked by depillaring with sand stowing underneath the BG panels. During extraction of Seam 4 and Seam 3; number of experimentation with mining sequences was done in the field to minimize the strata control problem. It was found that when 4 Seam is being worked first by depillaring with sand stowing followed by BG in 3 Seam with a lag of around 30–60m, the results were encouraging with significant improvement in roof rock strata condition.

4.3.1 Extraction Pattern in BG Method at Vakilpalli Mine, SCCL

The basic principle of Blasting Gallery Method as adopted in Seam 3 at Vakilpalli Mine of SCCL was to recover coal from 9.6m thick seam by drilling and blasting the

coal roof and sides of 4.2m wide and 2.7m height galleries developed along the floor of the seam at regular intervals. Ring holes up to 5-7m long are drilled in the roof and sides of galleries at regular distances varying between one to two meters by means of a Crawler mounted Jumbo drill (Fig. 6). Blasting is done with explosive cartridges separated by inert spacers and detonating fuses so that the explosive is distributed uniformly. Special custom-made Permitted Explosive (P-3) is used for Ring Blasting. Loading is carried out by Load Haul Dumpers fitted with remote control system, which enables the operator to stand under the supported roof and operate the LHD to load the blasted coal from the goaf. The LHD bring coal from the faces and discharge onto armoured chain conveyor from there to belt conveyor network, which transport coal to the surface Fig. 7.

It has been observed that caving of the immediate strata in the goaf was taking place regularly; as a result abutment pressure at the face was nominal which caused low convergence of the gallery roof with face advancement. Geologically disturbed areas containing slips and fault planes, shown very high convergence values before goaf formation in comparison to other areas.

4.3.2 Design of Support System for BG Method in Seam 3

For the design of suitable support system at the face and in the advance galleries, maximum required support load density at the face (obtained from the numerical models) has been taken into consideration, which came to 19.45 t/m^2. If two 40T capacity OC hydraulic props are used as support system with 150 x 150 mm^2 cross sectional roof bars (girders) of 3.8–4m length, in a row at an interval of 1.0m between two consecutive rows all along the original and split level galleries along with four number of 2.4m long full column cement grouted bolts in a row and at an interval of 1m between two consecutive rows, then applied load was estimated using the equation 4 as given below:

$$\textit{Applied Support Load} = \frac{n1\ x\ Hp + n2\ x\ G}{B\ x\ Sp1} + \frac{n3\ x\ C}{B\ x\ Sp2}$$

where, n1 is the number of hydraulic props in a row, 2; n2 is the number of girder in each row, 1; Hp is the bearing capacity of hydraulic props, 40T; G is the bearing capacity of girder, 4T; B is the gallery width, 4.2m; Sp1 is the spacing between two consecutive rows of the H.P, 1m; n3 is the number of bolts in a row, 4; C is the capacity of full column cement grouted bolts, 8T; and Sp2 is the spacing between two consecutive rows of the bolts, 1m.

Putting all the above values in equation 6, the applied support load density will be = 27.62 t/m^2. Therefore, safety factor of each support with single split of the pillars will be = 27.62/19.45 = 1.42 > 1.0. A longitudinal sectional view of the original or split level galleries supported with the recommended support system for both the cases is shown in Fig. 7.

In case of geological anomalies like slips/faults found in the roof, it can be supported by using additional cable bolts as shown in Fig. 8.

4.3.3Findings

Average production with BG Method of mining at Vakilpalli Mine of SCCL was around 1200 tpd and coal recovery within the panel was around 70%. Since the seam thickness was 9.6m, therefore, 70% recovery with indigenous support system was a very good achievement. This underground mine was also running in profit.

5 CONCLUSION

India is upgrading technology and the prospect of mass production technologies in the country is very bright which will contribute considerably in ramping up underground coal production. Case studies described in the paper reflect the efforts of mechanization for underground coal production enhancement in the recent years by introducing mass production technologies in Indian coal mines. These technologies are safe, fast, flexible and highly productive with limited capital investments. For its successful application, scientific studies need to be carried out carefully before its introduction in particular mines. The design of extraction methodology may be modified as per the requirement of the underground mining conditions.

R&D in Coal Sector in India

A. K. Debnath, V. K. Sinha, B. Prasad
CMPDIL, a subsidiary of Coal India Limited, Ranchi, India

ABSTRACT: There was a very little R&D in the Indian coal industry before independence. Recognizing the need for coordinated and sustained R&D work in coal sector, **s**oon after nationalization of the coal industry in early 70's the Government of India initiated Coal S&T Grant in 1975 and in-house R&D by Coal India Limited in 1997 to intensify research work for indigenous development of technologies suitable for the Indian coal industry and to meet the rising energy demand of the country. Since then a large number of research projects have been carried out which have yielded considerable benefits, resulting in operational improvement, safer working conditions, better resource recovery and protection of environment.

This paper gives a brief on R&D set up in coal sector in India, notable achievements of R&D efforts and also the need for enhancing quantum of R&D work needed to address the complexity of operations of coal industry.

Keywords: Coal, R&D, India

1 INTRODUCTION

India is the third largest producer in the world with present production of around 566Mt (2013-14) and, with a total coal resource inventory of about 302 Billion tons (Bt) as on 01.04.2014. Coal is one of the important abundant source of energy in the country, accounting over 50 percent share in commercial energy, is indispensable for economic growth and so are the research and development activities in Indian coal sector.

Since the start of organized research in coal sector in 1975, quite a good number of research projects were completed; and research projects, with outlay of 2.02 Billion INR are under implementation by various academic and research institutes in association with coal and lignite producing companies. While some of these completed projects, admittedly, did not produce the desired results, there have been many which have contributed significantly towards all round growth of the industry.

2 R&D SET UP IN COAL SECTOR

The S&T Grant is administered by the Standing Scientific Research Committee (SSRC) of the Ministry of Coal (MoC) and research funding of Coal India Limited (CIL) is administered through CIL R&D Board. Substantial funds are being earmarked annually by MoC and CIL R&D Board to carry out research work for improvement in production, productivity and safety in coal mines, coal beneficiation & utilization and, protection of environment and ecology. In addition inter sectorial research proposals are considered through Technology Information, Forecasting and Assessment Council (TIFAC) under the Department of Science and Technology (DST).

Central Mine Planning and Design Institute (CMPDI), a subsidiary company of CIL which carries out planning, design and exploration work for coal sector is the nodal agency to coordinate and monitor the R&D activities funded by MoC and CIL. CMPDI, besides being the nodal agency, a number of research projects were executed/are being implemented by CMPDI alone or in association with other organizations.

3 SALIENT ACHIEVEMENTS OF R&D EFFORTS

As mentioned above, many of these projects yielded considerable benefits in operational improvement, safer working conditions, and resource recovery and environment protection. While some research projects produced tangible impact on industry directly, there are others which strengthened mine planning, design and technical services required by mines/projects. Design tools developed specially for Indian geo mining conditions are now available for a variety of mining problems. Small selection of these is outlined below:

3.1 Rock Mass Rating

Rock Mass Rating (RMR) developed for quantifying roof strata through R&D efforts is now routinely being used for support design in underground mines. So far, over 800 underground workings in over 200 mines have been covered.

3.2 Blasting Gallery Method

Blasting Gallery was introduced through R&D funding with technical collaboration from CdF, France, in thick seams of CIL and Singareni Collieries Company Limited (SCCL). The system as adopted in India involves blasting of a series of holes drilled into the sides and roof of galleries in ring hole pattern. Remote controlled LHDs are employed for loading of the blasted coal and transporting to conveyors. The coal recovery is found to be about 70% in the panels, which is substantially higher than what is possible through conventional means.

3.3 Mining by Cable Bolts

A new mining method commonly referred to as Thick Seam Mining by Cable Bolts, was developed through research funding mainly for extraction of thick seams with developed pillars. The method was successfully tried in 6m thick seam at Chirimiri Colliery of South Eastern Coal Fields (SECL). Wire ropes of 19 to 22mm diameter and 6 to 8m length with safe bearing load of over 20 tons under tension were grouted into the roof to avoid roof coal from sagging and bed separation. A part of these cables so grouted went into the immediate roof strata up to a height of about 1.5m above the coal seam and provided support even after blasting of roof coal, which allowed coal loading under the supported strata. The coal recovery improved significantly (up to 75%) along with improvement in underground mine productivity.

3.4 Shortwall Mining

Shortwall Mining was successfully introduced at Ballrampur underground project of SECL with output of over 1000 tons per day. This is one of the future mining methods for liquidation of standing pillars with powered supports, and enhances production from underground mines which is stagnant from decades.

3.5 Controlled Blasting Technique

Controlled Blasting Technique developed through R&D is now being used for excavation in opencast mines near surface structures without endangering safety of inhabitants. This has enabled relaxation in the statutory provision of maintaining 300m distance from surface structures by the Directorate General of Mines Safety (DGMS), India.

Figure 1. Blasting near structures.

Regular production blasts are now being allowed up to 100m and in some cases even up to 50m away from structures by this technique. Consequently, over 150 Mt coal

was extracted in over 100 mines which otherwise would have remained sterilized.

3.6 Ground Penetrating Radar

For mine safety, a significant progress through R&D work has been made by introducing a modern technique, Ground Penetrating Radar for detection of old unapproachable water logged workings in underground mines.

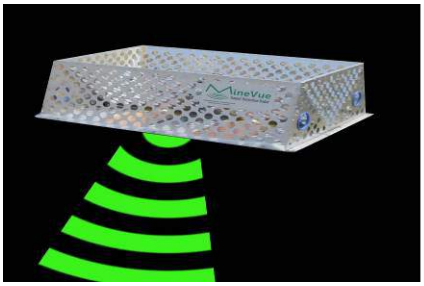

Figure 2. Ground Penetrating Radar.

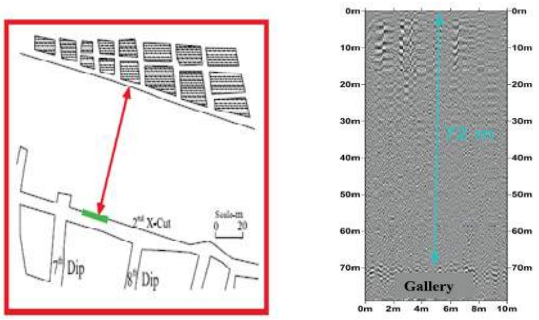

Figure 3. GPR Traverse & Data Obtained.

The developed GPR is capable of delineating barrier thickness of 60m or so towards blind water logged heading with an accuracy of ± 10%. After obtaining permission from DGMS, the GPR is now being used for detection of water logged workings in underground mines. This new technology provides a major tool for enhancing safety in underground mines close to water logged workings.

3.7 Coal Bed Methane

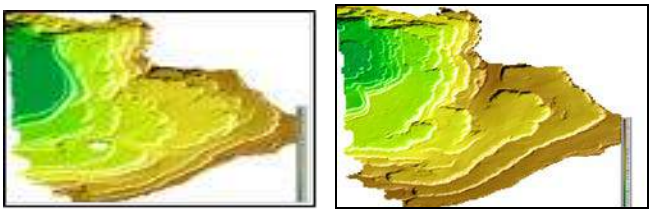
In India, reserve of *Coal Bed Methane (CBM)*, a clean energy source**,** is around 3.4 trillion cubic meters. A demonstration project on recovery of CBM and its utilisation, was successfully implemented through research funding at Moonidih project, Bharat Coking Coal Limited (BCCL).

Figure 4. CBM Rig & Gas Generators.

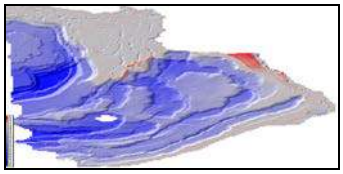
The recovered gas is almost 98% pure methane which is now being utilized to run 2x250kWh gas based generators and the electricity generated is being supplied to the Moonidih residential colony.

3.8 ALTM and TLS

A new technique - use of Airborne Laser Terrain Mapper (ALTM) and ground based Terrestrial Laser Scanner (TLS) have been introduced through research efforts for rapid volumetric analysis of excavated in situ overburden in CIL mines. Use of TLS measurement reduces 75% time and 50% manpower with respect to conventional survey.



(a) Dec 2008 (b) Dec 2007



(c) Volume calculation

Figure 5. Digital Terrain Model (DTM) based on ALTM data.

The methodology developed is being used in routine manner for OB measurement in the opencast mines of CIL and also

Singareni Company Coalfields Limited (SCCL) mines.

3.9 Development of Chock Shield

4X800T Chock Shield, with support density of around 140T/m^2, has indigenously been developed at a lower cost (about 50%) than what it would have cost coal companies to import similar equipment.

Figure 6. 4x800T Chock Shield.

3.10 Goaf Edge Supports

Self-Advancing (Mobile) Goaf Edge Supports (SAGES) have been developed indigenously for depillaring operations in underground coal mines to avoid the labor intensive and time consuming process in erecting wooden chocks and props at goaf edges for protection of roof during depillaring operations.

Figure 7. Goaf Edge Supports.

The supports were successfully tested at Bastacola underground mine, BCCL. These self propelled mobile supports of medium duty (2x220T) has closed and extended height range of 1.85 to 3.4 m and can offer support resistance of 71 T/m^2.

3.11 Two Way Communication Systems

Through-The-Earth (TTE) one way messaging system and two way voice communication and tracking system has been developed through research funding. The integrated system is now being used with digital wireless telephones in Bhurkunda mine of Central Coalfields Limited (CCL).

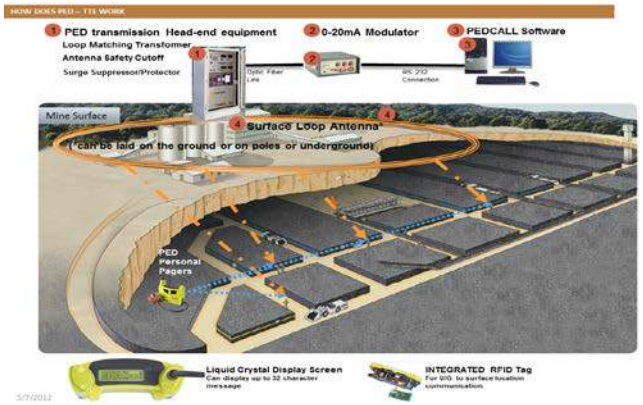


Figure 8. Two way communication system.

Now one can make and receive a voice call from anywhere to underground personnel. The another interesting aspect of the system is to send the text messages through TTE to the mine personnel working in underground mine through rocks right from the surface to below ground on all weather conditions across the entire length and breadth of the mine area and is not dependent on any underground infrastructure.

3.12 Dumper Collision Avoidance System

Indigenous Integrated Dumper Collision Avoidance System (DCAS) has been developed for safety in operating a large feet of heavy dump trucks in opencast mines in India. The system consists of anti collision devices to avoid head to tail collision between dump trucks and proximity warning system to avoid collision between dumpers and blind objects and also reverse safety system to prevent the dumpers from toppling down from the overburden (OB) dumps while unloading. The anti collision devices provide three layers of safety to detect objects on three sides within 10m range, provides directional and distance information of the other dumpers present in the vicinity of 100m and positional information of the dumpers through GPRS by sending SMS. The system is now

working successfully in one of the opencast mine of CIL.

Figure 9. Sensors fitted with Trucks.

3.13 Random Sampling and Testing of Explosives

An indigenous tool (AccuTime Instrument) for carrying out the job of random sampling and testing of explosives and accessories has been developed through R&D. The AccuTime Instrument is capable of measuring the unconfined VoD of various types of explosive products and precise delay time in nanoseconds instead of milliseconds for accessories like electronic detonators, nonelectronic detonators etc.

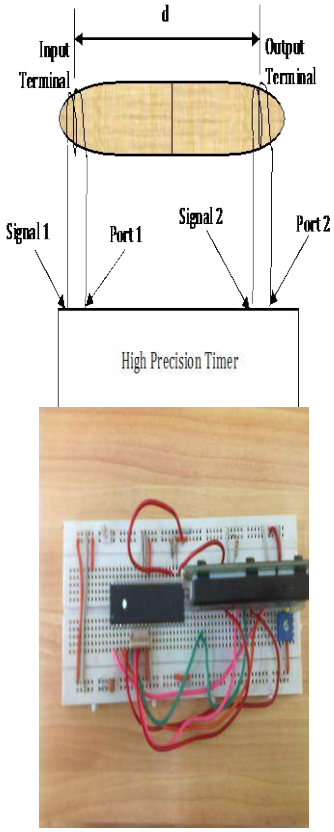

Figure 10. VoD measurement instrument & Microcontroller High Precision Timer.

Figure 11. AccuTime Instrument.

3.14 Use of Fly Ash

A number of research projects have been taken up in the area of environment and ecology to integrate coal mining activities with ecological conservation and to minimize air and noise pollution, land degradation and other environmental hazards due to mining. The findings of these research projects have made a significant impact on the industry resulting in the adoption of proper environmental control measures. Notable trials have also been made for re vegetation of mined out areas, use of fly ash and production of humic acid from lignite for use as fertilizer etc.

3.14.1 Utilization of lignite fly ash in agriculture

It was demonstrated that application of lignite fly ash maximum 200tons @20t/ha/year has found to increase the yield of groundnut and maize by 30% to 40%. Based on the outcome of field trials, fly ash is now being used by nearby villagers at Neyveli, Tamil Nadu through Krishi Vigyan Kendras.

Figure 12. Fly Ash treated Maize and Groundnut crops.

3.14.2 Application of lignite humic acid on crops

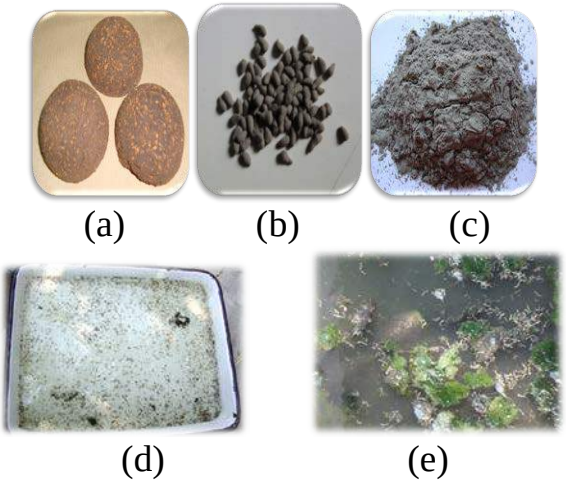
Application of humic acid extracted from Neyveli lignite has shown 35% increase in the yield in capsicum and tomato crops and substantial growth in other crops like onion, flower plants, Rose, Jasmine, Zinnia etc. Humic acid is now being used by the farmers in the states of Tamil Nadu, Karnataka, Andhra Pradesh and Kerala.

(a) (b)

Figure 13. Application of Humic Acid on Crops (a) Tomato, Cabbage and (b) Capsicum.

3.14.3 Lignite fly ash based pesticides

Lignite fly ash based bio pesticides developed under research study found to be highly effective against the immature stages of mosquitoes, which serve as vectors for malaria, filariasis, dengue, Japanese encephalitis, chikungunya etc.



(a) (b) (c) (d) (e)

Figure14. (a) Water Dispersible Powder (b) Granules (c) Briquettes (d) Live Mosquito Larvae and (e) Dead Mosquito Larvae

Figure15. Field Trials of Fly Ash Based Pesticides.

They can be used for the control of these disease vectors and ultimately control of the diseases transmitted by them. A single treatment with 1.5 to 2 g/m^2 was able to provide 100% mortality for up to 3 months.

3.15 Coal Beneficiation

With depletion in availability of good quality power coal and large scale mechanized opencast mining, the ash content in raw coal supplies to power sector has increased over the years. Ministry of Environment and Forest, Government of India has made it mandatory through a gazette notification that power stations located beyond 1000km, in critical, sensitive and urban areas will have to use washed coal with ash not exceeding 34%. A number of research projects have been carried out to tackle some of important issues related to coal beneficiation, especially for high ash Indian coals.

4 MAJOR RESEARCH PROJECTS UNDER IMPLEMENTATION

Application of robotics for online continuous monitoring of various mine parameters related to underground mine environment and roof strata, coal bed methane recovery and utilization, assessment of shale gas potentiality, indigenous development of catalysts for conversion of coal to liquid, greenhouse gas emissions in mine fire areas, dry coal beneficiation systems, development of integrated dumper collision avoidance systems, projects related to explosives use

in mines, solar photovoltaic powered micro grids for mining areas etc., are some at different stages of implementation.

5 SOME OF THE AREAS FOR FUTURE RESEARCH

5.1 Extraction Technology For Thick Coal Seams

In India, we have several thick coal seams. Also, there are large numbers of seams closely held together with varying partings of as little as 3m. Mining in multi flat/moderately inclined seam scenarios have a variety of difficulties such as stability of workings during mining in the immediate top and bottom seams, time delay between extraction of different seams, sequence of extraction, strata control problems, etc. A suitable method of extraction is required to be developed so that coal from these thick seams shall be extracted fully to avoid spontaneous combustion and other hazards.

5.2 Mining Methods for Extraction of Thick and Steep Coal Seams

The coal seams of North Eastern Coalfields (NEC), Assam are characterized by very steep gradient varying from 28 to 90 degrees, friable coal and weak roof and floor. Very high degree of gassiness and proneness to spontaneous combustion of the coal seams, high sulfur content of the coal and acidic mine water compound the problems of coal mining in the region. Various underground mining methods have been tried in NEC mines since nationalization, including various types of Russian Shield Mining Methods with Russian collaboration. Huge requirement of wood and metallic wire netting in these methods have resulted in high cost of production. A suitable mining method is required for extracting coal from these seams to improve substantially the present production level from these coalfields.

5.3 Water Jet Cutting Technology for Coal Seams on Fire

Huge reserves of good quality coal are blocked in seams on fire in Indian coalfields. A study is required to explore possibility of application of water jet cutting technology to extract these seams safely and economically. The technology which would be developed should include recovery of broken coal up to a dispatch terminal and arrangement of recycling of water.

5.4 Longwall Mining with Stowing

In India, a considerable amount of high grade coal is lying in moderate to steep gradient seams and these coals are not being extracted due to non availability of appropriate technology or due to surface constraints.

In the past, conventional longwall with stowing was tried with limited success.

Although, powered support longwall with stowing is an established technology and is being implemented successfully in China, Poland, New Zealand and other countries, but in India it was not tried either with powered supports or with continuous miner technology. A research study is required to adopt the available technologies with stowing in Indian geo mining conditions.

5.5 Hard Roof Management

Hydro fracturing or blasting in roof strata has been resorted to induce caving in several countries. In India, blasting from surface through bore holes has been tried in South Eastern Coalfields Limited (SECL) mines to avoid large overhangs. But it was found that it is not cost effective and is also associated with many difficulties in blasting. Further research on this important aspect may be required to explore various other alternatives like use of slow acting expansion cement / chemicals for application in drill holes into the roof strata to induce fractures to manage with hard

5.6 Warning Device to Indicate Impending Roof Failure

A reliable and a portable warning device is required to be developed which can provide early indication of roof falls. The device needs to be such that it can be operated on a regular basis during depillaring operations including for monitoring of roof condition at junctions.

5.7 Development of Portable Drilling Machine

At present, manually operated electric drills which are slow and insufficient and do not keep up pace with the drivage advance in mechanized developmental heads are being used for drilling the holes required for the bolting operations. There is a need to develop a light weight portable hydraulic drilling machine through R&D funding which would find application in all types of mine workings including in hard roof strata conditions.

5.8 Underground Coal Gasification

Earlier, some research work was carried out on Underground Coal Gasification(UCG) but unsuccessful by one or more reasons such as fear of pollution ground water, complex hydrogeology of the seams and also lack of continuous technical support. A pilot scale study may be undertaken through research funding to demonstrate techno economic viability of UCG technology for deep seated Indian deposits which cannot be mined through present mining technologies.

5.9 Liquefaction of Coal

Some limited research work on the subject was carried out in India in the past, the technology for conversion of coal to oil suitable for Indian coals for maximum yield at least possible cost is yet to be established.

As India has huge coal reserves and relatively small oil reserves, further studies are required to come out with a concrete result on feasibility of liquefaction of Indian coals to oil.

5.10 Shale Gas Assessment, Recovery and Utilisation

Although some research studies are being carried out through R&D funding, still there is a need to continue these efforts involving international expertise for developing methodology for shale gas assessment, recovery technologies and its utilization aspects.

5.11 Biological Debris Detection of Buried Body under Overburden Dumps

A Biological Debris Detector is required to detect burial of a dead body in case of dump failure in opencast mines. The device should be based on bio functions of a human body for predicting the orientation of the body buried under the OB dumps in opencast mines.

There are other areas like, fly ash based paste fill for void stowing in underground mines, capturing of ventilation air methane and its utilization, coal slurry transport where international expertise is required to take up research projects/or another other area of interest which would benefit coal industry either in financial terms or mine safety.

6. CONCLUSION

India has seen a lot of change in the forms of research work, especially over the last 35 years. Each of the approaches to research activity has had both merits and demerits from time to time. Some of the R&D efforts have translated into immediate gains for improvement in mine production, safety and conservation. Others are more indirect and long term gains.

There is also an increased impetus on development of renewable and other energy sources including coal based non conventional resources like Coalbed Methane, Coal Mine Methane, Underground Coal Gasification and new

energy sources like Shale Gas etc., are under focus.

Continuous efforts are being made to enhance R&D base in coal sector in India through wider participation of national and international scientific and academic organizations with adequate infrastructure and expertise to address the complexity of mine operations in Indian coal industry.

Selection of Recovery Sieve Size in Oil Agglomeration of Coal

E. Sahinoglu, T. Uslu
Karadeniz Technical University, Department of Mining Engineering, Trabzon-TURKEY

ABSTRACT The present study was undertaken to determine the effect of recovery sieve size on the performance of oil agglomeration of coal. An oxidized fine coal sample was subjected to oil agglomeration process. Combustible recoveries and ash-sulphur rejections were investigated. 72.90% of ash, 90.90% of pyritic sulphur, and 87.75% of sulphate sulphur was removed from the coal with combustible recovery of 76.53%. While increase in recovery sieve size had positive effect on rejections of ash and sulphur, it reduced combustible recovery sharply. It was concluded that use of recovery sieve whose size is higher than top feed size was not feasible at applied test conditions.

Keywords: Oil agglomeration, coal

1 INTRODUCTION

Mechanised mining has been resulting in production of large quantities of fine coals (Mehrotra et al., 1983; Cebeci et al., 2002; Sahinoglu and Uslu, 2013a). New environmental regulations as well as loss of valuable combustible matter with fine coal do not allow the current practice of discarding the coal fines with refuse. The finer the coal, the less efficient and more expensive are the conventional techniques of coal cleaning (Mehrotra et al., 1983; Capes, 1991). Therefore, flotation, selective flocculation, and oil agglomeration methods have gained importance to clean fine particles. Among these methods, flotation is most commonly used one. However, compared to flotation, oil agglomeration has important benefits, such as, quality of product in terms of pyrite, easy handling and transportation of the product, high recovery, suitability to oxidized coals and coals with clay slimes, simplicity and cheapness of dewatering stage (Mehrotra et al., 1983; Cebeci et al., 2002; Sahinoglu and Uslu, 2013a).

As with flotation, oil agglomeration of coal relies on the differences in the surface properties of hydrophobic coal particles and hydrophilic inorganic gangue (Laskowski and Yu, 2000). When a small amount of oil is introduced into an agitated suspension of coal particles, hydrophobic coal particles become oil coated and stick together to form agglomerates while the hydrophilic mineral water particles remain unaffected. The agglomerated particles can be separated from the other materials by a single screening operation or alternatively by floating and skimming. Performance of selective oil agglomeration depends on a great extent of the surface properties of solid particles (Gurses et al., 1997; Sahinoglu and Uslu, 2008; Sahinoglu and Uslu, 2013b). Hydrophobicity of coal surfaces, hydrophilicity of mineral matter surface and liberation of mineral matter from coal are required for efficient rejection of mineral matter in coal by this technique (Sahinoglu and Uslu, 2008).

Performance of the agglomeration process is affected by various parameters. One or more of the these parameters including, solid content, oil dossage, oil type, agglomeration time, agitation speed, coal particle size, pH of the medium, have been investigated by several authors (Aktas, 2002; Cebeci and Sonmez, 2006; Valdes and Garcia, 2006; Sahinoglu and Uslu, 2008; Aslan and Unal, 2011; Chary and Dastidar, 2012; Shaobin et al., 2012; Chary and Dastidar, 2013; Aslan, 2013; Sahinoglu and Uslu, 2014; Kumar et al., 2015).

Although recovery sieve size has vital importance for performance of the oil agglomeration process, very limited number of study has been reported relating to its effect on combustible recovery and ash-sulphur rejections. Therefore, another work is required to investigate the relationship between recovery sieve size and agglomeration performance in term of combustible recovery and ash-sulphur rejections. Coal sample used in this study differs from many coals used in agglomeration studies in that it shows typical characteristics of an oxidized coal with its brittle nature, high specific gravity, and high sulfate sulfur content. Waste sunflower oil was used as agglomerant. Moreover, pyritic and sulphate sulphur rejections of the process was investigated unlike the most of the previous coal agglomeration studies which have been contented with ash rejections.

2 MATERIALS AND METHODS

2.1 Materials

A coal sample from Muzret (Artvin-Turkey) coal deposit was used in this study. Proximate analysis of the sample shows that Muzret coal has high ash and pyritic sulfur content (Table 1). XRD analysis of the sample revealed that clay minerals (kaolinite, illite, montmorillonite), calcite, gypsum, quartz are present in the coal as mineral matters. Coal sample was dry ground to size fractions of -0.5 mm, -0.25 mm and -0.125 mm for oil agglomeration tests. The waste sunflower oil was used in the experiments.

Table 1. Proximate, sulphur and calorific value analyses of the coal sample.

Proximate Analysis	Air Dried	Dried
Moisture (%)	2.25	-
Ash (%)	34.85	35.65
Volatile Matter (%)	10.73	10.98
Fixed Carbon (%)	52.17	53.37
Sulphur Analysis	**Air Dried**	**Dried**
Sulphate Sulphur (%)	0.99	1.01
Pyritic Sulphur (%)	5.44	5.57
Organic Sulphur (%)	1.3	1.33
Total Sulphur (%)	7.73	7.91
Calorific Value Analysis	**Air Dried**	**Dried**
Calorific Value (kcal/kg)	4970	5084

2.2 Methods

Cylindrical glass vessel (11.7 cm in diameter) with four removable baffles of 1.1 cm in width was used for the tests. The agitation of vessel contents was performed using RZR 2021 type overhead stirrer equipped with a 45°-pitched blade turbine (four blade, 50 mm in diameter). Distilled water was used in the tests. Coal samples with different particle sizes (-0.125, -0.250 and -0.500 mm) were mixed with water (solid ratio: 10%). Coal-water mixtures were conditioned at 1000 rpm for 5 min. in order to achieve complete wetting of coal particles. Waste sunflower oil (10% of coal) was then added as bridging oil and coal-water-oil mixture was further agitated at 1400 rpm for 10 min. The tests were carried out at the natural pH of the coal-water-oil mixture. After agglomeration, the suspension was transferred to a recovery sieve to separate the agglomerates from water and tailings. Size of the recovery sieve changed in the range of 0.125-0.5 mm, 0.25-0.6 mm, and 0.5-1 mm for feed size of -0.125, -0.250 and -0.500 mm, respectively. In order to remove the entrained mineral matter, agglomerates were carefully washed with 1.5

L water. The agglomerates rejected from the sieve were vacuum filtered and de-oiled by washing with acetone. Oil-free agglomerates were dried at 105±5 °C. After drying, agglomerates were weighed and stored for analyses. Finally, agglomerates were analyzed for ash, pyritic sulphur and sulphate sulphur contents by using standard analyses methods. The combustible recovery, ash rejection, pyritic sulphur rejection, sulphate sulphur rejection were determined.

3 RESULTS AND DISCUSSION

As seen from the Figures 1-3, increasing of recovery sieve size had adverse effect on combustible recovery.

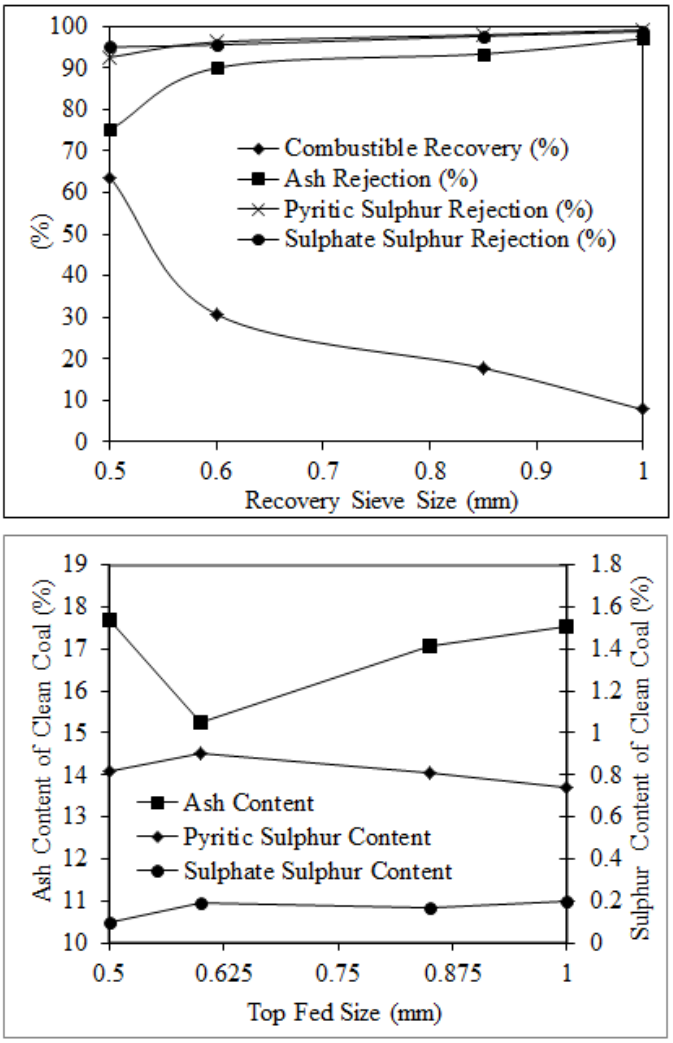

Figure 1. Effect of recovery sieve size on the performance of the oil agglomeration (feed size: -0.5 mm).

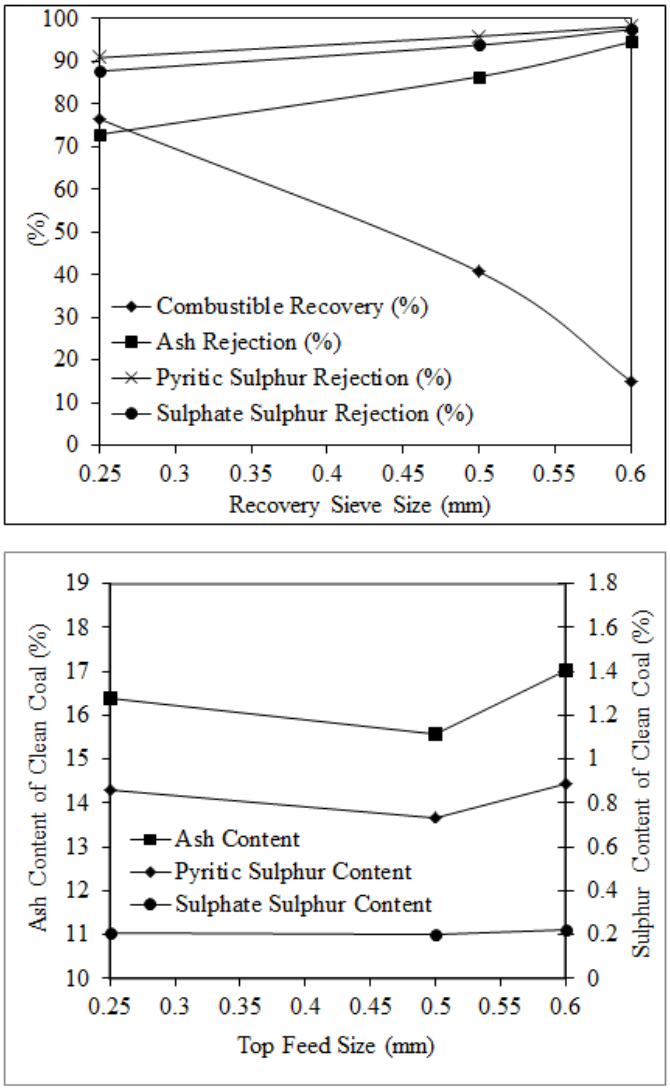

Figure 2. Effect of recovery sieve size on the performance of the oil agglomeration (feed size: -0.25 mm).

Because, small sized agglomerates could not retain on the sieve whose aperture size is over the top feed size and passed through the sieve apertures during agglomerate recovery and washing. Combustible recoveries obtained by using a sieve whose size is equal to top feed size are 55.54%, 76.53% and 63.62 % for feed size of -0.125, -0.250, and -0.5 mm, respectively. Adverse effect of increasing size of recovery sieve was observed. For the feed size of -0.5 mm, combustible recovery decreased by 87.69% as a result of doubling the recovery sieve size from 0.5 mm to 1mm.

For the feed size of 0.25 mm and 0.125 mm, reduction in combustible recoveries resulted from doubling of recovery sieve size whose size equals to top feed size were 46.80% and 79.36%, respectively.

Higher ash and sulphur rejections obtained at greater recovery sieve size shows that agglomeration process is more selective at higher sieve sizes. This can be attributed to easier passage of nonagglomerating and entrained mineral matter from higher sieve holes during agglomerate recovery and washing. Ash rejections, pyritic sulphur rejections and sulphate sulphur rejections achieved at the tests changed in the range of 72.90-97.56%, 89.04-99.23%, 87.75-98.79%, respectively. However, optimum values can be recorded as 72.90%, 90.90%, and 87.75%, respectively.

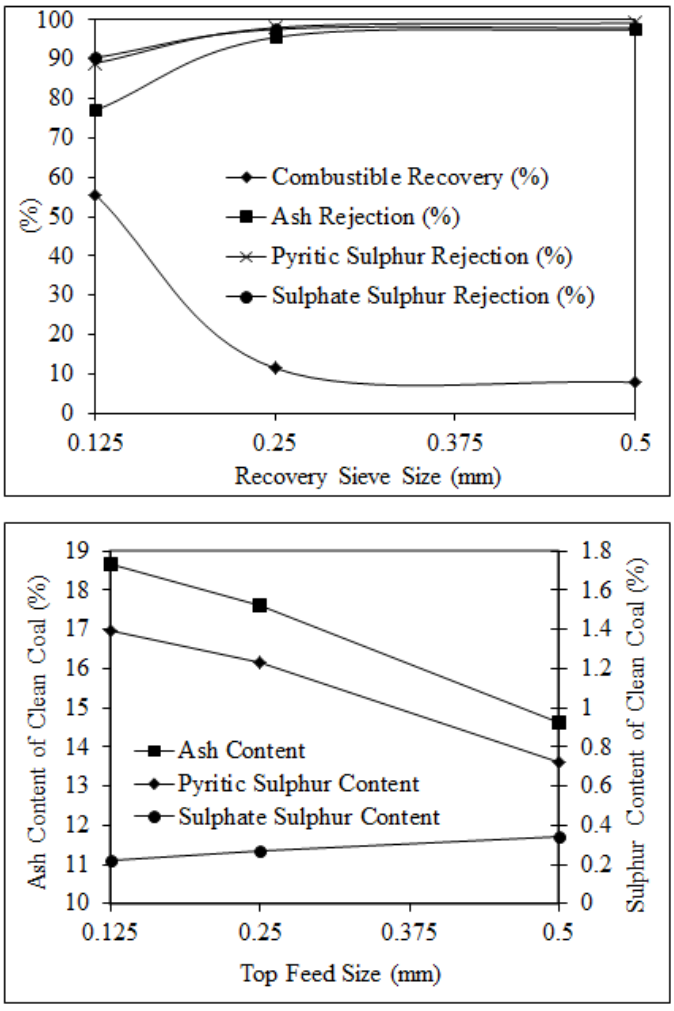

Figure 3. Effect of recovery sieve size on the performance of the oil agglomeration (feed size: -0.125 mm).

4 CONCLUSIONS

Although increasing recovery sieve sizes enhanced ash and sulphur rejection from coal, it had adverse effect on the combustible recovery. While cleaner agglomerates are produced, combustible matter reduces sharply as a result of increase in recovery sieve size. Further studies should investigate the relation between the agglomeration performance and recovery sieve size at higher oil dosages due to importance of oil dosage on growths and strength of agglomerates. Optimally, 72.90% of ash and and 90.90% of the pyritic sulphur and 87.75% of sulphate sulphur was removed from the coal at combustible recovery of 76.53%.

An Assessment of Turkish Lignite Fields for Underground Coal Gasification

Türk Linyitlerinin Yeraltı Kömür Gazlaştırma Yöntemi için Değerlendirilmesi

K. Het, Ş.Yürek
General Directorate of Turkish Coal Enterprises

D. W. Camp, J. L. Wagoner
Lawrence Livermore National Laboratory

ABSTRACT Underground Coal Gasification (UCG) is a way to convert *in-situ* coal into an energy-rich gas (synthesis gas). Like surface gasification, a combination of air, oxygen, and/or steam is reacted with the coal to produce a mixture of CH_4, H_2, CO, CO_2, H_2O, and lesser amounts of H_2S, NH_3, and assorted organics. UCG eliminates mining, transporting, pulverizing, cleaning, and handling the coal and most of its ash residue by doing the gasification in the coal seam in situ.

In this study, fourteen Turkish lignite fields were evaluated for their suitability to produce energy by UCG by Lawrence Livermore National Laboratory (LLNL) in the United States, together with Turkish Coal Enterprises (TKI) in Turkey. LLNL uses software during preliminary site assessments called UCG-ZEE (Underground Coal Gasification- Zonal Energy Estimator). This was one tool used to estimate the potential for UCG in coal fields in Turkey. By using the above-mentioned software, four important UCG parameters for each defined coal zone were calculated. These are: 1) the zone thickness, 2) the mass-average lower calorific value (CV) of the mixture of coal and rock layers within coal zone, 3) the maximum areal gas energy (MAGE) value for the zone, and 4) a figure of merit that combines CV and MAGE.

Keywords: Lignite, gasification , UCG-ZEE , MAGE

ÖZET Yeraltı Kömür Gazlaştırması (YKG), kömürü yerinde enerjice zengin bir gaza (sentez gazı) dönüştürmek için kullanılan bir yöntemdir. Aynen yüzey gazlaştırma işleminde olduğu gibi hava, oksijen ve/ve ya buhar kömür ile reaksiyona sokularak CH_4, H_2, CO, CO_2, H_2O ve az miktarda H_2S, NH_3 gazları ile çeşitli organikler üretilebilmektedir. YKG yöntemi, kömür gazlaştırma işlemini kömür damarının içinde gerçekleştirerek madencilik, nakliye, pulverizasyon (öğütme), yıkama ve kömürün kullanımı aşamalarını ortadan kaldırmakla birlikte, kömürün gazlaştırılması sonucundan oluşan kül artığının da kömür damarının içinde kalmasını sağlar.

Bu çalışmada, Türkiye'de bulunan on dört linyit sahasının YKG yöntemi ile enerji üretimine uygunlukları Amerika Birleşik Devletleri'nden Lawrence Livermore Ulusal Laboratuarı ve Türkiye'den Türkiye Kömür İşletmeleri tarafından değerlendirilmiştir. LLNL ön saha değerlendirme aşamasında UCG-ZEE (Yer altı Kömür Gazlaştırma-Bölgesel Enerji Değerlendirici) adlı yazılımı kullanmaktadır. Bu yazılım ile Türkiye'deki linyit sahalarının YKG potansiyelleri tespit edilmeye çalışılmıştır. Söz konusu yazılım kullanılarak tanımlanan her bir linyit bölgesine yönelik dört önemli YKG özelliği hesaplanmıştır. Bunlar: 1) Bölge kalınlığı, 2) Kaya ve linyit karışımına ait Kütle-Ortalama Alt Isıl Değeri (AID) 3) Maksimum alansal gaz enerji değeri (MAGE) 4) AID ve MAGE değerlerini birbirine bağlayan değer katsayısı.

Anahtar Kelimeler: Linyit , gazlaştırma, UCG-ZEE , MAGE

1 INTRODUCTION

Underground Coal Gasification (UCG) is a way to convert in-situ coal into an energy-rich gas called synthesis gas. Like surface gasification, a combination of air, oxygen, and/or steam is reacted with the coal to produce a mixture of CH_4, H_2, CO, CO_2, H_2O, and lesser amounts of H_2S, NH_3 and assorted organics. UCG eliminates mining, transporting, pulverizing, cleaning, and handling the coal and most of its ash residue by doing the gasification in the coal seam *in-situ*.

This is accomplished by drilling and completing wells into a coal seam; these wells are used for injecting the air/oxygen/steam and for the eventual recovery of the product gas. Modern UCG generally targets coal seams deeper than 200 meters. Similar to surface gasification, the product gas can be burned to make electricity or converted to one of many products such as methane (synthetic natural gas), methanol, liquid fuels, ammonia, and fertilizers. Moreover, CO_2 in the product gas can efficiently be separated for sequestration or other uses.

Over the past 80 years, a hundred or so experimental, pilot, and demonstration UCG operations worldwide have shown UCG to be technically feasible and the technology has continued to improve. A large effort to improve and commercialize UCG in the United States in the 1970's and 1980's hit a commercial dead end with the drop in energy prices in the 1980's. Significant modern efforts toward commercial-scale development are found in many parts of the world today, including Australia, South Africa, China, Canada and Eastern Europe.

UCG avoids the safety and environmental issues associated with mining, transport and processing of the coal and most of the ash. UCG has a similar potential for subsidence and subsurface structural changes as underground mining. UCG produces some contaminants and some small fraction of these contaminants is left underground. Proper site selection, design and operation practices have been demonstrated to manage this issue but it is still important to recognize, UCG should be done at depths and locations where a significant geological barrier can be assured between it and fresh groundwater aquifers.

Generally, UCG is best deployed where:

- Coal fields are technically well-suited for UCG,
- Energy (especially electricity and natural gas) costs are high and/or variable,
- Energy (especially natural gas) supply is not secure,
- There is an infrastructure to support UCG development,
- There is nearby use/demand/market/infrastructure for UCG product gas,
- Deep level underground coal mining is expensive or challenging.

In this study, fourteen Turkish lignite fields, listed in Table 1, were evaluated for their suitability to produce energy by UCG. At this stage of assessment, the purpose was not to produce quantitative predictions of performance and cost, but rather to guide the assessment of feasibility.

Table 1. List of Turkish lignite fields evaluated for UCG

Name of Lignite Field

Thrace Basin-Küçükyoncalı
Thrace Basin-Safaalanı

2 APPROACH TO UCG ASSESSMENT

2.1 Preliminary Screening

A preliminary screening of the lignite fields was performed to identify the most promising sites and those that might be suitable for additional analysis. Preliminary screening focused on easily available technical factors including depth of the coal zone, thickness of individual coal seam and rock layers and zones, and the coal heating values of those layers. Qualitative geographical factors were also considered, such as economic land use within the local area. The most important of the many technical factors considered in preliminary screening are summarized below in Table 2 according to their importance.

Table 2. Summary and approximate ranking of the most important technical criteria required for site selection

Ranking	Criteria
Most Important	Average as-received calorific value of coal zone
	Maximum areal gas energy (MAGE)
	Roof rock resistance to cavity growth/collapse
	Coal and rock geomechanical properties
	Depth of coal seam
Very Important	Coal and rock hydrological properties
	Fault distribution and characteristics
Important	Thickness of coal zone including partings
	Dip angle of coal seam
	Lateral continuity of coal seam
	Roof rock spalling propensity
	Proximate analysis
	Ultimate analysis
	Coal rank (avoid swelling bituminous)
	Decomposition of overburden rock minerals

2.2 UCG-ZEE Analysis

LLNL has developed a tool for preliminary site assessment called "UCG Zonal Energy Estimator" or UCG-ZEE. UCG-ZEE is a tool for assessing borehole data consisting of many layers of rock and coal having different heating values within a coal zone. The user defines or picks the boundaries of the zone, with the bottom and top layers being coal. The bottom layer is where the user estimates the lowest place where reactants can readily transport (the location of the injection well in horizontal "Controlled Retraction and Injection Point" or CRIP construct). The top layer is below where the user estimates that roof rock will hold well enough that next coal layer will not be involved. The model allows for three alternative picks of zone top and bottom to be chosen and evaluated. Once a zone is defined, the model calculates four metrics for that zone: the zone thickness; the mass-average lower calorific value (CV) of the mixture of coal and rock layers within it; the maximum areal gas energy (MAGE) value for the zone; and a figure of merit that combines CV and MAGE.

The maximum areal gas energy (MAGE) is the chemical energy per square meter of land surface area that would be embodied in the gas product if the zone were completely gasified using pure oxygen and the ideal amount of steam. MAGE assumes no heat losses but incorporates reasonable estimates for the final temperature of the hot remaining ash and for the temperature of UCG product gas. MAGE is the expected product gas chemical energy if the UCG operation on the zone in question underwent no heat losses to the surroundings, no roof spalling or collapse and no inward groundwater permeation.

In general, the greater the MAGE values and the greater the CV values for a seam, the higher value the seam has for UCG potential. But both parameters are important. For instance, a very thin layer of rich coal may have a high CV but an unacceptably low MAGE. A very thick zone with more rock than coal may have a high MAGE but an unacceptably low CV. At this point, "Figure of Merit" is a function of CV and MAGE

that is intended to correlate with expected UCG technical and economic performance.

For the purposes of screening of fields and of areas within fields, areas were divided into four categories (Favorable, Promising, Possible and Challenging) depicted in Table 3. The numerical thresholds for each quadrant were set by integrating LLNL's proprietary material and energy calculation results for Turkish lignites, knowledge of results from past UCG field tests and operations, knowledge of currently operating UCG projects around the world, and knowledge of many planned UCG operations around the world.

Table 3. Classification of the suitability coal zones for UCG based on UCG-ZEE screening

		MAGE		
		>80k	40k-80k	<40k
CV	>3500	Favorable	Promising	Challenging
	2500 - 3500	Promising	Possible	Challenging
	<2500	Challenging	Challenging	Challenging

Based on UCG-ZEE screening, regions in the Favorable quadrant of Table 3 are suitable for UCG deployment in terms of the parameters modeled. Of course, many other factors are important in the overall determination of UCG suitability. It is also possible that successful UCG may be conducted at regions in the Promising and Possible quadrants, depending on the outcome of detailed analyses, testing, and development. On the other hand, by using current state of knowledge, experience, and technology, UCG is unlikely to be successful and economic at regions in the Challenging quadrant.

2.3 Geological 3D Models and Visualization of UCG-ZEE Results

A second tool used in this study is Earthvision 3D geological modeling software. This software is extensively used for building and visualizing 3D geological models to characterize and better understand the subsurface geology. In this study, 3D geological models were only generated for four most promising UCG sites. The results from the UCG-ZEE analyses were incorporated into each local Earthvision models. These colored contour plots of CV, MAGE and Figure of Merit were draped over the 3D model and used to identify areas within the field that met defined criteria for being favorable, promising, possible and poor. These areas were then integrated for the calculation of total area.

In this study, 3D geological models were developed for the most promising coal fields by using Earthvision geological modeling software. Also colored plan view contour pilots including the UCG-ZEE results were constructed for the most promising coal fields. The 3D geologic model for the Tunçbilek-Domaniç region is illustrated in Figure 1.

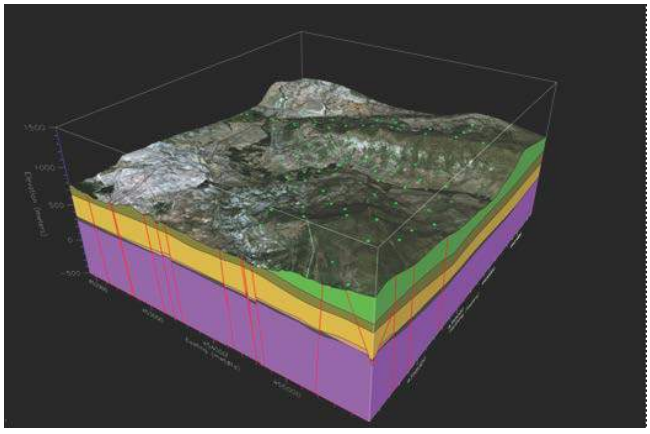

Figure 1. Earthvision 3D Geomodel for Tunçbilek-Domaniç region. Borehole collar locations are shown as green symbols. The stratigraphic units are (lowest to highest): Basement rock (purple), Coal (beige), Marl (yellow), Limestone (Light Green). The dipping faults intersecting the side of the model are shown as red lines.

3 SUMMARY OF ASSESSMENT OF ALL FIELDS

A high-level summary of many important characteristics of the fourteen fields is presented in this section. The fields were grouped as four best, three possible and six unfavorable. The four best fields were investigated in greater detail than the other ten fields.

3.1 Four Best Fields

Table 4 summarizes results for the following four best fields: Soma-Eynez, Tunçbilek-Domaniç, Muğla-Turgut and Soma-Evciler lignite fields. The scale for CV is relative to lignites, which tend to be lower than sub-bituminous coals. These fields have a combination of geographic, technical and energy economic characteristics that make them very well suited for both pilot and demonstration projects, and are leading candidates for commercial-scale energy production by UCG. In comparison to UCG projects being advanced around the world, two of these fields, Soma-Eynez and Tunçbilek-Domaniç appear to be at a similar or better level of favorability according to the factors considered. In addition, Turgut and Soma-Evciler have some advantages in certain important attributes.

Table 4. Summary results for the four best fields assessed in this study

Properties	Soma-Eynez	Tunçbilek-Domaniç	Soma-Evciler	Muğla Turgut
Average CV of entire zone coal + partings	Great	Very good	Good - Fair	Good - Fair
Zone MAGE (net energy in zone)	Great	Very good	Good-Fair	Good-Fair
Figure of Merit	Great	Very good	Good-Fair	Good-Fair
Depth	Good (Deep)	Good (Deep)	Most Good	Much Good
Over-burden	Massive Marl, Very Good	Mostly Marl, Probably Good	Marl, Probably Good	Weak
Summary	Probably Excellent	Probably Very Good	Probably Very Good to Marginal	Probably Good to Ok

3.1.1 Soma-Eynez lignite field

The Soma-Eynez Lignite field is the most promising lignite field in Turkey for UCG. Both technical factors and infrastructure/environment factors appear promising. The Soma-Eynez Lignite field may be amongst the better ones in the world for UCG based on the factors considered. The coal zone has outstanding CV and MAGE values everywhere and the area and the volume of this resource is very large. The coal characteristics and depth from the surface appear excellent for UCG. The marl overburden is massive and appears to be strong, at least at moderate temperatures; it also has a low porosity and water content. One factor that creates technical uncertainity for UCG at Soma-Eynez is the uncertainity of how the marl will behave surrounding a hot UCG operation. A combination of lab testing and a UCG pilot will be needed to quantify marl thermochemical behavior and the extent of its effect on the UCG operation. After this uncertainity is eliminated, Other factors such as environmental hydrology were not considered at this point in the evaluation. Pending results from further, more detailed and wider-scoped investigation, Soma-Eynez has the potential to be an internationally top-level opportunity for UCG.

3.1.2 Tunçbilek-Domaniç lignite field

Considering its technical and infrastructure/environmental factors, Tunçbilek-Domaniç is a very promising field for commercial UCG. The coal zone has very good CV and MAGE. The area and volume of good coal and MAGE is large but less than at the Soma-Eynez Lignite Field. The properties and depth of the coal are expected to be excellent for UCG. The overburden at the Tunçbilek-Domaniç field is somewhat variable and/or uncertain containing a number of lithologies including both marl and clastic rocks. In addition, underground mines in that area have had some problems with flooding, perhaps from intersecting faults. It is very likely that UCG can be run successfully in this field, at least at the pilot

and small demonstration scale, but the factors noted above suggest that a detailed characterization and a series of pilot and demonstration operations and design work are needed to accurately determine the exact performance and economics that would be expected from a commercial operation here.

3.1.3 Soma-Evciler lignite field

The Soma-Evciler lignite field appears to have stronger overburden than Muğla-Turgut lignite field but not as good coal and potentially more challenging geological structure; it is possible that UCG could successfully perform there. Commercial prospects at Soma-Evciler are uncertain because the energy content and the richness of its coal zones at the optimal depths are less than ideal, the area and volume of candidate coal zones for UCG are limited, and the geological structure is more complex. The overburden rock at Soma-Evciler is predominantly marl. This may be as strong and massive as at Soma-Eynez but the limited data and observations available suggest that it may be more heterogeneous have more fractures and lower rock mass strength value than Soma-Eynez. There are UCG design and operation approaches that can minimize these disadvantages and at this stage it cannot be judged whether a commercial operation there would be good, medium or poor. It would need a more detailed site characterization and preliminary design estimates followed by a pilot and better design calculations to know how economical a commercial operation could be there.

3.1.4 Muğla-Turgut lignite field

The Muğla-Turgut lignite field appears to be very good for at least a UCG pilot, and possibly for a commercial operation. Muğla-Turgut warrants additional characterization and design to determine feasibility. The coal zone has more ash, water and rock partings than Soma-Eynez but its CV and MAGE values are such that UCG appears possible. In particular, large-scale and commercial prospects at Muğla-Turgut are uncertain due to weak overburden. This issue could be managed by narrow UCG cavities to minimize the roof collapse. Such an approach is expected to produce good technical performance but economic performance will not be as good as at a field with strong overburden. The costs may be acceptable and energy can be produced by UCG from this lignite field. What is needed next for Muğla-Turgut lignite field is a more detailed site characterization. Once better understood, preliminary design estimates for Muğla-Turgut lignite field would be created, followed by a pilot and better design calculations to determine the best approach to this field.

3.2 Three Possibly Feasible Lignite Fields

Three fields (Bursa-Keles-Davutlar, Thrace Basin Çerkezköy 1 and Thrace Basin Çerkezköy 2) may possibly be feasible for UCG. Bursa-Keles-Davutlar has good coal zones locally but the field is shallower than general good UCG practice would employ in commercial operations. Thrace Basin Çerkezköy 1 and Thrace Basin Çerkezköy 2 are deep lignite fields but have coal zone energy characteristics that are marginal for UCG. It is possible that UCG could work there but technical and economic performance would probably be less than the four best sites noted above. Table 5 summarizes results for the three possibly feasible lignite fields.

Table 5. Summary of the results for the three possibly feasible lignite fields

Properties	Bursa-Keles-Davutlar	Thrace Basin Çerkezköy 1	Thrace Basin Çerkezköy 2
Average CV of entire zone coal + partings	Some Good CV	Medium-Low CV	Medium-Low CV
Zone MAGE (net energy in zone)	Some Good MAGE	Medium-Low MAGE	Medium-Low MAGE
Figure of Merit (FOM)	Some Good FOM	Medium-Low FOM	Medium-Low FOM
Depth	Shallow coal >120 m	Deep Coal	Deep Coal
Summary	Possible	Possible	Possible

3.3 Seven Unpromising Lignite Fields

Unless new information appears or UCG technology changes dramatically, the following seven fields do not appear suitable for commercial UCG deployment: Tunçbilek-Demirbilek, Adana-Tufanbeyli, Thrace Basin-Edirköy, Thrace Basin-Küçükyoncalı, Thrace Basin-Safaalanı, Thrace Basin-Vize, Konya-Beyşehir. Some of the boreholes in some of these fields show possibility of supporting small pilot tests for the purpose of training or research investigation. For example in two or three boreholes in Demirbilek, rich coal zones can be found that are thick enough to potentially support underground coal gasification technically, but the economics would be poor.

4 PLOTS OF MAGE AND CV RATINGS FOR THE FOUR BEST FIELDS

For the four best fields, a UCG-ZEE analysis was done for two or three zone picks for each different coal zone in each borehole. For each borehole the most favorable coal zone pick was identified, mainly on the basis of the UCG-ZEE figure of merit. Each of these best picks has a MAGE and a CV value. Given a MAGE and a CV value, Table 3 was used to assign a relative UCG suitability rank of "promising", "possible" or "challenging". These descriptors are in a commercial context. Pilot tests could be run successfully in "possible" areas.

Figures 2 to 5 show color contour plots of these suitability rankings from the Earthvision models. It is important to remember that these plots only consider MAGE, CV and depth and not the many other important factors.

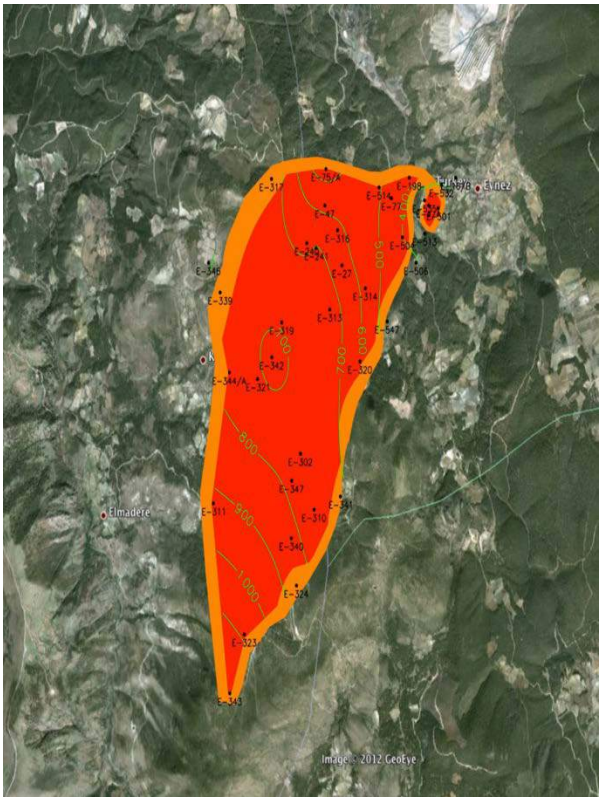

Figure 2. Coal zone suitability for the Soma-Eynez Lignite Field. Red=Favorable; Brown=Promising; Yellow=Possible; Uncolored areas with boreholes=Challenging. Green contours are depth to coal seam.

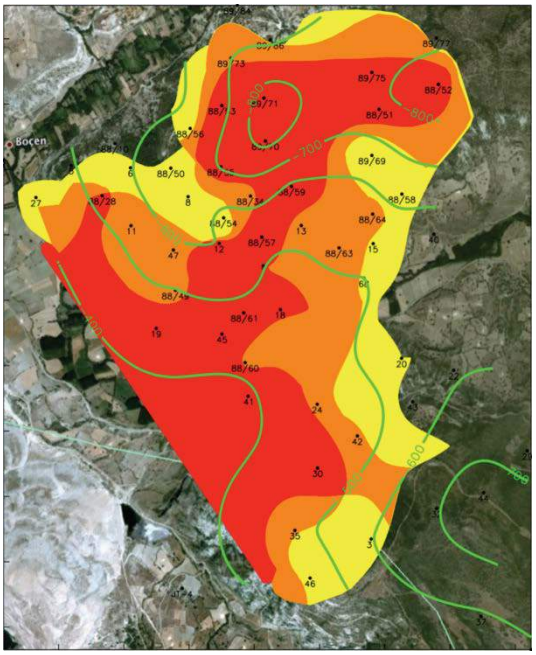

Figure 3. Coal zone suitability for the Tunçbilek-Domaniç Lignite Field. Red=Favorable; Brown=Promising; Yellow=Possible; Uncolored areas with boreholes=Challenging. Green contours are depth to coal seam.

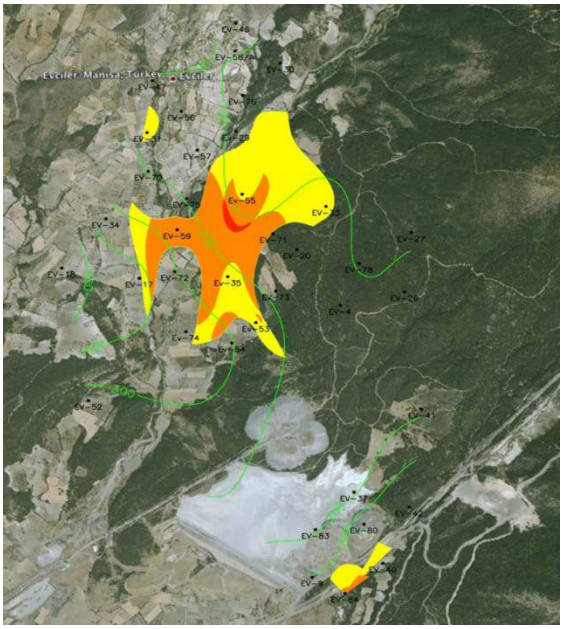

Figure 4. Coal zone suitability for the Soma-Evciler Lignite Field. Red=Favorable; Brown=Promising; Yellow=Possible; Uncolored areas with boreholes=Challenging. Green contours are depth to coal seam.

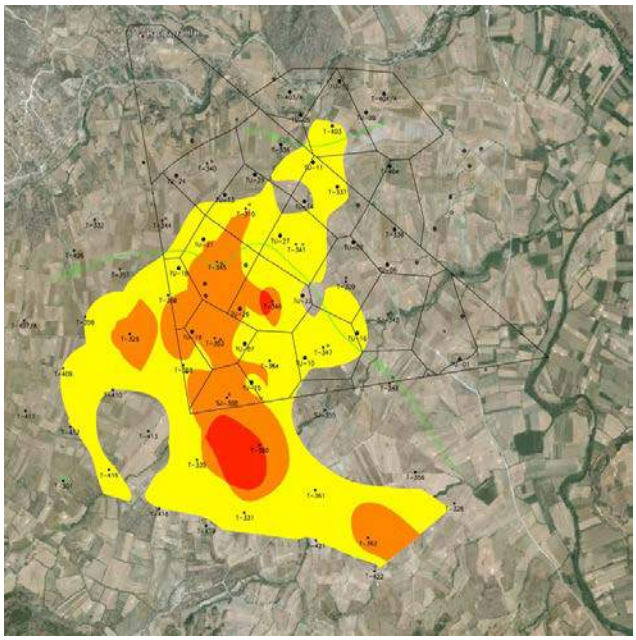

Figure 5. Coal zone suitability for the Muğla-Turgut Lignite Field. Red=Favorable; Brown=Promising; Yellow=Possible; Uncolored areas with boreholes=Challenging. Green contours are depth to coal seam.

Table 6 gives the approximate number of square kilometers for each of the four best sites that are favorable, promising, or possible in terms of their MAGE and CV values for the best some pick of each borehole. No other factors are considered here.

Table 6. Approximate number of km^2 in each category for the best fields

	Favorable	Promising	Possible
Soma-Eynez	9.2	0.3	0
Tunçbilek-Domaniç	3.8	1.3	0.8
Soma-Evciler	0.01	0.4	0.4
Muğla-Turgut	0.1	0.6	3.0

5 CONCLUSIONS

Underground coal gasification in selected Turkish lignite fields can enable the use of Turkey's indigenous low-rank coal resource to increase useful energy production in a safe and environmentally responsible way. This would enhance Turkey's energy security, and the economics may be favorable. Turkey's

energy, political and economic situation is very well suited for UCG.

- High and variable gas and oil prices from foreign suppliers,
- Growing demand for electricity, gas fuels and liquid fuels,
- Infrastructure for expanding and building electrical generation and distribution and industrial conversion plants,
- Strong science and engineering educational and research institutions capable of staffing and leading new technology projects.

Turkey has several lignite fields that are technically well suited to UCG. These fields are in locations that can provide the workforce and infrastructure and energy market (electrical production and distribution) to support UCG. The following conclusions are based on this study and current knowledge.

- Soma-Eynez lignite field is an outstanding target for UCG commercial deployment. Early and focused attention is needed to confirm that the behavior of the marl overburden is good under UCG conditions, and that the hydrology is favorable.
- Tunçbilek-Domaniç lignite field may be a very attractive target for UCG commercial development. Early and focused attention is needed to assess the behavior of the various overburden materials under UCG conditions and to characterize and design for fault-related hydrologic aspects.
- Muğla-Turgut lignite field is a good place for a pilot program and may prove to be good for commercial development. UCG module construction and operation will need to be tailored to manage the weak overburden strata.
- Soma-Evciler lignite field is a good place for a pilot program and may prove to be good for commercial development. In addition to confirming marl overburden behavior, a commercial mine plan would need to be designed to accommodate faults and dips.
- Bursa-Keles-Davutlar and Thrace Basin Çerkezköy 1 and Çerkezköy 2 lignite fields would be acceptable locations for a pilot program and/or have some potential for commerical development.

UCG projects are being advanced at locations around the world that have worse combinations of energy situation and coal resource. Turkey is unfortunate in having a challenging situation with expensive unreliable gas and oil imports. Turkey is fortunate to have domestic lignite resources that are very good for UCG that can help solve this problem. UCG can provide a secure Turkish energy supply from Turkish coal resources with production costs that should not fluctuate as much as natural gas or oil prices.

ABSTRACT
The proposition of this paper is to propose a sorting platform aiming to increase quality on recycled aggregates by supplementary use of mineral processing techniques and more sorting. The difficulty of liberation is discussed and the methodology currently used in mineral processing is proposed. Jigs, hydrocyclones and sensor-based sorting are equipments considered as having good performances to sort adequately recycled aggregates.

The new perspectives of sorting and liberation for recycling aggregates are discussed. Based on current process in recycling platforms, the new process with supplementary sorting of the concrete recycled is presented. The gain in density and the reduction in water absorption were studied. The relation between the water content and the density of aggregates is analysed for three quality levels of recycled aggregates.

The gain in density and the reduction in water absorption were linked with rates of replaced aggregates. In our study, replacing a lower quality aggregate by another with medium quality leads an expected gain in density about 4%. On the other hand, if replaced by superior quality, the expected gain will be 8.4%. As consequence, 34% on reduction in water absorption could be obtained too.

Keywords: Gravity concentration, sensor-based sorting, aggregate recycling

1 INTRODUCTION

The construction industry is a major solid waste generator around the world (Ulsen, 2013). Construction and demolition waste (CDW) is generated through the construction, renovation, and demolition processes of residential or commercial buildings, roads, bridges, etc. The CDW material usually is not (re)used and becomes an important environmental problem (Raoa et al., 2007). They can be stock in landfields, or the inert part is traditionally in roads, dams, etc.

In order to facilitate recycling, automatic optical sorting were developed in mining industry to process different ores. Gülsoy et al. (2012) studied optical sorting with CCD cameras in coal beneficiation. The technique was used to improve coal beneficiation for coals with high near-gravity materials. Optical sorting was tested with positive results for materials having significant colour differences. Ergün et al. (2012) used optical sorting to treat iron and chromium ores. For iron ores, samples were taken from a magnetite processing plant. The purpose of the study was to concentrate hematite that

was mixed with silicates. Optical sorting depends of many factors, such as, particle size, surface conditions, light source, feed rate, etc.

Dehler et al. (2012) conducted two tests with borates treatment, by the use of near-infrared sorting. CCD cameras were used as sorting sensors, which have opened new possibilities for sorting in the mining industry. The difference is based on the wavelength of response spectrum.

In urban and metropolitan areas, the building materials recycling industry has used stationary plants to process concrete and masonry demolition waste. A relatively pure, high quality granulates are produced with recycling requirements. Considering these environmental context, the aim of this paper is to make more attractive the sorting systems, i.e. less energy consumption and less emissions. They can produce different flows with more homogeneous composition and provide a specific reuse or a recycling. The process detailed in this paper is based on the use of gravity concentration and sensor-based sorting.

2 MINERAL PROCESSING APPLIED IN CDW

2.1 Difficulty of Liberation

Several studies about recycled concrete have been published in the last years (Gomez-Soberon, 2002; Oikonomou, 2005; Akbarnezhad, 2010; Marie et al., 2012). Recycled concrete is produced by reducing the size of concrete debris through multiple crushing stages. According Akbarnezhad (2010), depending on the size, the crushed concrete particles can present middlings, which contains particles of natural aggregates mixed with mortars (Figure 1).

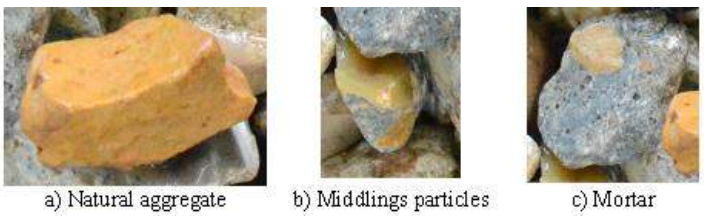

Figure 1 - Recycled aggregate (6-10 mm) (Source: PN Recybéton project, 2011.

After comminution, a mineral can be totally or partially liberated. The particles liberation depends on the mineralogical origin, the quality of the concrete, the angularity of the original aggregates, the comminution process, size, etc. In order to increase liberation, a preparation circuit should be used, to allow more intensive use of the recycled materials. With the beneficiation of recycled concrete material, more liberated particles can be achieved. In this sense, the use of innovative separation techniques in quarries, as sensor-based sorting or/and gravity concentration, will increase the quality of the products generated, as well as the price that they can be sold. These mining techniques, which are common in mining industry, could ensure a more efficient sorting in quarries.

2.2 Use Of Mineral Processing Techniques With Recycled Concrete

Gravity concentration is defined as the process whereby particles of different sizes, shapes and densities are separated from each other by gravity or by centrifugal forces. It is called gravity concentration once the separation is performed mainly based on the density (specific gravity) (Sampaio, 2005). Gravity concentration processes show high mass throughput and low investment and operational costs. Moreover, there is no limit for the maximum particle size and can be used for particles with wide size ranges. Furthermore, reagents are not used and this contributes significantly for low operational costs as well as for low environmental impacts.

Jigging is a separation process which consists of repeated expansion (dilatation) and contraction (compression) of a vertical bed of particles by a pulsating movement of water or air (Agricola, 1950)(Lyman, 1992). The result is the stratification of the bed. The particles are deposited in layers with increasing densities from the top to the bottom. Jigs were and still are widely used mainly due to their costs. They present low operational costs, are robust, have high capacity, are easy to operate and can treat

ores with a wide particle size range. They are also capable of working with large fluctuations of ore contents, feed rate and solids amount. For this reason, they are largely used in the treatment of alluvial ores.

Water-Only Cyclone (WOC) is a hydrocyclone in which the density is the major separation property. The shape of the hydrocyclone was changed to improve the influence of the particle density and to diminish the influence of the particle size and shape (O'Brien, 1976) (Weyher, 1969). There are several different names used in the industry to name WOC, such as wide-angle cyclone, circulating bad-concentrator (CBC), autogenous hydrocyclone, etc.

The use of optical sorting devices are increasing each year in the mining industry (Nienhauss et al., 2014) (Raulf et al., 2012). There are several reasons for the ever increasing use of this kind of sorting: ability to automate the sorting process, possibility of separation (quantity and accuracy), add an economic value to the final products in relation to the traditional separation process, etc. In recycling, Angulo (2013) performed experiments on optical separation of bricks from CDW in Brazil. The main difficulty faced was the non-homogenous Brazilian waste. Angulo identified significant variations in their characteristics such as density and water absorption. The origin of these fluctuations, such as porosity, is due to red tiles, bricks and mortars. Density and water absorption are related to the porosity. The higher is absorption of water, the higher is porosity. That is the main problem of mixed particles in aggregates; porosity has an important impact on the quality of concrete.

3 NEW PERSPECTIVES OF SORTING AND LIBERATION FOR RECYCLING AGGREGATES

Despite techniques for sensor-based sorting, as well as for gravity concentration processes, are widely used in material recycling and in ore treatment (Sampaio, 2005; Wills, 2006), the choice of concentration equipment to be installed depends, besides the desired cut precision, on the physical properties of the material to be beneficiated. Therefore, an extensive characterization before the mineral processing is indispensable. The main characteristics to be studied are porosity, water absorption and density distribution because they are associated with liberation. Many different techniques of separation or concentration may be used, alone or associated with others. Gravity concentration processes, as for instance jigs and cyclones, has many positive characteristics suggesting that they can be used to treat CDW.

3.1 Current Advanced Process

Many studies show that RCA with different replacement rate provides concrete building of quality. The recent standards provides for the possibility of introducing recycled aggregates in structural concrete, limiting the rate of substitution. In the quarries, the material can be processed by stages: a first stage of sorting by many techniques as manual sorting and/or screening; in a second stage, a sensor-based sorting and/or a gravity concentration is used. In addition, sand fraction had a relative importance in this context. If quarries produce a significant amount of fine particles during the process, on the other hand, recycling plants need to produce all size fractions from recycled aggregates, including sands.

Nowadays, there are the pre-sieving and segregation of ferrous scrap by overhead magnetic separators. The use of picking belts enables separation of large disturbing substances, before material with a particle size of > 45 mm is transformed into granulates, mainly by impact crushers. After repeated segregation of separated ferrous scrap, follow a fractional sieving and separation of light substances by air classifiers. This technique allows the production of well qualified, close size fraction granulate mixtures. Products being processed in this way are of high quality and can be assigned as recycling materials (RCA1). In many countries, this material is currently used on roads and terracing. They

rarely are used on concrete structures. In general, the aggregate for these applications are obtained from well mastered sources (specific demolition sites, producing a large amount of not contaminated concrete).

3.2 Process With Supplementary Sorting Of The Concrete Recycled (First Improved Process)

Aiming to increase the recycling rate on concrete formulation, the use of high quality recycled aggregates during recycling off-site or on-site is suggested. In this stage of recycling, gravity concentration by jigs and sensor-based sorting are used to separate different particles (2/20 mm) as bricks, tiles, gypsum and glass, previously concentrated. The aim is to have high quality particles and more liberated particles. These particles have similar colours and could not be separated by conventional optical sorting by colour. Impurities here are can represent around 14% of total waste according Coelho (2013) and Ulsen (2013).

These recycled aggregates, before concentrating, still contain a significant amount of adhered mortar. Firstly, the jig will treat the coarser particles of recycled aggregates in two different density fractions. The fraction with density > 2.1 g/cm^3, that represent 90% according Sampaio (Sampaio, 2005), is sent to an optical sorting to generate a concentrate called Recycled Concrete Aggregate (RCA2). The impurities from sensor-based sorting that represent at least 11% considering jig efficiency, and the fraction with density < 2.1 g/cm^3 from jig are called Light Recycled Aggregate lower quality and they sent to next stage.

3.3 Process With Supplementary Production With High Quality Recycled (Second Improved Process)

This process aims at further increase recycling rates, perhaps beyond 100% substitution of gravel. A priori, this process is developed for recycling or reuses the on-site materials to minimize the production of waste leaving the site. In addition, the lower density recycled sand may have applications in the manufacture of new cements or on public works applications with better binding properties, for instance, their use as an addition (after re-grinding) during production concrete on site. We limit ourselves in this work to study how to sort recycled aggregates and the advantage of increasing the degree of substitution of aggregates at the site.

This stage of sorting receives Light Recycled Aggregate with low quality (density < 2.1 g/cm^3) and impurities of jig and sensor-based sorting. All granulates are crushed at size < 4 mm in order to liberate mortar that is adhered to the sand fraction (0/4 mm). Gyratory crusher has high efficiency to release aggregates but another type of crusher can be used (PN Recybéton, 2011). Then WOC beneficiate the fines particles of RCA lower quality in two different density fractions. The first fraction with density > 2.1 g/cm^3 is sent to Concrete Aggregate High Quality (RCA3). The second fraction with density < 2.1 g/cm^3 from WOC is sent to improve terracing (Figure 2).

This last stage is yet dedicated to increase the quality of the products considered inferior, aiming at the production of top-sands for high quality concrete and earthworks. The advantages are a best concrete, or more extended use of recycled material or less cement consumption, or maybe better road aggregates. The reduction of sorting in the current process can save costs. It means reduction of gypsum still present in the mixture, by the replacement of picking belts. The disadvantages are the costs that will be discussed later.

The efficiency of air jigs are lower than the same type of process using water (water jigs). Air jigs have larger feeding rate as a function of the equipment size, due to the fact that the particles settle in air faster than in water (Sampaio, 2005). It makes the investment and operational costs lower. The jig can be used primarily for the removal of part of the light particles (density < 2.1 g/cm³), as a rougher stage. The pre-concentrate (density > 2.1 g/cm³) will be treated in the sensor-based sorting. In this

way, many of the low density particles will be removed in the jig and the final concentrate will be quite pure. A major disadvantage of using air jigs for fine particles treatment is its low efficiency. Particles below 2 or 3 mm are treated with very low efficiency in air jigs. In these sizes, wet processes are always recommended.

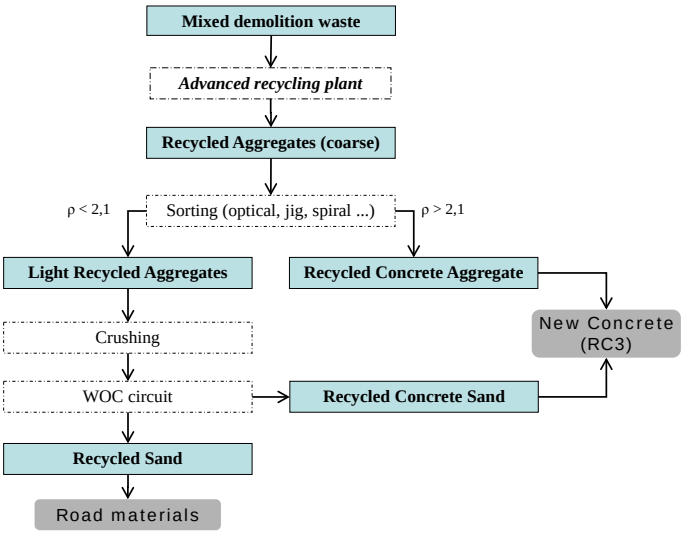

Figure 2 – Scheme of recycling production of high quality recycled concrete production (Paranhos et al, 2015).

All the particles will be comminuted under 4 mm (size of sands). In this last stage, a circuit of water-only cyclones was chosen, due to, besides the size of the particles to be treated, its versatility in gravity concentration. Investment costs of a WOC circuit are very low. When they are used in series of 2 or 3 equipment, they present quite good cut efficiencies.

4 METHOD OF COMPARISON

4.1 Method to Fix the Substitution Rate For a Given Concrete Application

A standard formula is proposed (for example: Aggregates = 1000 kg, Sand = 900 kg, Cement = 280 kg and Water = 180 kg), without recycled aggregate, to allow an identical result at the product RCA3. The products are based on a typical concrete formulation and the density of a mix concrete can be calculated according its proportions and densities in the mixture:

$$D = \frac{FA}{100} \times \left(\frac{subst_{FRA} \times d_{FRA} + (100 - subst_{FRA}) \times d_{FNA}}{100} \right) + \frac{CA}{100} \times \left(\frac{subst_{CRA} \times d_{CRA} + (100 - subst_{CRA}) \times d_{CNA}}{100} \right)$$

Where:
D – Weighed density of concrete mixture;
FA – Percentage or fine aggregates used in the mixture;
CA - Percentage or coarse aggregates used in the mixture;
substFRA – Replacement level (%) of fine natural aggregates with fine recycled aggregates;
substCRA – Replacement level (%) of coarse natural aggregates with coarse recycled aggregates;
dFRA – density of fine recycled aggregates;
dFNA – density of fine natural aggregates;
dCRA – density of coarse recycled aggregates;
dCNA – density of coarse natural aggregates.

To solve the above equation, it is necessary to know the water absorption of gravel and sand recycled. These values are determined taking into account the average density of the aggregates.

4.2 Price of Transportation and Taxes

It is important to determine transportation costs of aggregates or recycled materials mainly of the construction and demolition works. The price of transportation Pr can be calculated in function of distance, as indicated:

$$\Pr = \left(VC \times d + FC \times \frac{(\frac{d}{s} + t)}{10} \right) \times (1 + m) / w$$

Where:
Pr = price per tonnes (€/tons)
VC = variable costs (€/tons)
FC = fixed costs (€/day)
d = distance (Km)
w = weight per truck (tons) = 20 tons fixed
t = time to charge and discharge (h)
s = speed (Km/h)
m = profit margin

The transport costs by trucks can be related with the transport of virgin aggregates to construction sites or with the transport of CDW to recycling plants. They always have linearity with distance travelled. These results were obtained considering truck speed of 63 km/h, time to charge and discharge of 2 h, fixed costs of 156.01 €/day, variable costs of 0.43 €/km and business's margin of 0.33.

5 RESULTS AND DISCUSSIONS

5.1 Optimal Substitution Rate

The estimation of water absorption of the recycled aggregates from sorting plants, according to the rate of replaced aggregates is presented in Figure 3. The average absorption and density of natural aggregates were considered as 0.8% and 2650 kg/m³, respectively. This figure shows clearly that the treatment improves a lot of quality on recycled aggregates changing water absorption (and densities) of the products easily. According to the plant described (Figure 2), the water absorption of RCA1 was 11.7%, 7.0% of RCA2 and 3.6% of RCA3. Densities were 1900 kg/m^3, 2085 kg/m^3, 2210 kg/m^3 and 2650 kg/m^3, respectively.

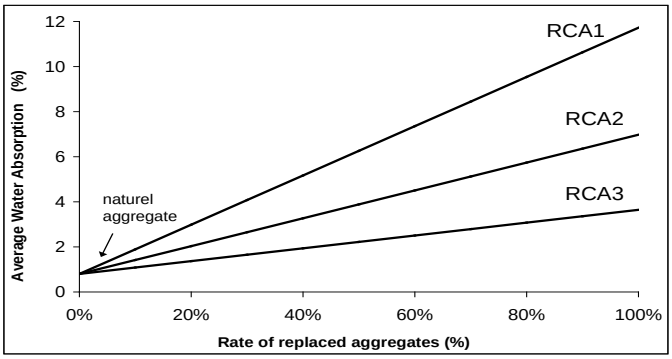

Figure 3 – Estimation of water absorption of recycled aggregates RCA1, RCA2 and RCA3 obtained from treatment according the rate of replaced aggregates

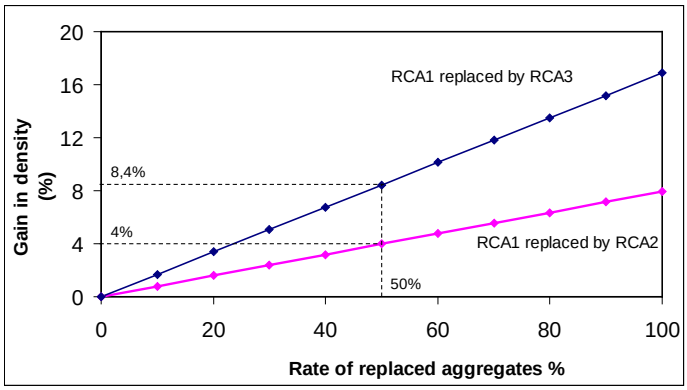
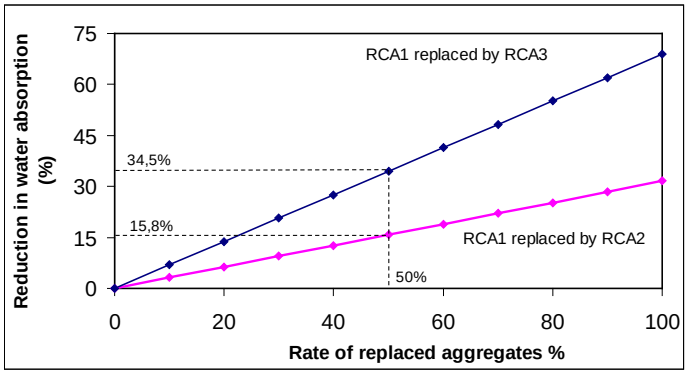
5.2 Gain in Density and Reduction in Water Absorption

Figure 4 shows the possibility of quality increasing of recycled aggregates by the use of a recycling plant. The probable gain on density or reduction on water absorption is linked with the percentages of replaced aggregates. If 50% of RCA1 were replaced by RCA2, the expected gain in density will be 4% (Figure 4a). On the other hand, if RCA1 were replaced by RCA3, the expected gain will be 8.4%. The same situation concerning reduction on water absorption is showed in Figure 4b. The levels of quality described in this analysis (i.e. levels of density and water absorption) can be assured by fine adjustment of gravity concentration equipment mainly changing the cut-off grade. The mass balance and the metallurgical balance should be carried out after any adjustments.



a) Gain in density



b) Reduction in water absorption

Figure 4 – The potential gain in density and the reduction in water absorption, linked with rates of replaced aggregates.

By the methodology proposed, the real possibility of gain in quality can be measured by the economic advantages obtained using the processing plant. In this context, the choice of improve or not improve sorting is related with the costs balance including transport, distances and indirect costs.

6 CONCLUSIONS AND PERSPECTIVES

The improvement of recycled concrete is the main subject of this paper. As an alternative to the heat treatment, the proposition is increase quality on recycled aggregates by supplementary use of mineral processing techniques.

A sorting plant is proposed. Fine and coarse aggregates are treated by gravity concentration processes, which are widely used in mineral processing. During all stages of sorting process, it is possible to adjust the quality of recycled aggregates, i.e. density and water absorption. An approximate graphic method has been used to estimate mixed aggregates proportion.

The main advantages of recycling plants are the superior quality of the materials. It is possible to increase the rate of recycling in concrete and save costs. The main disadvantages are the investments in sorting equipment. Their maintenance was not evaluated in this work. However, the gain in density and the reduction in water absorption were studied.

In the study, replacing a lower quality aggregate by another with medium quality, for instance RCA1 replaced by RCA2, leads an expected gain in density about 4%. On the other hand, if RCA1 is replaced by RCA3 (superior quality), the expected gain will reach 8.4%. As consequence, there are 34% reductions in water absorption.

ABSTRACT One of the affecting parameters on production rate of dimension stone quarries is the tension in diamond cutting wire which itself can change the cutting rate. Achievement to an optimum cutting rate could be an effective step toward increasing production and reduction of costs. So, this study aims to determine the optimum cutting wire tension for different block dimensions. For this purpose, 30 cutting surface with various dimensions and under different thrust forces have been evaluated in Targh travertine quarry. These surfaces were divided into groups based on their area which varied from 50 to 100 m^2 and then each group were cut with 6 different wire tension values ranging from 45 to 65 A and eventually all of observed data were recorded. Results showed that in order to achieve the optimum cutting rate, the cutting wire tension should be high for small blocks and low for large blocks.

Keywords: Diamond wire cutting, travertine, cutting wire tension, cutting rate

1 INTRODUCTION

Nowadays diamond wire saw is widely used for cutting and shaping dimension stones in quarries, which is considered as a costly operation in these quarries. Since any increase in productivity of cutting wire leads to a reduction in total cost of stone mining, stone industry researchers always have been working on identifying the affecting factors on cutting process and improving the cutting tools efficiency.

Generally based on Mikaeil et al. (2011) opinion, affecting factors in stone cutting process are classified into three major class, including: a) stone characteristics b) cutting characteristics and c) management characteristics. Cutting characteristics and management characteristics are among controllable parameters which are influencing in efficiency, cutting capacity and cutting process. There have been many researches on how each of these parameters can affect cutting process.

In a series of researches on disk cutting process, Ertingshausen (1985) found that in shallow cuts, up-cutting mode exhibit less power consumption compared to down-cutting mode. Luo & Liao (1995) showed that while the diamond particles in segment structure have the same hardness, by reducing the diamond particles size, their chipping capacity will be reduced and as a result, more energy is required for cutting the unit surface. Kahraman et al. (2004) showed that increasing the disk diameter leads to reduction in cutting rate. Özçelik (2007) demonstrated that in cutting process of carbonate rocks, increasing the particles size cause a decrease in wear rate of beads. By investigating 6 type of granite stones, Buyuksagis (2007) found that the specific energy amount in downward cutting mode is lower compared to upward cutting mode.

Mikaeil et al. (2012) examined 7 carbonate and travertine rock samples to achieve an empirical relation for predicting the electricity power consumption for

different rocks. In the resulted relation, all of major operational parameters including disk peripheral speed, feed rate, cutting depth and rock sawability index, which represents all of rock characteristics in practice, are involved. Sengun & Altindag (2013) showed that rock strength, hardness and porosity have stronger effects on specific energy than other rock characteristics.

Unlike other researches in these field which investigate hard and soft rocks separately, Mikaeil et al. (2013) by examining 17 different rock types showed that there is an empirical relation between B3 brittleness index and production rate of granite, marble and travertine rocks with a high correlation. Mikaeil et al. (2014) in a recent study obtained some valuable relations between system vibration and operational characteristics and brittleness indexes.

There have been less investigation concerning diamond cutting wire than cutting disk, however the history of their usage are almost the same. Investigating different diamond beads, Tönshoff & Warnecke (1982) found that in high production rate condition, diamond particles density on segment should be high but their size have to be medium, and in low production rate condition, both particle size and their density should be low.

Ozcelik et al. (2004) by characterization of rock texture found a significant relationship between texture coefficient and unit wear and cutting rate of carbonate rocks so that any increase in texture coefficient, increases the unit wear of diamond particles and decreases the cutting rate.

Cai et al. (2007) conducted a research on the effects of cutting wire entrance angel and concluded that increasing the cutting angel will increase the cutting rate and this effect intensifies in higher speeds. Besides, they found that for a constant cutting area, any increment in cutting speed leads to a decline in cutting wire lifetime. In other hand, they believe that by reducing the cutting speed with the aim of increasing the lifetime of the cutting wire, the energy consumption will increase.

Ataei et al. (2011) by examining 14 carbonate rocks in 14 different quarries, found some logical empirical relations between cutting rate and rock characteristics. Ghaysari et al. (2012) by cutting 7 type of carbonate rocks with diamond wire saw, found a relation between rock textural characteristics and the cutting rate. Yarmohamadi & Yarahmadi (2012) presented a classification system named DSRMR for dimension stones at first, and then they showed that with the increase of this index, stone cutting rate increases. It is remarkable that they neglected the presence of discontinuities in the classification system, because the data validation showed that removal of this parameter strengthens the validity of the results.

The number of diamond beads in unit length is another affecting operational parameter. Bagherpour et al. (2014) recorded the cutting rate in different faces of a working travertine quarry and concluded that the optimum beads number in unit length equals to 31.

One of the main operational parameters in diamond wire saw method is the thrust force or the pull-back force. Despite great importance of this parameter, there is no research in this field among previous studies. This study, by using performed experiments in a travertine quarry, investigates the effects of thrust force on the cutting efficiency. For this purpose, cutting of 30 surfaces with various dimensions and by different thrust forces have been evaluated. The area of these studied surfaces varied between 50 to 100 m^2 while the pull-back force range was between 45 to 65 amp. Using the recorded cutting performance parameters during these cutting and then analyzing and processing them, some results have been concluded which demonstrate the optimum state of this operational parameter.

Required data for this study have been recorded on some active working faces of Targh quarry, which is one of the largest travertine quarry of Iran. This quarry is located about 3 kilometers away of Targh village, which is located in Natanz county in Isfahan province. The experiments and field

studies of this research took benefit of the great extent and presence of various working faces in this quarry.

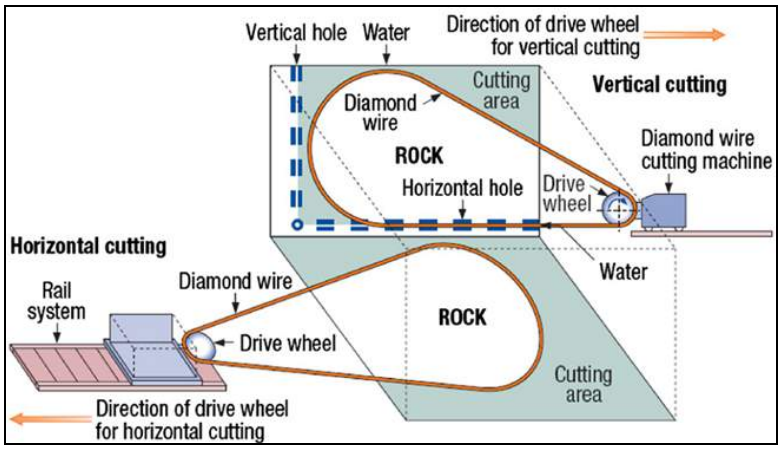

Figure 1. Diamond wire saw method in dimension stone quarrying (Ozcelik & Yilmazkaya, 2011)

2 DIAMOND WIRE SAW METHOD AND CUTTING PROCESS

Diamond wire saw method is the most common method of dimension stone mining in most countries, which has been illustrated in Figure 1. This method is widely using in dimension stone quarries and have been passed multiple developmental stages already.

Diamond cutting wire consists of some cutting beads that some springs set them apart and all of them are mounted on a steel cable formed by several strands of metal wire twisted into a helix (wire rope). Every bead is simply a steal cylindrical ring, which is equipped with some abrasive material by sintering or electroplating techniques.

Stone cutting by these beads takes place by abrasion of rock forming particle of the stone by some abrasive diamond grits. Depending on the position of beads in relation to the cutting face, various amounts of forces apply to the cutting face. Molfino & Zoppi (2012) Believe that the maximum force applied to the cutting surface occurs when the bead is about to leave the cutting surface and at this point, the chipping process will be accomplished. This process occurs for all of beads and in this way, the cutting process of the stone happens.

3 AFFECTING PARAMETERS ON CUTTING CAPACITY IN DIAMOND WIRE SAW METHOD

As can be seen in table 1, all of affecting parameters on the cutting process are divided into two categories of controllable and uncontrollable. The uncontrollable parameters are constant in all cutting methods including disk cutting, sawing, and wire cutting, while controllable parameters differ from a method to another and one can optimize them to achieve a higher production rate.

Table 1 is a developed version of what other researchers including Ozcelik (2010), Ataei (2012) and Mikaeil (2011) have used in their published researches.

During performance evaluation of a system in order to achieve optimal conditions, there are different criterion that considering each of them is important. In diamond wire saw method, the electricity power consumption, cutting rate, cutting wire cost, cutting wire efficiency of lifetime, diamond bead wear rate and cutting specific energy are the most important criterions. Achievement to any correlation between these criterions and the parameters listed in Table 1 can be effective in planning and optimization of cutting process. However, during investigation the correlation of a variant, it is so important to keep all of other parameters invariant, which is impossible in many cases and brings some uncertainty into the results. As previously

mentioned, this study intends to investigate the correlation between pull-back force and the production rate. In order to achieve reliable results, it is necessary to perform all of cuttings with the same machine and tools. Table 2 summarizes operational parameters of cutting machine, which maintained constant during all of field studies.

Table 1. Effective parameters of diamond wire saw method

Uncontrollable parameters	Controllable parameters	
Rock characteristics	**Cutting characteristics**	**Management characteristics**
❖ **Physical properties**	❖ **Tool Properties**	Skilled manpower
Density	Main Motor power	Machine vibration
Porosity	Machine required voltage	Environmental conditions
Texture	Pulley diameter	
Particles size and shape	Bead type (sintered or electroplated)	
Cementation type and degree	Bead Matrix structure	
Quartz content	Diamond grits size, type and density	
Water absorbtion coefficient	❖ **Operational properties**	
Water content	Cutting wire linear speed	
Waves conductivity	Pull-back force	
❖ **Mechanical properties**	Cutting wire entrance angel	
Strength properties	Block dimensions	
Hardness	Wire length	
Abrasiveness	Cutting type (vertical or horizontal)	
Brittleness	Wire geometry during cutting	
Elasticity	Distance between machine and face	
❖ **Structural properties**	Number of beads per meter	
Discontinuities	Orientation and quantity of Water used	

Table 2. Operational parameters of cutting machine

Parameter	Description
No. of beads per meter	30-32
Power of machine (Main motor)	37 KW
Wire peripheral speed	30-35 m/s
Voltage	380 V
Wire length	60-75 m
Pulley diameter	800 mm
Diamond beads (sintered)	0.63 carats/bead

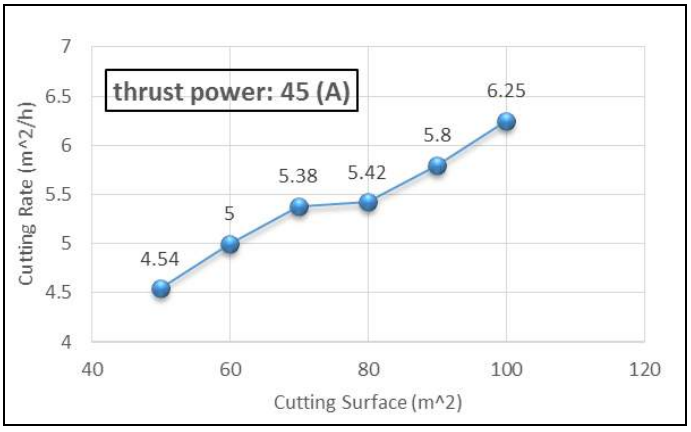

Figure 2. Cutting efficiency against cutting surface

4 CORRELATION OF THRUST FORCE AND CUTTING EFFICIENCY

The pull-back (thrust) force is typically set on 45 to 65 amp for cutting travertine stones. As table 3 shows, by fixing the thrust force on 45 amp, it can be seen that as the cutting surface decreases, the cutting rate decreases also. In other words, the highest cutting efficiency occurs with cutting surface of 100 m^2 while the lowest cutting efficiency happens with cutting surface of 50 m^2. Figure 2 demonstrates the trend of these variations.

Table 3.Cutting efficiency for thrust 45 A

Cutting dimensions (m)	Cutting surface (m^2)	Cutting time (hour)	Cutting efficiency (m^2/h)
10×10	100	16	6.25
10×9	90	15.5	5.80
10×8	80	14.75	5.42
10×7	70	13	5.38
10×6	60	12	5
10×5	50	11	4.54

It is wondering that how the thrust force can affect the cutting efficiency. In order to answer such questions, by changing the thrust force, the efficiency values of cutting blocks with various dimension are recorded. Tables 4–7 report the cutting efficiency for different thrust cases including 50, 55, 60 and 65 amp.

Table 4. Cutting efficiency for thrust 50 A

Cutting dimensions (m)	Cutting surface (m^2)	Cutting time (hour)	Cutting efficiency (m^2/h)
10×10	100	18	5.55
10×9	90	16	5.62
10×8	80	15	5.33
10×7	70	13.5	5.18
10×6	60	11	5.45
10×5	50	10	5

Table 5. Cutting efficiency for thrust 55 A

Cutting dimensions (m)	Cutting surface (m^2)	Cutting time (hour)	Cutting efficiency (m^2/h)
10×10	100	19	5.26
10×9	90	16	5.62
10×8	80	14	5.71
10×7	70	12	5.83
10×6	60	10.75	5.58
10×5	50	9.25	5.40

Table 6. Cutting efficiency for thrust 60 A

Cutting dimensions (m)	Cutting surface (m^2)	Cutting time (hour)	Cutting efficiency (m^2/h)
10×10	100	20	5
10×9	90	17	5.29
10×8	80	14	5.71
10×7	70	11	6.36
10×6	60	10	6
10×5	50	8	6.25

Table 7. Cutting efficiency for thrust 65 A

Cutting dimensions (m)	Cutting surface (m^2)	Cutting time (hour)	Cutting efficiency (m^2/h)
10×10	100	20	5
10×9	90	17	5.29
10×8	80	14	5.71
10×7	70	11	6.36
10×6	60	10	6
10×5	50	8	6.25

As can be seen in table 4, thrust force of 50 brings the highest cutting efficiency for blocks with cutting surface of 90 m^2, while the efficiency decrease with any increase or decrease in cutting dimensions. Table 5 shows that in thrust force of 55, the highest efficiency is achieved with the cutting dimensions of 70 m^2. According to table 6, the highest efficiency with thrust force of 60, belongs to cutting surface of 70. Table 7 which reports the cutting parameters for the highest thrust force, shows that the highest thrust force in this case occurs with cutting surface of 50 m^2.

5 DISCUSSION

It can be concluded from previously mentioned tables that it is better to use lower levels of thrust force when the block dimensions are high, and as the cutting surface decreases, it is better to increase the thrust force. Besides, as it can be seen in figure 2, which is based on table 3 and table 6, for thrust forces of 45 and 65 the cutting rate shows a totally reverse correlations. In other words, for thrust force of 45 A increasing the dimensions will lead to increased cutting efficiency while for thrust force of 65 A as the dimensions increases, the cutting efficiency reduces.

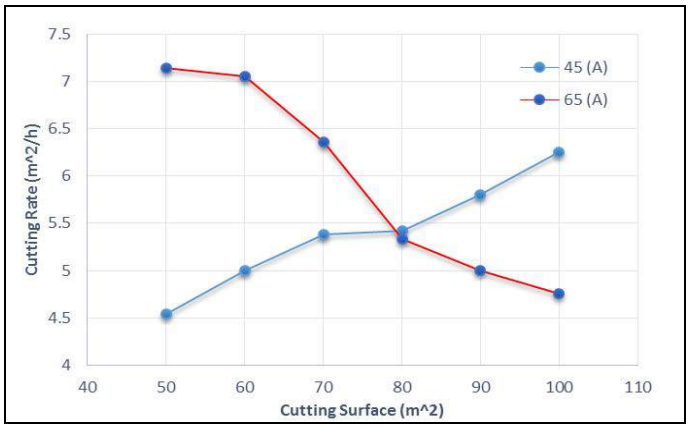

Figure 3. Cutting efficiency against Cutting rate

Of course, this fact cannot be ignored that excessive increase in pull-back force, rises the wire tension consequently and increases the likelihood of wire rupture. Wire rupture reduces the safety level of working place and

induces some financial and time loss to the quarry.

There is not any analysis on cutting surface of 80 m^2 in above discussions. So it seem that in order to achieve a more comprehensive analysis it is required to summarize tables 3 to 7 in a single table. Therefore, table 8 summarizes the cutting efficiency of cutting operations for all values of thrust forces.

Table 8. Cutting efficiency values for various thrust forces

Block Dimensions (m^2)	Cutting efficiency				
	Thrust: 45	Thrust: 50	Thrust: 55	Thrust: 60	Thrust: 65
100	6.25	5.55	5.26	5	4.76
90	5.80	5.62	5.62	5.29	5
80	5.42	5.33	5.71	5.71	5.33
70	5.38	5.18	5.83	6.36	6.36
60	5	5.45	5.58	6	7.05
50	4.54	5	5.40	6.25	7.14

The following results can be conclude from table 8:

1. For the cutting operations with cutting surface of 90 m^2, both thrust forces of 50 and 55 produces the same cutting efficiency, so in order to enhance the safety condition of working place it is suggested to use the thrust force of 50 A.
2. In case of cutting surface of 80 m^2, both thrust forces of 55 and 60 produces the same highest efficiency, so one must choose the thrust force of 55 because of the same reason mentioned previously.
3. for the cutting operations with cutting surfaces of 70 m^2, however the thrust force of 65 A produces the same efficiency, the thrust force of 60 A is suggested.
4. For cutting surface of 60 m^2 and below, the maximum thrust of 65 A is suggested.

It must be noted that practical experiences in quarries will examine the validity of these results. Besides, in higher thrust forces there should be more consideration about the cutting machine power.

6 CONCLUSION

- In order to achieve the optimum efficiency, it is better to lower the pull-back force as the cutting surface area increases.
- In case of lowest thrust force, an increase in block dimension associates with increasing the cutting rate, while the reverse is true for the highest thrust force.
- For cuttings that have cutting surface below 60 m^2, the highest efficiency achieves with higher thrusts, so if the machine can afford the required power, the highest thrust should be chosen for the cutting operation.
- While the cutting efficiency is the same for two different thrust values, it is better to operate with the lower thrust due to safety reasons.
- All results of this study appertains to travertine rocks, which can be generalized for all carbonate rocks. But for granite and other hard rocks some further studies should be performed.
- Data uncertainty arises from two source in this study: a) measurement of values in a workshop environment, which is totally affected by human errors b) effects of other operational parameters on cutting efficiency. Therefore, in order to perform a more detailed and precise evaluation, the investigation should be done in a more controllable condition in a standard laboratory. These kind of studies are following up at Isfahan University of Technology.

ABSTRACT Production process in dimension stone quarries, which are exploiting with diamond wire cutting method, has a close relationship with cutting machine properties. Cutting wire length is among these affecting properties which this study intends to find out the governing relationship between this parameter and cutting efficiency according to empirical findings in Targh travertine quarry. For this purpose, the cutting wire length has been changed by changing the cutting machine track position relative to the face entry. To do so, in 3 different mode of cutting height of 7, 10 and 12 m and with various cutting length, distance between the track position and the face has been changed. Evaluation of cutting rate during these cuttings specified the optimum condition in each mode of height. Results showed that increasing the cutting height from 7 to 12 m, leads to increasing the optimal cutting machine distance from 3 to 4.5 meters.

Keywords: Diamond wire cutting, Travertine, Optimization, Machine-Face distance

1 INTRODUCTION

Selection of mining method in exploitation of dimension stone is usually based on parameters such as physical, mechanical, textural and geological characteristics of rocks, blocks exploitability and production capacity. Nowadays, nearly all of travertine quarries are being exploited by diamond wire cutting method. Since the costs of cutting wire constitute a big portion in exploitation costs, its optimization can lead to great improvements in mining economy. So, in order to minimize the operational costs, some investigations about the optimum cutting parameters are essential.

The important point on efficient usage of diamond wire cutting is to produce blocks at minimum cost by adjusting the effective cutting parameters adequately (Ozcelik et al. 2004). These parameters can be divided in two groups; controllable and uncontrollable. Uncontrollable parameters consist of physical and mechanical properties, geology and texture of rocks and the climate conditions. Controllable parameters are mainly in relation to heavy machineries (such as cutting and boring machine) performance. One can change the controllable parameters by changing the designs and decision, but uncontrollable parameters cannot be changed by human being. Parameters that can affect cutting efficiency are given in Table 1 (Ozcelik 1999).

After determination of uncontrollable parameters, one can achieve a suitable cutting process with modifying controllable parameters. There have been some studies in order to reply how each of these parameters can affect cutting process. Burgess correlated sawability to hardness, abrasion resistance, grain size and mineralogical composition (Burgess & Birle 1978). Moreover, Sengun and Altindag conducted some researches in order to find some relations between specific energy of cutting process and some strength

Table 1. Effective parameters of diamond wire saw exploitation performance (Ozcelik 1999)

Uncontrollable parameters	Controllable parameters	
Rock properties	Cutting machine properties	Operating conditions
• Hardness	• Machine power	• Technical personnel
• Strength	• Machine position	• Vibration of machine
• Water content	• Number of beads per meter	
• Degree of alteration	• Cutting angel between wire and horizontal level	
• Discontinuities	• Amount of cutting area relative to angel variation	
• Mineralogical properties	• Wire speed	
• Textural characteristics	• Amount of water used	
	• Bead structure	

properties of 12 carbonates rocks (Sengun & Altindag 2013). Regression analysis showed that high correlations exist between specific energy and uniaxial compressive strength, Shore and Schmidt hardness, bulk density, apparent porosity, and flexural strength. However, Bayram believes that Cone indenter hardness, Shore hardness, and brittleness are the dominant properties for prediction of sawing performance in marbles (Bayram 2013). Ertingshausen studied on the power consumption during granite cutting in up-cutting and down-cutting modes (Ertingshausen 1985). Jennings and Wright carried out a general evaluation on affecting parameters on sawing performance. They concluded that small diamond grains must be used in hard rock cutting (Wright & Jennings 1989). Ozcelik completed extensive researches on diamond wire saw method. Ozcelik and Kulaksiz studied the relationship between cutting angle and wear of beads in diamond wire method (Ozçelik et al. 2000). He also investigated the wear of diamond beads in cutting process for different rock types with ridge regression (Ozçelik et al. 2002). Ozcelik worked on the optimum working conditions of cutting machines for marble rocks (Ozçelik 2005). Also, he studied on the relation between textural characteristics of rocks and their sawability with diamond-mounted saws (Ozçelik 2007). Ataei used a statistical analysis to develop a prediction model for production rate of diamond wire saw method (Ataei et al. 2011). Mikaeil et al. found a mathematical relation between production rate and rock brittleness indexes for stone sawing in rock processing plants (Mikaeil et al. 2013).

The cutting wire length is one of the controllable parameters which is associated with the cutting machine position. There is no considerable research on this parameter in previous studies, so this study intends to investigate the effect of cutting wire length on the cutting efficiency by using some experiments carried out in a real operational scale. For this purpose, the cutting efficiency has been evaluated in three different cutting height state of 7, 10 and 12 meters. In order to determine the optimum length of cutting wire in each mentioned states, by changing the distance between the cutting machine and the working face, different cuttings with various length have been performed and then the cutting efficiency of all of these cuttings have been recorded. Using the resultant data and processing them, concluded with some diagrams for selection the optimum conditions.

Field studies of this research performed in an active travertine quarry located in Isfahan province near Natanz city belonging to Ahrar-e-Sepahan Company. The quarry has geographical coordinate of 39 S 572979 3692785 in (WGS 84) UTM system and it lies near Natanz road, after YahiaAbad and Targh villages. These travertine rocks are a part of Urmia-Dokhtar (northwest- southeast) zone and have 1 or 2 km distance from some active faults. According to these faults, the main formation factor of the deposits is the local tensions in overlapped sheet of faults (Momenzade & Heydari 1988).

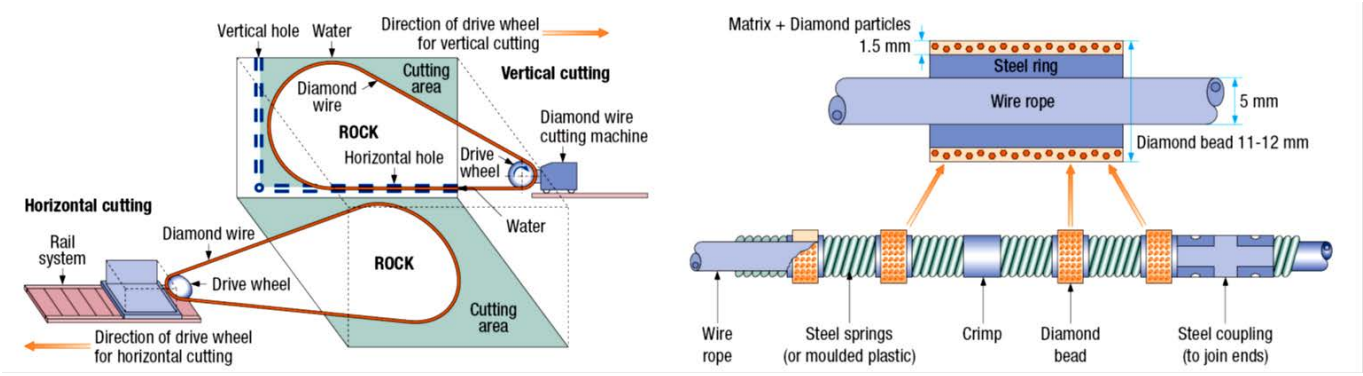

Figure 1. Schematic view of diamond wire saw method and the cutting wire (Ataei et al. 2011)

2 EXPLOITING BY DIAMOND WIRE SAW

Diamond wire cutting machines have been used in marble industry since 1985 and have affected the production rate and efficiency considerably (Ozcelik 2005). Today, they are widely used in more than 90% of the natural stone quarries (Momenzade & Heydari 1988). In diamond wire cutting machines, cutting process takes place through some abrasive diamond wires. The diamond wire is simply a steel cable on which small beads, bonded with diamond abrasive, are mounted at regular intervals with spacing material placed between the beads (Ozcelik 1999; (Özçelik et al. 2000). The diameter of diamond wire saw and steel cable are 10-12 mm and 5 mm respectively. Number of beads varies between 30 and 35 in one meter of the wire that makes intervals between 25 and 32 mm. Controlling of cutting machine parameters such as rotation, tension force and speed is performed through an automatic control panel. An electrical engine supplies the force of cutting machine and makes a drive wheel to rotate the diamond wire. Whole of cutting machine is mounted on a rail, which enables the machine to move back and forward. Figure 1 illustrates a schematic view of diamond wire cutting method and cutting wire.

3 CALCULATION OF CUTTING EFFICIENCY IN VARIOUS SITUATIONS

The amount of rock surface cut in a unit time interval (typically one hour) is called cutting efficiency which depends on physical and mechanical characteristics of rock, cutting tool characteristics and operator skills. In order to assess this parameter and optimize the cutting process through changing the cutting wire length, data are collected during a period of 10 month of travertine quarrying. During all stages of this experimental study, a single type of cutting machines with the same operating parameters has been used. The operational characteristics of this cutting machine are reported in Table 2. Also, all of investigation carried out on the same rock with the same mechanical characteristics. In other words, all of the affecting parameters were remained constant except the targeted parameter.

Table 2. Cutting machine operational parameters

Parameter	Description
No. of beads per meter	30-32
Power of machine (Main motor)	37 KW
Wire peripheral speed	30-35 m/s
Voltage	380 V
Wire length	60-75 m
Pulley diameter	800 mm
Diamond beads (sintered)	0.63 carats/bead

Figure 2 shows a schematic view of cutting geometry in a typical quarry. This figure illustrates geometrical parameters of stone cutting including cutting height, cutting length, cutting machine distance from the face and the cutting wire length. In an individual cutting operation, cutting machine travels on a rail, which changes the distance of cutting machine from the face. So in this

study the meaning of cutting machines distance from the face simply refers to the distance between the rail beginning and the face or in other words the distance between the cutting machine and the face when the cutting process begins (the minimum distance between cutting machine and face).

During the field experiments, the required data of quarrying 60 blocks have been collected and recorded. As previously mentioned, all of field experiments are divided into three categories based on their cutting height including 7, 10 and 12 meters. The research procedure in each cutting height case, in 4 different cutting length, the cutting operation performs in 5 various distance of cutting machine from the face. Therefore, for any cutting height case, 20 distinct cutting operation performed and their associated data are recorded. Each of these cutting scenarios is analyzed individually in the following sections.

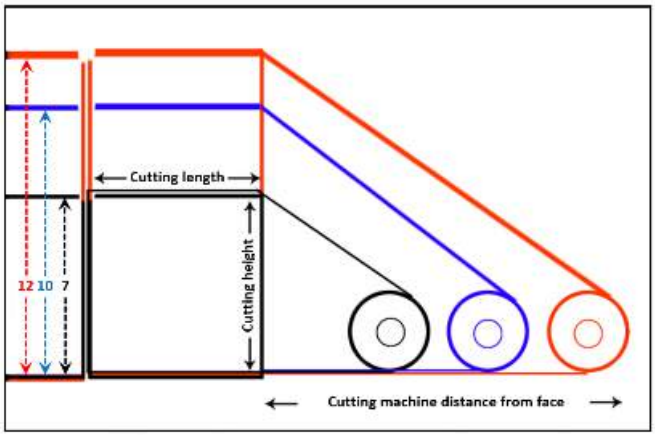

Figure 2. Cutting geometry of diamond wire cutting

3.1 Cutting Height 7 m

In this scenario, all of cuttings perform with the smallest cutting height, which equals to 7 m. Nevertheless, these cutting operations are done with 4 different cutting lengths of 5, 6, 7 and 8 meters. Also, in each of these cutting length situations, distance between cutting machine and working face varies in five modes of 1.5, 2.5, 3, 4 and 5 meters. For each cutting operation in addition to cutting dimensions and distance of cutting machine from face, some other cutting parameters such as wire length and cutting time are also recorded. Two parameters of cutting surface and cutting time are required in order to calculate the cutting efficiency. The cutting surface is simply obtained by multiplying the cutting length by the height and then by dividing it by the recorded cutting time (in hour), the cutting efficiency would be resulted. Based on this procedure, by using all of obtained data during cutting of blocks with heights of 7 m, the cutting efficiency of every individual cutting operation has been calculated. Table 3 shows the detailed summary of the data and results values. This table has been divided into 4 sections based on the length of cutting surface.

By summarizing all the 20 initial cuttings, a diagram can be obtained which has been shown in Figure 3. In this diagram, the cutting efficiency is plotted against the cutting machine distance to face individually for each cutting length. This diagram shows that for all different cutting length, an increase in cutting machine distance, increases the cutting efficiency at first and then decreases it. The maximum cutting efficiency, which is the optimum value, occurs in distance of 3 meters for all 4 cases. Therefore, it can be concluded that while the cutting height is 7 meters, the optimum distance of cutting machine from the working face equals to 3 m.

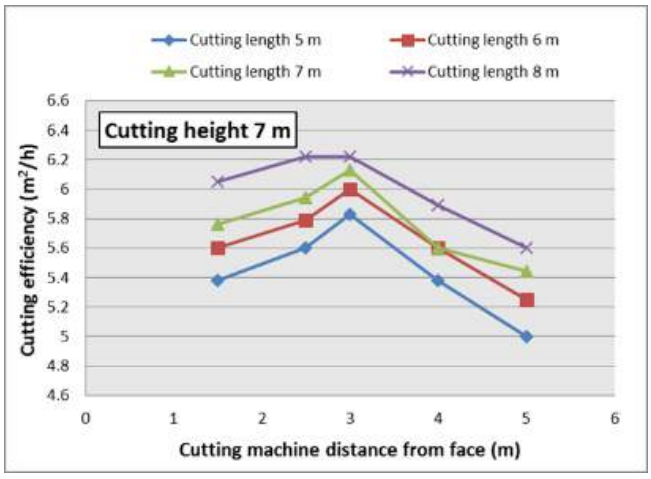

Figure 3. Cutting efficiency for cutting height 7 m

3.2 Cutting Height 10 m

In this scenario, all of cuttings are performed with the cutting height of 10 m. This second 20 cutting are divided into 4 groups based on the cutting length which are equal to 7, 8, 9

and 10 meters. Besides, for each cutting length case, the cutting machine distance changed between 1.5, 2.5, 3.5, 4.5 and 5 m. Similar to previous scenario, the required cutting data are recorded during the cutting process and then, by using these data, the cutting efficiency of each cutting operation can be calculated. Based on this procedure, all recorded data as well as the cutting efficiency of all cutting processes with the cutting height of 10 m are summarized in Table 4. This table has been divided into 4 sections based on the length of cutting surface.

Table 3. Cutting parameters for cutting height of 7 m

No.	Wire length (m)	Cutting dimensions		Machine distance to face (m)	Cutting time (hour)	Cutting efficiency (m^2/h)

38	47	10	10	3.5	14	7.14
39	48	10	10	4.5	14.25	7.02
40	49	10	10	5	15.5	6.45

Cutting efficiency behaviors against the cutting machine distance from the face for cutting height of 10 m is plotted as a diagram in Figure 4. In this figure, the associated information of the second 20 cuttings are separated based on the cutting length. This diagram indicates that, as the previous scenario, with increasing the cutting machine distance, the cutting efficiency initially increases and then decreases. However, the optimum value, which is the maximum efficiency, occurs with the machine distance of 3.5 m for all 4 cases. The other concluding fact of this diagram is that for nearly all of specified machine distances, any increase in cutting length leads to increasing the cutting efficiency. Eventually, it can be concluded that while the cutting height is 10 meters, the optimum distance between cutting machine and the working face equals to 3.5 meters.

3.3 Cutting Height 12 m

In this scenario, similar to the two previous scenarios, 20 unique cutting operations are performed with cutting height of 12 m. The cutting length changes between four states of 7, 8, 9 and 10 m and for each of these cutting length states, the cutting machine distance from face differs in five different distances of 2, 3, 4, 4.5 and 5.5 m. During all of these 20 cuttings, all of required data for calculation of cutting efficiency are recorded. With these information (cutting time and cutting surface area), the efficiency of each individual cutting have been calculated. All of recorded data as well as the cutting efficiency values are reported in Table 5. This table has been divided into 4 sections based on the length of cutting surface.

Based on provided information in Table 5, one can plot the diagram of cutting efficiency against the cutting machine distance. This diagram is presented in Figure 5. Data trends in this diagram show that with increasing distance from the face, the efficiency increases at first and then decreases. However the optimum efficiency occurs in distance of 4.5 meters for all kinds of cutting length. On the other hand, the diagram shows that for all distances, an increase in cutting length increase the cutting efficiency. As a result, these researches turned out that while the cutting height equals to 12 m, the optimum distance between cutting machine and the working face equals to 4.5 meters.

4 CONCLUSION

This study investigated the governing relationships between cutting machine distance from the face and the cutting efficiency by using empirical finding at Targh travertine quarry. For this purpose, in three cutting height scenarios of 7, 10 and 12 meters with various cutting surfaces, the distance between the cutting machine and the working face has been changed. Evaluation of cutting efficiency during each of these cutting operations determined the optimum conditions for each of cutting height scenarios. The results showed that for cutting height scenarios of 7, 10 and 12 meters, the optimum cutting machine distance equals to 3, 3.5 and 4.5 meters respectively. Moreover, for all of cutting situations and for all of machine distances, increasing the cutting length led to increasing the cutting efficiency. Besides, among the different cuttings with different cutting height, the maximum cutting efficiency belonged to blocks with cutting height of 10 meters. The results of this study came up from observation on travertine rock and might be generalized for all kind of carbonate rocks. Further researches are required for igneous and metamorphic rocks.

ACKNOWLEDGEMENT

Authors would like to thank Ahrar -e-Sepahan Company for their great cooperation during this study.

ABSTRACT The coefficient of utilization of rock directly affects the profitability of the dimension stone deposit exploitation. Dimension stone is a highly valuable raw mineral material per unit of product. Past experience and literature show that for a certain amount of commercial dimension stone blocks, a significantly larger volume of raw rock mass should be dug up. Mineral residue as a result of the extraction of the commercial dimension stone blocks is usually the material of less or even minor value per product unit. Profitability of the exploitation of dimension stone in a reservoir is directly dependent on the rock coefficient of utilization. It is therefore a priority task and a challenge to improve the efficiency of dimension stone deposit and to reduce the accumulation of mineral residue that would ultimately increase profits. Numerical models can clearly demonstrate the influence of the coefficient of utilization on the exploitation profitability of the dimension stone deposit, which is presented in this paper. From the analysis of the real "in situ" performance and numerical models, the coefficient of utilization can be determined whereby the exploitation of dimension stone deposit is on the edge of profitability.

Keywords: Numerical modelling, utilization coefficient, dimension stone, exploitation profitability

1 INTRODUCTION

Dimension stone is highly valuable raw mineral materials per unit of product and it is mostly used in the final stages of construction and less to produce supporting structures. Market value of dimension stone is several times greater than the value of other types of non-metallic minerals (Vidić, D., 2012.).

Profitability of the exploitation of dimension stone in a deposit directly depends on coefficient of utilization of that deposit, and any activity that can improve the exploitation of deposits of dimension stone may have a decisive impact on the economy of operations of the company which is engaged in the exploitation of dimension stone.

From the literature and practice it is well known that for a certain quantity of commercial blocks of dimension stone a significantly larger volume of rock mass, in natural condition, needs to be dug up (cut) (Galić, I., 2003).

Importance of ratio of the usable quantities of commercial dimension stone blocks and the total quantity of excavated rock is most vividly displayed in the case studies and models.

This paper will analyse the impact of coefficient of utilization on profitability of dimension stone exploitation, in other words the sensitivity of mining project of dimension stone exploitation regarding the coefficient of utilization.

2 MODELLING OF DIMENSION STONE RESERVES CALCULATION

In expert literature, there is some controversy and disagreement about the definition of concepts and calculation degree of utilization of dimension stone deposits. Recently, the degree of utilization of dimension stone deposits is defined by coefficient of utilization, exploitation losses and correctional coefficient.

2.1 Model 1 – Calculation of the reserves from the total quantity of rock

Correctional coefficient (k_p) is the loss of rock mass through the surface waste (unless separately calculated), rock mass in fragmented areas, and non-commercial pieces of stone. The correctional coefficient expresses the loss of rock mass of dimension stone caused by the conditions prevailing in the deposit, and it is used in calculating the balance reserves, according to the expression:

$$Q_{bil} = Q_u \cdot k_p, m^3 k_i = \frac{O_{kb}}{O_u} \quad (1)$$

Where is:
Q_{bil} – balance reserve (m^3)
O_u – total volume of cut rock mass (m^3)
k_p – correctional coefficient

For a large number of dimension stone deposits in the Republic of Croatia, waste rock located on top of exploitation reserves of rock mass is not separately calculated and is shown trough correctional coefficient. Usually this is the case in the deposits with no surface waste rock in the classical meaning of the word (humus, clay, earth, etc.) but it is the karst surface area that is not clearly separated from the exploitation rock parts (Archives, 2011).

When large quantities of waste rock are located on top of exploitation rock mass, the waste rock is usually calculated separately.

The correctional coefficient is directly dependent on geological conditions of deposit in which the exploitation of dimension stone is performed, and primarily on thickness of waste rock, structural-tectonic set of deposit, the size of rocks that have commercial value, etc.

The correctional coefficient is different for every dimension stone deposit, and in the Republic of Croatia, it is usually in the range between 0.18 and 0.22, extremely up to 0.54 (deposit "Kanfanar" in Istria).

Exploitation loss (E_g) is loss of rock mass mainly caused by destruction of rock mass by various tools (chain saw, diamond wire saw, etc.) and it can be exactly calculated or obtained by statistical analysis of data. Substituting exploitation loss in expression (1) we get the equation for calculating the exploitation reserves;

$$Q_{eks} = Q_{bil} \cdot E_g, m^3 \quad (2)$$

Where is:
E_g – exploitation loss (m^3)

Quantity of exploitation losses, in contrast to correctional coefficient, is not dependent on deposit's geological conditions in which the dimension stone exploitation is preformed but primarily on the thickness of cutting elements of chain saw and diamond wire saw, and ranges from 8 to 10% of the balanced reserves. Exploitation loss is calculated by the expression:

$$E_g = Q_{bil} \cdot p, m^3 \quad (3)$$

Where is:
p – share of exploitation loss, %.

Coefficient of utilization (k_i) is, in general, the ratio of usable substances of raw mineral materials and the total quantity of excavated rock. In the case of dimension stone, the coefficient of utilization is the ratio of the volume of commercial blocks and the

total volume of the rock mass that needs to be cut out for a commercial blocks to be formed (Galić et al, 2011; Dragičević et al, 2009). The volume of commercial blocks is actually a volume of extraction reserves in a deposit. The coefficient of utilization is obtained by calculation from expression:

$$k_i = \frac{O_{kb}}{O_u} \quad (4)$$

Where is:
O_{kb} – volume of commercial blocks (m^3)

In conclusion, it can be determined that the coefficient of utilization integrates the correctional coefficient and exploitation losses.

2.2 Model 2: Calculating the total quantity of rock according to the planned quantity of blocks

In the introductory section the expressions and the process of calculating the exploitation reserves for any raw mineral material, including dimension stone, are clearly defined. However, when it comes to calculating capacity or planned production, the procedure is completely inversed.

In the Model 2 the assumed yearly dimension stone production is 1 000 m^3, the correctional coefficient k_p = 0.18 and exploitation loss p = 10%. The main task is to determine the total volume of the rock mass that needs to be cut out annually in order to obtain 1 000 m^3 of commercial dimension stone blocks.

Since the planned annual production is actually an annual exploitation reserves in the quantity of 1 000 m^3, it is therefore necessary to add that the exploitation losses and the annual balance reserves will be calculated by the following expression:

$$Q_{bil} = Q_{kb} \cdot \frac{100}{100-p}, m^3 \quad (5)$$

It follows that the annual balance reserves are:

$$Q_{bil} = 1\,000 \cdot \frac{100}{100-10} \cong 1\,111, m^3$$

From that exploitation losses are:

$$E_g = 1\,111 - 1\,000 = 11\ m^3$$

To calculate the total annual quantity of the rock mass that needs to be cut (dug) out it is necessary to predict the loss of rock mass through correctional coefficient in the form of surface waste rock, rock mass in fragmented areas. Therefore the total quantity of excavated rock mass will be:

$$Q_u = \frac{Q_{bil}}{k_p}, m^3 \quad (6)$$

It follows that the total annual quantity is:

$$Q_u = \frac{1\,111}{0{,}18} \cong 6\,172\ m^3$$

Of which the stone waste is:

$$Q_{k.o.} = Q_u - Q_{bil} = 6\,172 - 1\,111 = 5\,061\ m^3$$

Coefficient of utilization in the Model 2 is:

$$k_i = \frac{O_{kb}}{O_u} \quad (7)$$

$$k_i = \frac{1\,000}{6\,172} \cong 0{,}162$$

3 INFLUENCE OF COEFFICIENT OF UTILIZATION ON DIMENSION STONE DEPOSIT EXPLOITATION

The utilization coefficient has the crucial influence on profitability and investment return and operation of company which carries out exploitation of dimension stone in the deposit.

Coefficient of utilization is different for every deposit, and in the deposits in the Republic of Croatia it is usually in the range between 0.14 and 0.20, and exceptionally more.

Following the previously stated report, further analysis of dependence of investment profitability on the coefficient of utilization shows the economic sensibility of mining operation when the coefficient of utilization ranges from 0.14 to 0.20.

3.1 Model 3: The input parameters of the test model

For the most realistic analysis a specific example from existing deposit will serve as test model and the data from Mining project of dimension and technical building stone exploitation on deposit field "Dolit" (Živković, S. A., 2005).

The basic input data taken from test model design, on which the analysis of the dependence of investment profitability on the correctional coefficient was done, are as follows:

- planned production of all categories of commercial blocks is 1 560 m^3;
- average market price of all categories of commercial blocks is 367 \$/m^3;
- total annual revenue from the block sale is 572 000 \$;
- initial investment is 1 440 000 \$;
- annual cost of exploitation for gaining 1 560 m^3 of commercial blocks is 505 523 \$;
- correctional coefficient kp= 0.20;
- exploitation losses E_g = 10%;
- coefficient of utilization ki = 0.18.

3.2 Model 4: Output parameters for the test model

Based on the input parameters of the test model the total volume of rock mass is calculated which should be cut out in order to get the planned 1 560 m^3 of commercial blocks. Based on the exploitation loss p = 10% and correctional coefficient k_p = 0.20, it was calculated that 8 667 m^3 should be cut out. With these parameters coefficient of utilization k_i = 0.180.

Table 1 - Output parameters of the test model

Gross valume O_u (m^3)	Exploitation losses E_g (%)	Correctional coefficient k_p	Coefficient of utilization k_i	Volume of commercial blocks O_{kb} (m^3)	Total cost of cutting blocks (\$)	Block production price (\$/m^3)	Block market price (\$/m^3)	Total revenue UP (\$)	Profit (\$)
8 667	10	0.23	0.207	1 794	505 523	282	367	658 398	152 875
8 667	10	0.22	0.198	1 716	505 523	295	367	629 772	124 249
8 667	10	0.21	0.189	1638	505 523	309	367	601 146	95 623
8 667	10	0.20	0.180	1 560	505 523	324	367	572 520	66 997
8 667	10	0.19	0.171	1 482	505 523	341	367	543 894	38 371
8 667	10	0.18	0.162	1 404	505 523	360	367	515 268	9 745
8 667	10	0.17	0.153	1 326	505 523	381	367	486 642	-18 881
8 667	10	0.16	0.144	1 248	505 523	405	367	458 016	-47 507

Analysis in Table 1 is created under the assumption that employees, machinery and equipment per year could cut out up to 8 667 m^3 gross volume of the rock mass and that the selling price of 1 m^3 block of all categories is fixed to the amount of 367 \$/ m^3.

Table 1 shows profitable threshold of mining company, under the given conditions, when coefficient of utilization is in the range from 0.162 to 0.153.

It is significant to notice that the increase of coefficient of utilization from k_i = 0.180 to k_i = 0.207 the annual gross profit of the mining company is increasing from 66 997 \$ to 152 875 \$, that is more than double.

Should the coefficient of utilization decrease from k_i= 0.180 to k_i= 0.162, when utilization of rock mass is decreased by less than 2%, the annual profit of the mining company would decrease to 9 745 \$, that is about eight times.

4 BUSINESS PROFITABILITY DEPENDING ON THE COEFFICIENT OF UTILIZATION

Profitability is defined as an indicator of economic operating performance and is

commonly based on loss and profit data. The most commonly used formula is:

$$E = \frac{UP}{UT} \quad (8)$$

Where is:
UP – total income ($),
UT – total costs ($).

Obtained result indicates:
$E > 1$ – profitable business,
$E = 1$ – business at the border of profitability,
$E < 1$ – business is not profitable.

4.1 Model 5: Determining the profitability threshold by computation

Determining profitability threshold of dimension stone deposit in which the gross volume of rock mass could be cut out is 8 667 m^3 with the selling price of all commercial block of all the categories is 367 $/$m^3$, could be done by computation or graphically.

For a profitability threshold to be determined by calculation, first the smallest quantity of commercial blocks should be calculated that will ensure profitable business. In other words, we need to calculate the minimum quantity of blocks whose exploitation costs will be equal to revenue from their sale.

Following the stated, we set this relationship:

$$Q_{min} = \frac{UT}{CT} \quad (9)$$

Where is:
Q_{min} – minimal quantity of blocks for company to be profitable (m^3)
UT – total exploitation costs ($/$m^3$)
CT – average sale value of 1 m^3 block ($/$m^3$)

Substituting the output values obtained from the test model we obtain:

$$Q_{min} = \frac{505\,523}{367} = 1\,379\ m^3$$

Therefore, the minimum quantity of blocks that must be cut out from total volume of 8 667 m^3 and the average sale price of 367 $/$m^3$, for a business to be profitable, is 1 379 m^3.

By setting the relationship between minimum quantities of blocks that need to be obtained from the total volume so the business is profitable (Q_{min}) and the total volume (Q_{uk}) from which the minimum quantity of blocks was obtained, gives us marginal coefficient of utilization with which the business will be marginally profitable.

$$k_{igr} = \frac{Q_{min}}{Q_{uk}} \quad (10)$$

$$k_{igr} = \frac{1\,379}{8\,667} = 0{,}159$$

Thus, marginal coefficient of utilization – profitability threshold, at the fixed volume of 8 667 m^3 and fixed price of 367 $/$m^3$, the k_i = 0.159.

Marginal correctional coefficient of the coefficient of utilization ki = 0,159 and exploitation loss E_g = 10% is:

$$k_{pgr} = \frac{Q_{min} \cdot \left(\frac{100}{100-Eg}\right)}{Q_{uk}} \quad (11)$$

$$k_{pgr} = \frac{1\,379 \cdot \left(\frac{100}{100-10}\right)}{8\,667} = 0{,}177$$

Reducing the coefficient of utilization under 0.159 or correctional coefficient under 0.177 the mining company would operate with a loss.

4.2 Model 6: Determining the profitability threshold graphically

Figure 1 shows the success of the mining company operations during dimension stone exploitation considering the coefficient of utilization.

It is noticeable that when the coefficient of utilization ki = 0.162 the minimal annual income will be 9 745 $, and when ki = 0.153 mining company will create year loss of 18 881 $.

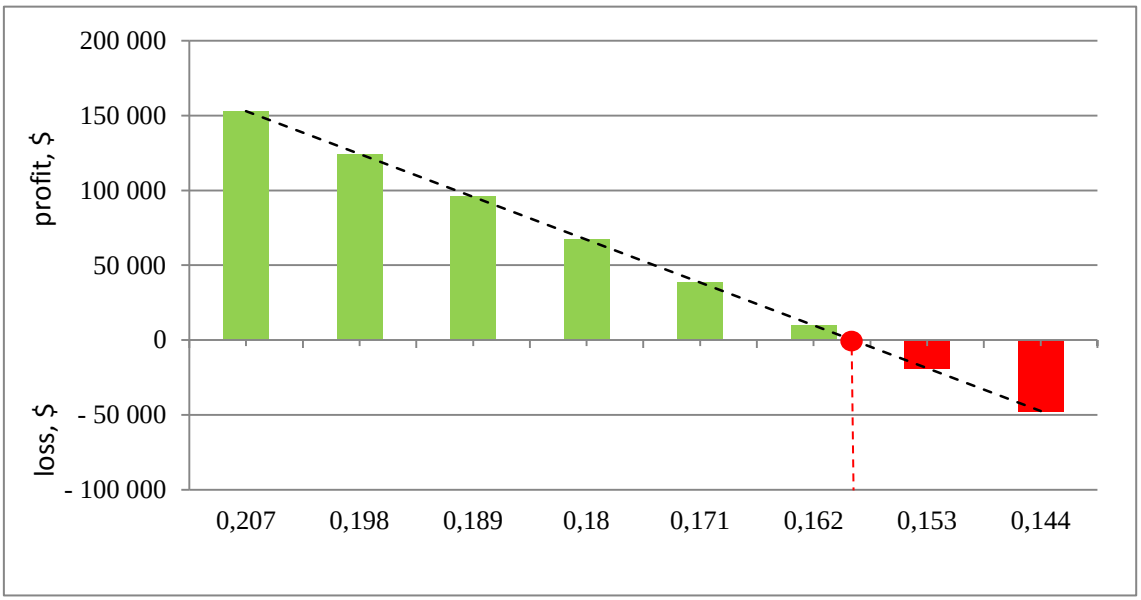

Figure 1. Diagram of business success depending on the coefficient of utilization

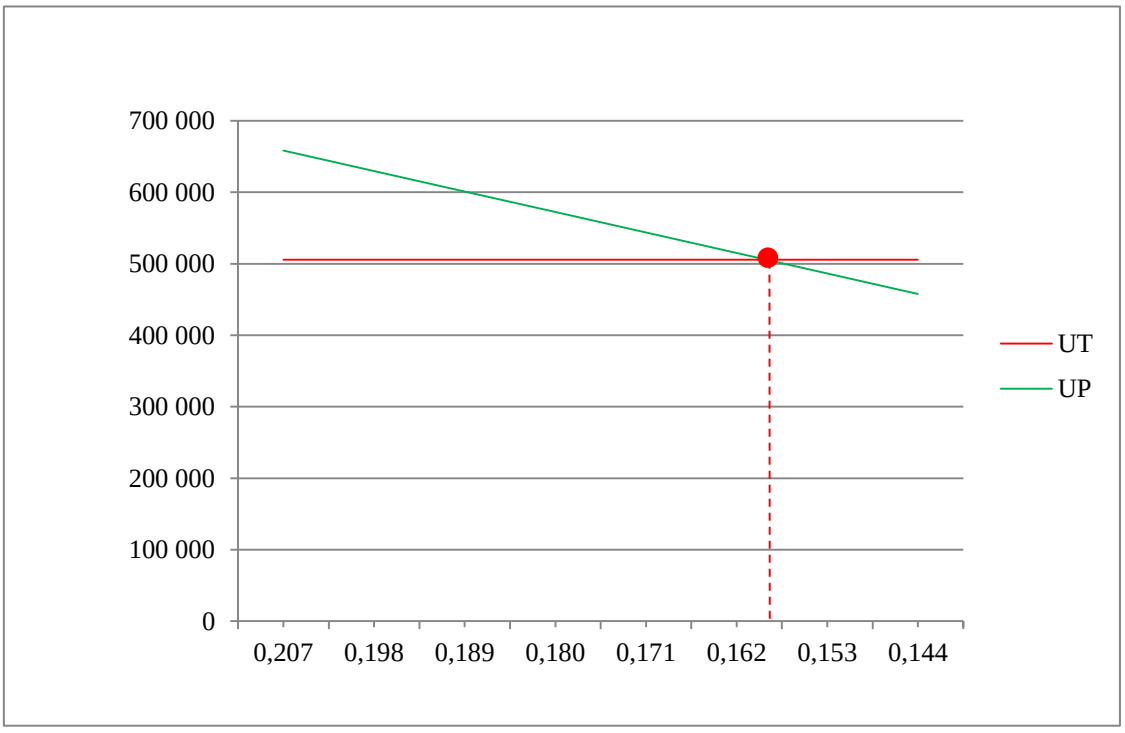

Figure 2. Diagram of profitability threshold

Intersection of lines that show total annual costs (UT) and total annual revenue (UP) represents the mining company's business profitability. Figure 2 clearly shows that total annual costs are fixed (505 523 $), and total annual revenue is reduced according to the reduction of coefficient of utilization.

Figure 3 shows the direct dependence of the production cost ($/m^3) on the amount of coefficient of utilization where the gross cut-out mass is limited to 8 667 m^3 due to the capacity of the available machinery.

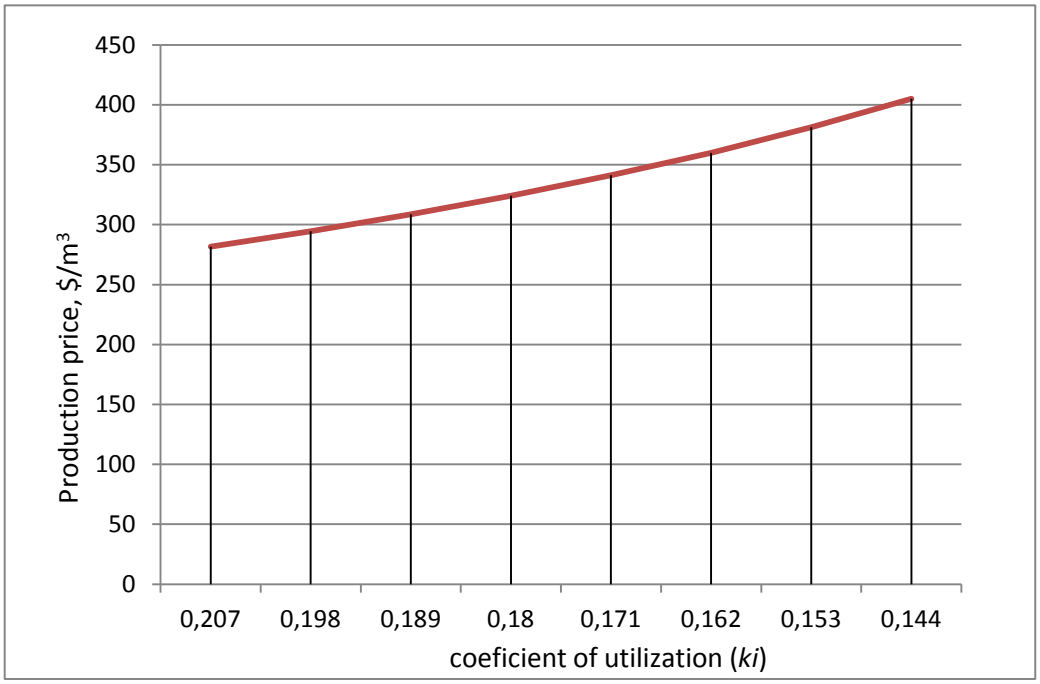

Figure 3. Coefficient of utilization dependence on exploitation cost

It is evident, from Figure 3, that with a fixed annual production, production price increases almost in proportion to the reduction of the rock mass coefficient of utilization.

With coefficient of utilization k_i = 0.207, production price is approximately 280 \$/m^3, while with coefficient of utilization k_i = 0.144 production price is approximately 405 \$/m^3.

5 CONCLUSION

In numerical models the correctional coefficient and exploitation losses of dimension stone deposit exploitation were analysed and in the end summarized in the coefficient of utilization.

This analysis showed a very large dependence of mining operation of dimension stone exploitation on the coefficient of utilization. This dependence is so large that it is recommended to express the coefficient of utilization with three decimal digits.

A real example from practise was taken as the test model, with planned annual exploitation of 1 560 m^3 of commercial blocks of all types and average market price of commercial blocks of all types in the amount of 367 \$/m^3. The planned coefficient of utilization of the deposit is k_i= 0.18 (correctional coefficient k_p = 0.20, exploitation loss E_g = 10%). Based on the design solutions total gross cut-out volume of the rock mass is 8 667 m^3.

Based on the analysed data, from the test model, the obtained results can serve as reference data for making the final decision on economic justification of dimension stone deposit exploitation, but also for the optimization of investment, designed capacity and necessary equipment.

All the above shows the necessity of extremely cautious and detailed planning of the dimension stone exploitation in the deposit.

Particular attention should be paid to dimension stone deposits research data interpretation, determination of rock structural set, space orientation of discontinuities and other data that influence the coefficient of utilization.

Therefore, before exploitation, it is necessary to explore and learn about the planned deposit, in other words to determine the coefficient of utilization as accurately as possible.

Mining engineers and geologist, who are engaged in exploration and exploitation of dimension stone, are the only ones capable and authorized to precisely determine the

coefficient of utilization in the new dimension stone deposit, by using the existing and recognized methods (e.g. method of linear and spatial integrity), but also new scientific methods.

Design of Mineral Processing Plants and Beneficiation Methods

A Technology for Force Field Separation in Vibrofluidized Layers of Granular Materials

L.A. Vaisberg, K.S. Ivanov, S.V. Dmitriev, A.O. Mezenin
REC "Mekhanobr-tekhnika", St. Petersburg, Russia

ABSTRACT The work presents a technology for electrostatic and magnetic separation of vibrofluidized granular materials. This approach allows extended adjustability of the process rate and extraction through control of vibration excitation parameters. This feature guarantees more flexibility and better adaptation of the process for particular materials in comparison with traditional technologies. This approach also allows avoiding the use of water as a dispersion phase. The technology was tested on apatite rocks, sphene concentrate, and Fly ashes.

Keywords: Vibrofluidized granular materials, electrostatic separation, magnetic separation

1 INTRODUCTION

Over one billion tons of solid minerals are mined annually in the Russian Federation, forty percent of which are further enriched with the use of water as the process fluid. The water is used to ensure transportation and subsequent separation of rock mass components after disintegration. Water consumption in mineral processing reaches 3 to 10 cubic meters per ton of ore, resulting in an overall rate of more than two billion cubic meters of water per annum.

Even today, the water is already becoming a scarce commodity. The use of water in mineral processing fuels both environmental problems (due to the negative impact on the environment by flooded tailings) and technical and economic problems (due to the high costs of pumping of process water and suspensions, dehydration of concentrate and safe storage of tailings). Moreover, it is not always possible to use the full water cycle in mineral processing.

Against this background, finding ways to reduce the amount of water consumed in mineral processing is becoming crucial.

Dry methods of ore processing for grain sizes of over 5 mm are well known, while the creation of dry processing methods for crushed ore with grain sizes of 0 to 5 mm is of particular interest and enables the extensive use of the vibration technology.

In particular, due to the fact that most minerals are hydrophilic, water often acts as a dispersion medium, leveling autohesive mineral particle interactions and thereby smoothing the production processes. However, a similar anti-autohesion effect may be ensured by means of vibrational fluidization, a well-known effect of intensification of processes occurring in a gas/solid system [1].

When under vibration, polydisperse powders may reach various dynamic states of total or partial destruction of contacts between the particles, which are, in a way (within the mathematical description), similar to the aggregation states of substances. In the semi-liquid state, material particles are displaced relative to each other with partial contact losses. In the state as a granular gas, particles are detached from each other and subject to vigorous mixing.

2 PRACTICAL APPLICATIONS

2.1 Separation by Magnetic Properties

Iron ore processing is one of the most high-scale industries, which, in particular, mainly uses magnetic separation.

Dry magnetic separation processes are hindered by dry friction type forces emerging between the particles. The presence of dry friction forces reduces the

efficiency of separation of the magnetic concentrate from non-magnetic products, which makes it advisable to apply the granular gas effect. It may be expected that this type of extraction of magnetic particles from the layer would result in the recovery of magnetic particles from the entire bed thickness and not only from its surface.

In its relevant research, Mekhanobr-Tekhnika Research and Engineering Corporation has developed the EVS-15/5 separator [2] (Fig. 1). The device is distinguished by the fact that, when transferring the material processed, its vibratory feed tray ensures the creation of a granular gas effect.

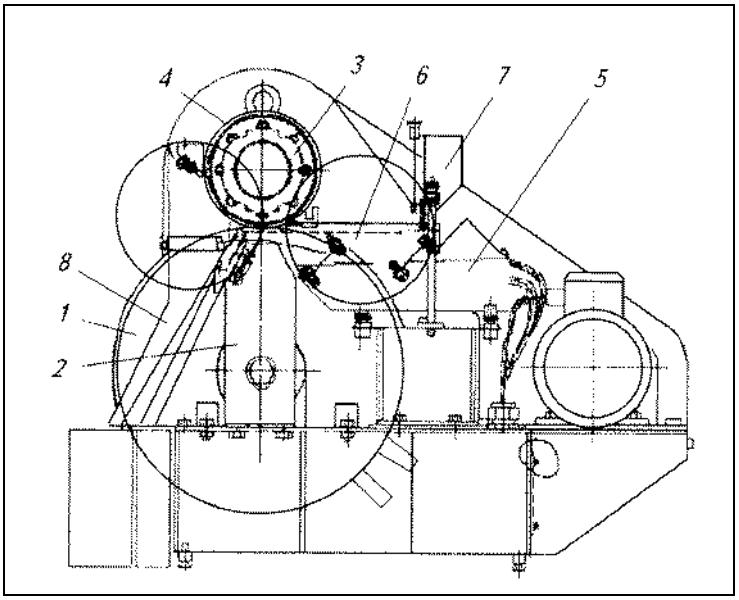

Figure 1. EVS–15/5 Separator Design

Theoretical estimates and experimental results [3, 4, 5] demonstrate that increased electromagnetic separation efficiency may be expected for the values of overload factor of $w \geq 2.5$. Moreover, the average velocity of the material may be adjusted in accordance with the process requirements by changing the vibration frequency and amplitude using the functions included in the EVS-15/5 separator.

A hematite ore sample for the technological research was prepared as follows.

The original material sample was screened to separate grains of 0 to 2 mm and +2 mm. The content of grains of 0 to 2 mm was 57.1%, and those of +2 mm was 42.9%. The grains of +2 mm were dry crushed to the grain size of -2+0 mm.

The resulting two products were combined and used as the source feed for the magnetic separation in EVS-15/5.

In accordance with the requirements of metallurgy, iron content in the magnetic concentrate must be within 61% to 63.5%, and the content of Al_2O_3 must amount to 1.8% to 3%.

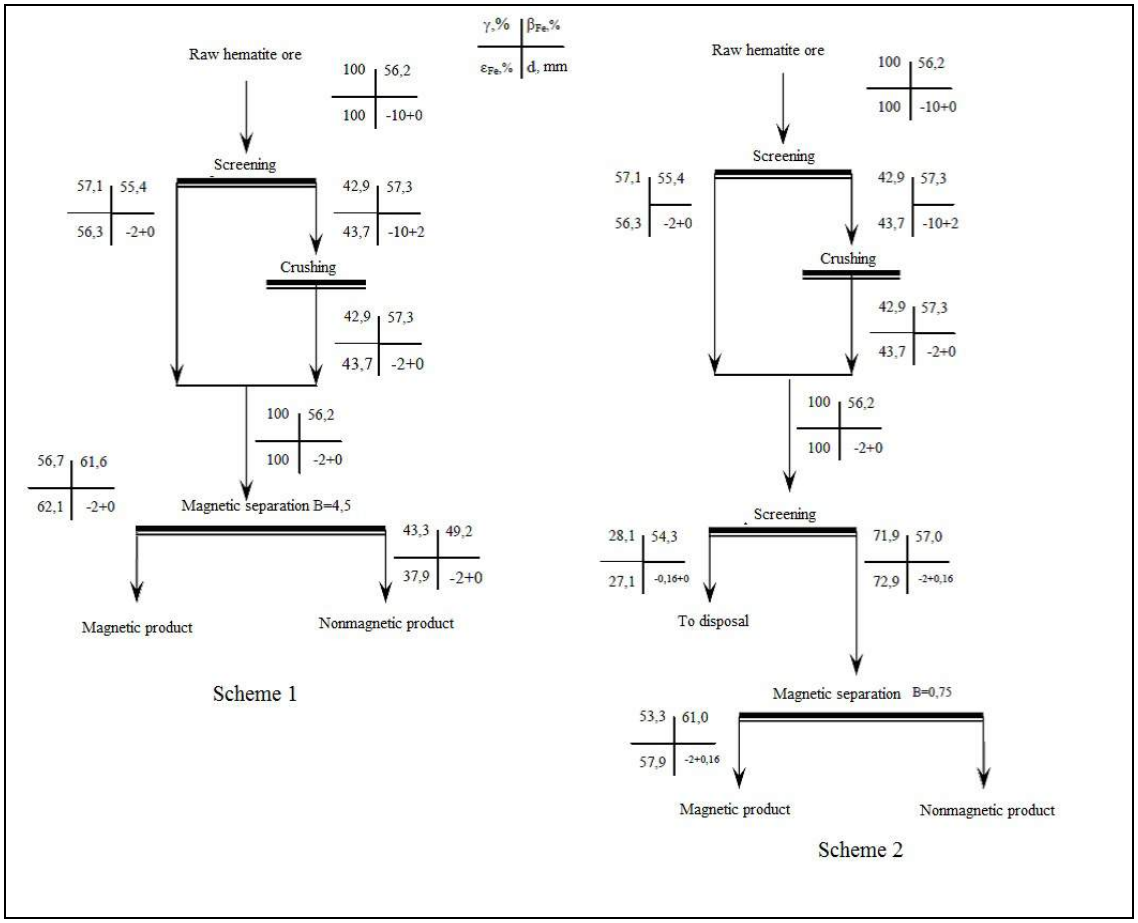
In order to study the influence of the granular gas effect on magnetic separation process parameters, experiments were conducted in conditions of material transportation via the vibratory tray in the form of a fluidized bed and in conditions of regular conveying (Fig. 2).

An analysis of the resulting figures suggests the following conclusions:

– the feeding of non-dedusted material particles of -2+0 mm in the form of a fluidized bed ensures a higher iron content in the magnetic concentrate (60.2% versus 59.2%) as compared to regular conveying with a 1.5-fold yield (7.2 kg/h against 4.9 kg/h), but with lower iron yield (71.3% vs. 80%).
– dedusted material particles of -2+0.16 mm demonstrates doubled processing yield with similar indicators of iron content in the magnetic concentrate for a fluidized bed and regular conveying (of 61.0% vs.

61.6%), but with a higher iron yield (79.4% vs. 72.9%);
- the content of Al_2O_3 in the magnetic concentrate is within the allowable range of 3% even at the iron content of 59% or more, which suggests that at the standard iron content of 61% the content of Al_2O_3 will automatically satisfy the requirements set.
- The research covered two different process flow sheets:
- magnetic separation of non-dedusted material particles of -2+0 mm (Figure 6, Option 1);
- magnetic separation of dedusted material particles of -2+0.16 mm (Figure 6, Option 2).

The main process parameters are shown in the Table 1.



Figue 2. Magnetic Separation Flow Sheets

Table 1. Comparison of Process Parameters of Hematite Ore Magnetic Separation

Scheme	Process Flow Sheet 1	2
Magnetic Concentrate Yield, %	56.7	53.3
Iron Content, %	61.6	61.0
Iron Yield, %	62.1	57.9

A comparison of the indicators listed in Table 1 demonstrates that Option 1 ensures higher process parameters of iron content (61.6% vs. 61.0%) and iron yield (62.1% vs. 57.9%).

When the iron content in the magnetic concentrate is 59% or more, the standard content of Al_2O_3 does not exceed 3%.

A fluidized bed is effective in magnetic separation of non-dedusted material particles of -2+0 mm, while for dedusted material particles of -2+0.16 mm the influence of the fluidized bed is barely noticeable.

Therefore, the developed and manufactured modified design of a laboratory separator for processing weakly oxidized iron ores eliminates the use of

water as a dispersion medium and improves the separation efficiency.

2.2 Separation by Electrical Properties

Fly ash of coal-based thermal power plants is formed by mechanical treatment of waste flue gases and contains a significant amount of unburnt carbon, thus complicating the re-use of this type of waste.

It was suggested to remove the unburnt carbon using the flotation process; however, upon interaction with water, the mineral fraction of fly ash loses its binding properties, greatly reducing its value for the building industry where it is otherwise in the highest demand.

Given that fly ash has a grain size of less than 0.5 mm and is prone to aggregation in dry form and that its components (carbon and mineral fractions) have different electrical conductivity, the approach was applied that is used for dry magnetic separation of iron ore, implying conversion of the powder into a state of a granular gas with subsequent separation in an electrostatic field.

The schematic diagram of an electrostatic separator is shown in Figure 3.

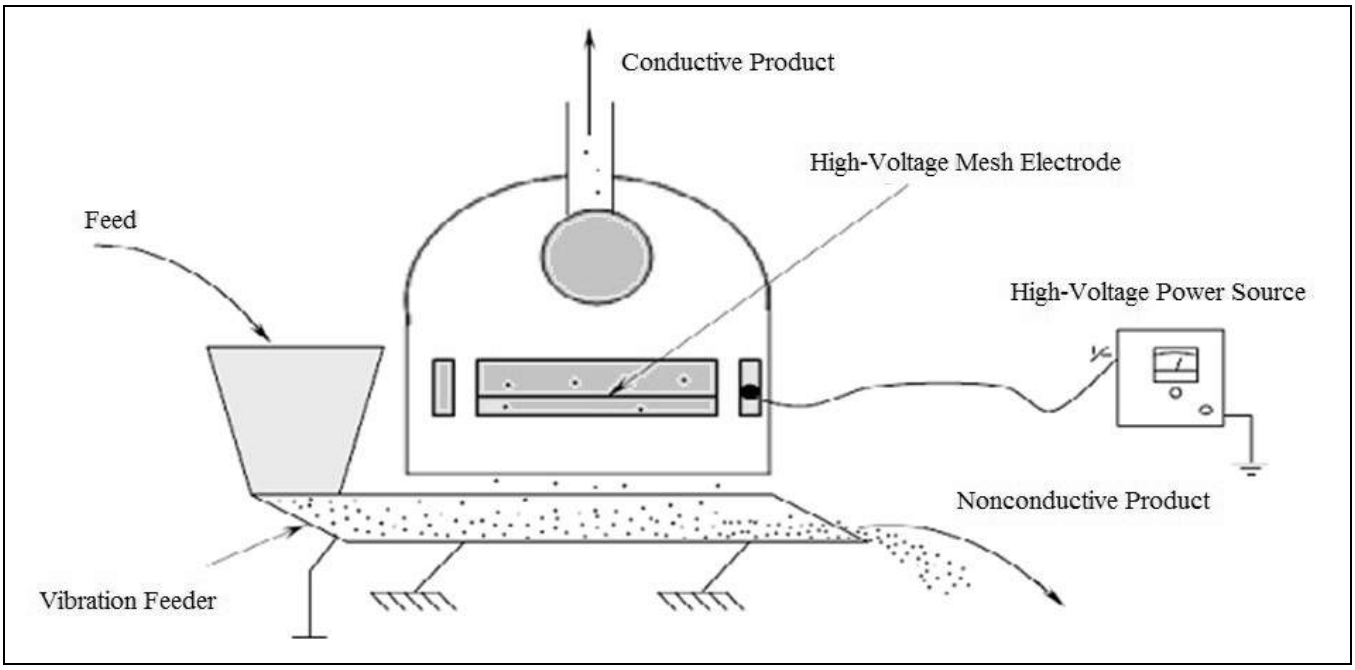


Figure 3. Schematic Diagram of an Electrostatic Separator with Fluidization

Initial dry fly ash is screened to 40 microns. The resulting particles of +40 microns are transferred for dry magnetic separation yielding magnetic and non-magnetic products. The non-magnetic product is fed for electric separation, with prior material fluidization, and is then separated in an electrostatic field into conductive and non-conductive products. As a result, the initial ash with the carbon content of 6.2% is transformed into a commercial product with the content of the carbon component of not more than 4.0% at a yield of 88.5%. The respective flow sheet is shown in Figure 4.

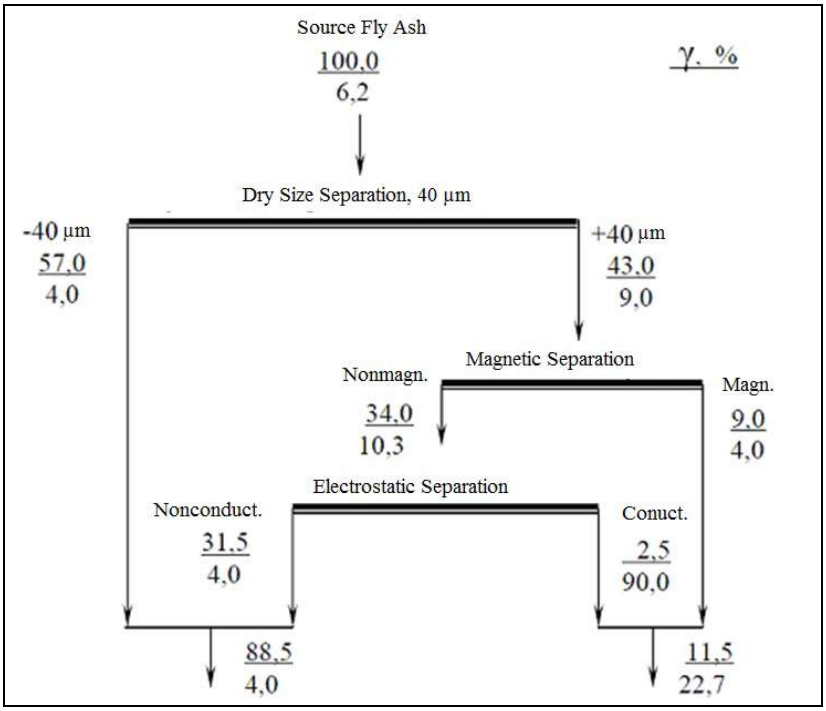

Figure 4. TPP Fly Ash Separation Flow Sheet

The application of vibratory impacts, therefore, enables efficient separation of fine mineral particles in an electric field with sufficient capacity to replace the flotation technology.

3 CONCLUSIONS

The use of vibrational technology, particularly in the processing of granular materials in the state of a granular gas, allows minimizing or totally eliminating the use of water in mineral processing, which not only expands the range of process tools available to engineers, but may provide significant economic benefits.

ABSTRACT With pressures to improve energy efficiency in mining, reducing energy usage in comminution has become the focus of innovation. Several advances have been made however the uptake of innovations and technologies is slow. A Technology Readiness Level guide has been developed for other industries that may be a useful tool for the mining industry. Examination of selected successful energy efficient technologies provides some insights and lessons that may provide direction for advancing new technologies. This paper presents the present state and future opportunities for innovation to reduce energy usage for comminution. The main focus will be in relation to pathways to shorten the timelines to advance technologies through stages of readiness for commercialization for the risk averse mining industry.

Keywords: Comminution, energy, efficiency, innovation, technology readiness level

1 BACKGROUND

1.1 Energy Usage in Mining and the Role of Technology

Mining is an energy intensive activity and as such is vulnerable to risks associated with fluctuating energy costs as well as costs associated with government regulations aimed at reducing environmental impacts such as greenhouse gas (GHG) emissions. As a consequence the mining sector is motivated to become proactive in approaches to improve energy efficiency. Initiatives such as the Towards Sustainable Mining (TSM) implemented by the Mining Association of Canada (MAC) have identified Energy and GHG as one of three main areas of focus to improve the sustainability of mining. To support improvements, the MAC has generated several tools for industry including management guidelines that promote Research and Development and Technology Demonstration.

The Mining Energy Value Chain starts at the face and extends to smelting and refining of the metal product. The main energy consumption results from material transport and for underground mines ventilation, but in general the greatest energy consumer is comminution. More energy efficient technologies in each of these areas will result in significant reductions in overall energy usage. The Coalition for Energy Efficient Comminution (http://www.ceecthefuture.org) state that comminution accounts for 53% of all energy used in the mining industry.

Defining energy efficiency as the energy required for breakage divided by the energy used by the mechanical system, the energy efficiency for comminution is reported to range from 0.1% to 2% (Fuesrstenau and Abouzeid, 2002; Tromans and Meech, 2002). Based on fundamentals of fracture

mechanics, Tromans (2008) hypothesized that there is a maximum limiting energy efficiency for comminution of between 5% and 10%.

Figure 1 presents the main technology types responsible for comminution along the energy value chain. The main energy consumers are blasting, crushing and grinding. Also presented in the figure are technologies that can contribute to reduced energy usage including continuous mining technologies, ore sorting, rock weakening and improved size classification. Systems engineering approaches of the integration of mining and processing activities have led to concepts of Mine to Mill and Geometallurgy that result in strategies for optimization of energy use.

1.2 Technology Readiness Level

One approach to advancing technologies for commercialization is the Technology Readiness Level that was developed for the aerospace industry (http://www.esto.nasa.gov/files/TRL_definitions.pdf, 2015). The approach is the basis for a roadmap that can be followed during research and development to validate concepts, scale-up and adapt the technology to the industrial environment. Table 1 presents the nine technology readiness levels that have been used. Researchers are very effective at developing technologies from TRLs of 1 to 3. To achieve TRLs 7 to 8, end users need to be active participants in the process. Key to the success of commercialization is advancing the technology through TRLs of 4 to 7 referred to as the “valley of death”. It is at these TRLs that many innovations become stalled.

2 ENERGY EFFICIENT TECHNOLOGIES

2.1 Recent Innovations

Over the past 20 years several novel technologies that greatly reduce energy usage have been developed. However, new technology is perceived as a risk to the mining sector and as such the acceptance and implementation of these technologies have been slow. The conservative mining culture reflects on the need for greater efforts to focus on technology development through efforts such as demonstration to shorten the timeline for acceptance.

Mine to mill and geometallurgical concepts were introduced to the mining industry over 30 years ago. Despite knowledge of the benefits of these concepts, they are not used by all operations. High Pressure Grinding Rolls and High Speed Stirred Mills represent step changes in energy efficiency, yet both technologies are only considered for niche applications. Looking forward, innovations in particle weakening through technologies such as

electric pulse and microwave treatment offer benefits related to energy usage as well as improved mineral separation through enhanced liberation. Sensing and sorting technologies for rock rejection or bulk separation improves our abilities to discriminate between ore and waste and thereby allow us to avoid grinding waste resulting in direct energy savings. Technology areas that require innovation include increasing the level of automation and new developments in specific areas such as size classification.

Over the past 25 years several process technologies have been introduced to the mining industry that impact comminution energy usage. Of note were the introduction of Mine to Mill concepts and technologies such as High Pressure Grinding Rolls (HPGR) and High Speed Stirred Mills (HSSM). Each has significant energy benefits plus several other advantages related to operating costs and metallurgical performance. While the technologies have been applied at the industrial scale, their application is still somewhat tenuous.

Table 1. List of Technology Readiness Levels(www.esto.nasa.gov/files/TRL_definitions.pdf, 2015)

TRL	Description
1	Basic principles observed and reported
2	Technology concept and/or application formulated
3	Analytical and experimental critical function and/or characteristic proof-of- concept
4	Component/subsystem validation in laboratory environment
5	System/subsystem/component validation in relevant environment
6	System/subsystem model or prototyping demonstration in a relevant end-to-end environment
7	System prototyping demonstration in an operational environment
8	Actual system completed and "ready for implementation in mining operation" through test and demonstration in an operational environment
9	Actual system through successful application at mining operations

2.1.1 Mine to mill

The Mine to Mill concept integrates information about lithology, mineralogy and mining systems to identify synergies that would benefit downstream processing. The greatest focus has been to promote particle fragmentation by blasting in order to reduce energy usage or increase throughout in downstream grinding. Several case studies have demonstrated energy savings of up to 20%, which translates into comparable increases in throughput for existing operations (McKee et al, 1995, Dance et al, 2011). Environmental benefits resulting from waste and tailings reduction are also significant. Since the development of Mine to Mill approaches, about one hundred mines globally have applied Mine to Mill to improve either production rates or energy efficiency (Dance, 2015). In relative terms, Mine to Mill concepts were commercialized quickly because they were developed by operators at operations resulting in almost immediate application following the development of the concepts. This approach accelerated the concept up the readiness level scale. Concepts were developed and accelerated through the TRLs such that trials at operations advanced the concept through TLR's 7, 8 and 9. The involvement of operations willing to apply the concept was critical to commercialization. Despite proven benefits of Mine to Mill, the uptake has not been fast which may be attributed to a lack of incentives to motivate implementation.

2.1.2 High pressure grinding rolls

Based on fundamental work on fracture physics, Professor Klaus Schoenert (1979) concluded that increased energy efficiency could be achieved by breaking particles in compressive beds. He applied the concept to the development of High Pressure Grinding Rolls in which material is choke fed between two counter rotating rollers, one of which is fixed and the other is floating in connection with a hydraulic cylinder. The material forms a compressive bed between the two rollers resulting in interparticle breakage (Schoenert, 1988). Energy savings of

between 15 and 30 % over SAG Mill Circuits have been reported (Rosario, 2010; Rosario et al., 2011). Energy benefits relate to improved energy efficiency from compression breakage but also result from micro-fractures that lower the Bond Work Index by about 10% for subsequent grinding (Drozdiak, 2011).

In the early 1990s, the HPGR found applications for the breakage of soft materials such as clinker (Patzelt, 1992) and kimberlites. For diamond ores, the ability of the HPGR to break kimberlite host rocks without breaking diamonds added significant value motivating the implementation (Anguelov et al., 2008). The first hard rock application was in 1995 at Cyprus Sierrita in Arizona, which demonstrated that wear issues needed to be overcome (Thompsen et al., 1996; Morley, 2008). The introduction of studded liners that trapped particles at the roll surface and thereby created an autogenous layer greatly improved wear life and led to the successful installation of the HPGR at the Cerro Verde copper mine in Peru in 2007.

Since then, the HPGR technology has been used at a number of operations although it is still primarily considered only for niche applications such as for very hard ores. Perceptions are related to dust issues, extensive material handling systems. Specific criticisms relate to the complexity of material handling in environments that can freeze, causing operational problems and the inability to operate at high moisture levels in high rainfall areas. Despite these challenges, HPGR circuits result in energy savings for comminution that range from 10 to 30%. When considering that up to 70% of all electrical power in large open pit mines is consumed by semi-autogenous-ball milling-crushing (SABC) circuits, the advantages of the HPGR are substantial. There are presently six manufacturers of the HPGR namely Polysius, Koeppern, KHD, Metso, FLSmidth and Citic. While the HPGR is perceived to be the comminution technology of the future, it still has not received full acceptance by a technical community who are most comfortable with SABC circuits. However the technology is receiving considerable interest and its application is expected to increase. An indication of the strong interest is reflected by the number of technical publications on the subject. For the upcoming SAG 2015 Conference, the HPGR is considered to be a competing technology to SAG milling and as many as 25% of all presentations will focus on this topic. As a result, the conference title has been changed to International Conference on Semi-Autgenous Grinding and High Pressure Grinding Rolls (SAG 2015, http://sagconference.com).

In terms of the Technology Readiness; Level, the concept was developed in 1979 and 46 years later (2015) there is good industry acceptance of the technology. Over this period barriers to commercialization included a range of technical issues that were addressed. However equally important is that the perception of low TRL and low incentives for change (such as low energy prices) likely slowed the development. The Cerro Verde Mine (http://www.fcx.com/operations/Peru_Arequipa.htm) that installed the HPGR in 2007 was key to acceptance of the technology.

2.1.3 High speed stirred mills

Mount Isa Mines were the first to apply high speed stirred milling as a means of liberating fine grained polymetallic ores. The scale-up of the Netzsch Mill, that had been applied to pigments and other specialized industrial mineral products, to a size that could be applied for metal mining led to the development of the ISA Mill (Gao et al., 1999). The technology represented a breakthrough because it could reduce particle size to below 10 microns with relatively low energy input as compared to regrind tower mills or ball mills. For fine regrinding applications, energy savings of 50% were demonstrated over Verti-Mills at target size of 80% passing 18 microns. For grinding below 10 microns energy savings were even greater.

Mount Isa maintained exclusive use of the technology until the late 1990’s when they

marketed the technology under Xstrata Technology. The development of the technology was led by a mining company, which was key to the advancement through the TRLs and commercialization in a relatively short period of time.

Within a decade of developing the concept to scale-up the Netzsch mill to meet the demands for large scale ultrafine grinding, several operations around the world had applied the technology. With respect to technology readiness level, the ISA Mill technology advanced quickly. This likely relates to development of the technology by a mining operation to prove and demonstrate the concept in an industrial environment to help it attain industry acceptance.

More recently, efforts have been put towards adapting the technology to applications requiring a coarser grind where it has also demonstrated energy benefits over tower mills and ball mills. It is now over twenty years since the ISA Mill was first developed and while it has gained significant market access, it is still considered primarily for ultrafine regrind applications. There are presently four manufacturers of high speed stirred mills (Outotec, FLSmidth, Metso, Xstrata Technology).

2.2 Energy Savings

A number of studies have been conducted to quantify the energy savings that can result from combining Mine to Mill, HPGRs and High Speed Stirred Mills. Using process simulation, Valery and Jankovic (2002) determined that a novel system involving high intensity blasting, HPGR and Verti Mills required about 45% less energy than a conventional SAG Mill – Ball Mill Circuit. Based on pilot scale studies, Drozdiak et al. (2011) compared a conventional cone crusher-ball mill circuit to a novel HPGR-ISA Mill circuit that reduced comminution energy requirements from 17.8 kWh/t to 14.8 kWh/t, which is about a 17% reduction in energy usage. Plant operating energy usage for an SABC circuit was compared to a novel two stage HPGR circuit – ISA mill circuit and demonstrated 30% energy savings (Wang 2013; Wang et al, 2013). There is sufficient information to show that each technology represents a step change in energy efficiency and that by combining the technologies in innovative processes, energy usage can be greatly reduced.

3 EMERGING AND FUTURE TECHNOLOGIES

Several technologies have been developed at the conceptual stages that if developed through to commercialization would represent a significant breakthrough. Continuous mining equipment has been developed for soft ores and efforts have been made to evolve these technologies to hard rock mining. Hydrofracking has been investigated for breaking coal and the technology has been considered for block caving to improve control of the caving process. There is ongoing work to improve blast control evolving intensive blasting to reduce energy usage in downstream comminution. A significant breakthrough has been made using microwaves that fragment or weaken rock. The application of microwaves induces differential thermal expansion of minerals of different composition that weakens the rock and promotes breakage along grain boundaries reducing the energy input needed for downstream breakage from crushing and grinding and potentially improving mineral liberation (Charikinya and Bradshaw, 2014). Similarly high voltage pulse technology has been developed that weakens rocks by inducing electrical explosions causing shockwaves (Cabri et al, 2008, Zou et al, 2014; van der Wielen et al., 2014). The weakening results in lower grinding energy and breakage is reported to be preferential along grain boundaries enhancing liberation. One area that requires innovation is high capacity size classification in particle size ranges where screening rates become slow and above sizes where classifying with hydrocyclones can be applied. Another emerging technology area is sensor based sorting, which rejects barren rock ahead of

downstream comminution resulting in energy savings that are directly proportional to the amount of rock rejected.

3.1 Sensing and Sorting Systems

Sorting has been applied for some time to mining such as the case of radiometric sorting of uranium ores in Canada in the 1960s. X-ray sorters have been a standard separation technology in the diamond industry since the 1980s when they introduced in the Argyle diamond mines in Australia. With the development of recycling technologies in Europe, several manufacturers developed sorting technologies that are commercially available with a range of sensor technologies. These companies have applied the sorting technologies to mining applications. Despite several benefits related to energy and material handling, particle sorters have found only niche applications in the mining industry. The two main barriers to broader application relate to sensors that can discriminate barren rock particles from valuable ore particles and the limited capacity of industrial machines (Wotruba, 2006; Klein et al., 2011).

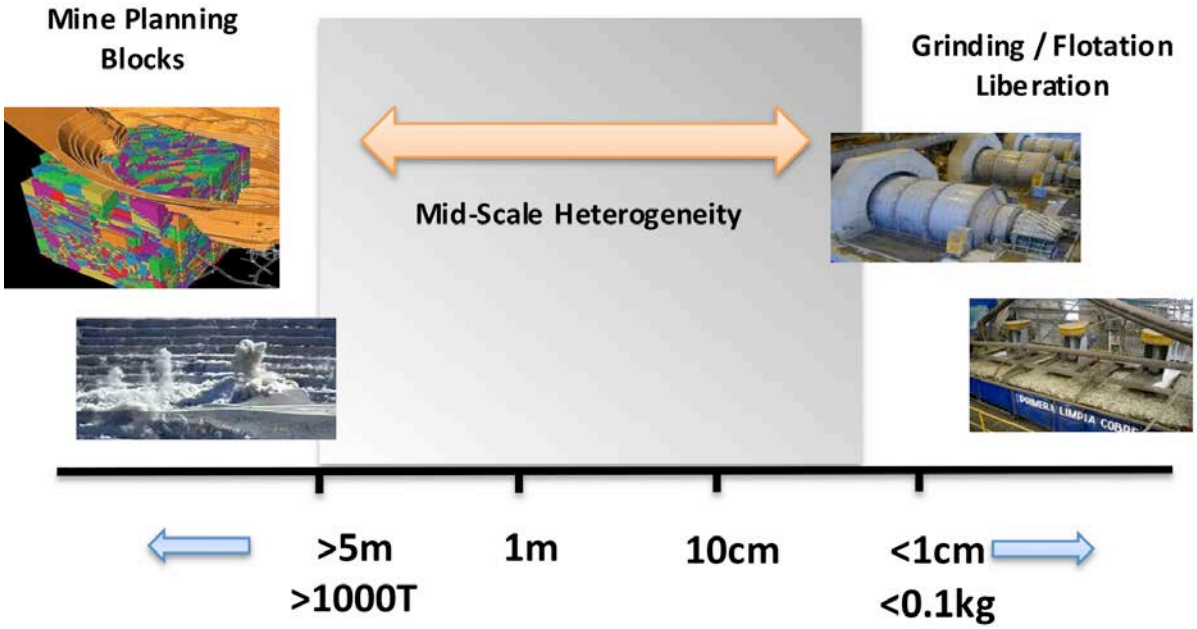

Figure 2. Schematic Illustrating Midscale Heterogeneity (courtesy of MineSense Technologies Ltd. 2014)

3.2 Heterogeneity and Sensing Systems

There are several potential benefits to ore sorting including reduced material handling costs, lower operational costs associated with energy consumption particularly for comminution, more consistent feed grades and higher grade of ore reporting to the concentrator, and it also enables the application of lower cost bulk mining methods over more selective mining potentially allowing a lowering of the mined cut-off grade. A key to successful sorting is the heterogeneity of the ore that will be exploited. In mining systems, heterogeneity is exploited at the bulk ore body scale to distinguish between ore and waste rock as well as at the mineral separation stage where liberation determines separation. Sorting focuses on exploiting heterogeneity in sizes intermediate to these two extremes. The scale of heterogeneity can vary considerably as presented in Figure 2.

One approach to quantifying heterogeneity was proposed by Pierre Gy (Pitard, 1993) and is referred to as Constitution Heterogeneity (CH). For a “lot” of particulate materials (such as a stockpile), CH is the difference between the composition of various units in the lot (such

as the particles that make up the units) and not between the individual units themselves; for example the grade of each rock compared to the other rocks and average grade of the lot (Gy, 1992).

$$CH_L = s^2(h_i) = \frac{1}{N_F}\sum_i h_i^2 = N_F \sum_i \frac{(a_i - a_L)^2}{a_L^2}.\frac{M_i^2}{M_L^2} \quad (1)$$

where α_i and α_L are the grades of the fragment *i* and the lot, respectively, while M_i and M_L are the masses of fragment *i* and the lot. If the fragments are part of a much larger lot, N_F in equation (1) should be substituted by N_F*-1*.

When it comes to assessing sorting of a specific ore deposit, two approaches are available: Sorting either targets the metal of interest, such as copper or gold; or focus is on rejection of waste, such as silica. In some cases it could be beneficial to sense and reject gangue rather than attempt to recover metal.

Early stage assessment of amenability to sorting should focus on characterization of heterogeneity. To exploit heterogeneity, a range of sensors can be applied. Approaches include measurement of sensor responses and calibrating against rock assays. In addition to the individual sensor signals, methods that should be considered include:

1. Analysis of sensor response signatures rather than relying on a single threshold level.
2. Combining sensor responses to improve discrimination.
3. Analysis of proxies for target metals.
4. Assessing heterogeneity of gangue phases for rock rejection.
5. Applying regression analysis to sensor signals.
6. Assessing rock size heterogeneity.

While work is required to improve the resolution and speed of sensors, the above methods need to be applied in order to assess the potential for sorting. Present studies evaluate sorting on the basis of sorting machines that are commercially available. In some cases the ability to apply the commercially available sorters is the basis for classifying the ore as sortable or not sortable. As a consequence ores are prematurely considered not sortable based on a general misconception that "if our machine cannot sort the material then it is not sortable". Research and development that relies on better sensors and applies innovative approaches that relate geology and mineralogy are needed to improve the resolution of sensing. As such sensing systems presently available will have a technology readiness level of 9, but much work is still needed to be conducted at the conceptual TRLs of 1 to 3 to enable broader application of sorting.

3.3 Throughput Limitations – Rock vs. Bulk Sorting

In order to address capacity challenges, efforts are being directed towards bulk and/or semi-bulk sorting. Platforms exist for rock sorting that requires screening of feed into narrow size fractions and then feeding the sorter with a mono layer of particles that can be sensed and subsequently accepted or rejected using pneumatic or mechanical particle ejectors. While these technologies have a proven track record for selected ores, their application is limited by the throughputs that are achievable. The case for sorting can be made for low tonnage operations, however, rock sorters cannot be applied to low grade deposits that utilize less selective mining methods and operate at high production rates.

The approaches aimed at increasing through focus on semi-bulk or bulk sorting. Sensors along the material handling system can be applied to discriminate between ore and waste. Conservative strategies aimed at waste rejection reduce the risk of sending ore to waste dumps. MineSense Technologies are developing systems that incorporate sensors in the material handling equipment such as shovels and on conveyor belts (http://minesense.com). For example, sensors in a shovel loading waste can inform the operator that the shovel contains ore.

Similarly, the sensors can inform the operator that the shovel contains waste. Conveyor sensors can trigger deflection of ore from waste at head pulleys. Keys to these systems are sensors that are calibrated to properties of the ore and the waste. Also, while considerable heterogeneity may exist when the material is being excavated at the face, through material handling and stockpiling, the ore flows through stages of mixing and blending reducing the level of heterogeneity. Therefore, the opportunity for bulk sorting is best closest to the face.

The technology readiness level of rock sorting has been demonstrated for selected applications. Bulk or semi-bulk sorting has been applied in niche applications such as for high phosphate versus low phosphate iron ores (Kiruna). There are similar opportunities for other ores but the technology is at a lower state of readiness. The application of bulk sorting needs to be developed for ore types such as porphyry, laterites or iron ore and then refined for individual deposits. Potential applications to large tonnage ores such as nickel laterites, copper porphyrys and iron ores will greatly impact resource utilization and profitability.

4 CONCLUSIONS

Several advances have been made that reduce energy usage in comminution. Individual technologies such as intensive blasting, HPGRs and high speed stirred mills represent a step change in energy efficiency. Combining these technologies in innovative flowsheet designs amplifies the amounts of energy savings. The key to technology acceptance was the participation of mining operations in the development process. Early stage participation accelerated the advancement of the concepts from TRL 3 through the “Valley of Death” to TRL 9. Emerging technologies should engage mining operations as soon as possible which will reveal technological barriers and demonstrate the opportunity to the implementers of the technologies. Sensor based sorters for rock separation are commercially available, however they have found only niche application. Improved sensor systems along with the development of higher capacity sorters that rely on semi-bulk and/or bulk sensing systems will support broader application. The key to advancing the technology through to commercialization requires participation between researchers, manufactures and end users.

APPENDIX

Definition of Technology Readiness Levels

TRL 1 Basic principles observed and reported: Transition from scientific research to applied research. Essential characteristics and behaviors of systems and architectures. Descriptive tools are mathematical formulations or algorithms.

TRL 2 Technology concept and/or application formulated: Applied research. Theory and scientific principles are focused on specific application area to define the concept. Characteristics of the application are described. Analytical tools are developed for simulation or analysis of the application.

TRL 3 Analytical and experimental critical function and/or characteristic proof-of- concept: Proof of concept validation. Active Research and Development (R&D) is initiated with analytical and laboratory studies. Demonstration of technical feasibility using breadboard or brass board implementations that are exercised with representative data.

TRL 4 Component/subsystem validation in laboratory environment: Standalone prototyping implementation and test. Integration of technology elements. Experiments with full-scale problems or data sets.

TRL 5 System/subsystem/component validation in relevant environment: Thorough testing of prototyping in representative environment. Basic technology elements integrated with reasonably realistic supporting elements. Prototyping implementations conform to target environment and interfaces.

TRL 6 System/subsystem model or prototyping demonstration in a relevant end-to-end environment (mining operation): Prototyping implementations on full-scale realistic problems. Partially integrated with existing systems. Limited documentation available. Engineering feasibility fully demonstrated in actual system application.

TRL 7 System prototyping demonstration in an operational environment (mining operation): System prototyping demonstration in operational environment. System is at or near scale of the operational system, with most functions available for demonstration and test. Well integrated with collateral and ancillary systems. Limited documentation available.

TRL 8 Actual system completed and "ready for implementation in mining operation " through test and demonstration in an operational environment (mining operation): End of system development. Fully integrated with operational hardware and software systems. Most user documentation, training documentation, and maintenance documentation completed. All functionality tested in simulated and operational scenarios. Verification and Validation (V&V) completed.

TRL 9 Actual system "operations proven" through successful implementation at a mining operation): Fully integrated with operational hardware/software systems. Actual system has been thoroughly demonstrated and tested in its operational environment. All documentation completed. Successful operational experience. Sustaining engineering support in place.

Comparative Study of Mineral Processing Applied To The Local Feldspar's Assessment

R.Akkal, M.Ouldhamou
National Polytechnic School of Algeria, Alger's, Algeria

ABSTRACT In the field of ceramics and glassware, feldspars are extensively used worldwide as cooking or melting additives. Feldspars act as a flux to melt the silica into a liquid glass. This is caused by the high amounts of Potassium in the pot ash feldspar, Sodium in the Soda ash Feldspars and Lithium in Spodumene. The amount of coloring iron substances must be low. The main objective of this study is focused on the mechanical preparation of Algerian crude feldspar with a view to extract the information about the comminution and the coloring iron rate distribution, on the one hand, and to remove the oxides of iron, on the other hand, main impurities of crude feldspar by magnetic separation, flotation and more particularly by chemical bleaching (leaching). The bleaching chemical used is the nitric acid reducing medium to replace sulfuric acid and dithionite as reducing agent, the application tests have yielded negative results.

Keywords: Feldspar, Ain Barbar, chemical purification

1 INTRODUCTION

Feldspars are essential constituents of igneous rocks, plutonic or extrusive (59.5% of the minerals of magmatic rocks). Their chemical composition varies with the nature of the rocks : acidic rocks contain alkali feldspar, intermediate rocks of alkali feldspar and plagioclase means, basic rocks calcic plagioclase. Feldspars belong to the family tectosilicates.

Analysis of feldspars allows them as more or less homogeneous mixtures of three basic components : KAlSi3O8 : Orthose (Or) (Sanidine ou microcline), NaAlSi3O8 : Albite (Ab) et CaAl2Si2O8 : Anorthite [1–3]. They generally occur together with quartz, mica, iron oxides, rutile and hornblende. Basically, the two properties which make feldspars useful for downstream industries are their alkali and alumina content. Feldspars play an im- portant role as fluxing agents in ceramics and glass applications, and are also used as functional fillers in the paint, plastic, rubber and adhesive industries [4–8].

Presence of iron in feldspar is not desirable as it imparts color to the final product, and therefore, iron content has to be kept below a certain value, 0.10% for glass making and 0.07-0.08% for ceramics [5, 9]. Several conventional enrichment techniques, such as hand sorting, comminution, magnetic separation and flotation, are employed to remove coloring impurities including iron bearing minerals from feldspar. These techniques are used for the treatment of particles larger than 40 microns. Other technics are applied for the ultra-fine particles treatment(slimes) , less than 40 micron such as flocculation [10]. The mechanical properties
of feldspathic rock have a direct impact on eight yields different size fractions for purification and marketing ; therefore they affect the selection and sizing of comminution and screening equipment. Any method of treating an ore often requires that it be reduced or broken at a dimension that allows the release of its ingredients (minerals and gangue products) making the separation of the latter accessible. As part of this work, which was to achieve optimal locate a chemical purification feldspar of Ain barbar conditions using nitric acid in the presence of ammonium bifluoride as the reducing, we prefer to review all the results of all characterization and optimization tests

achieved in the past. This allowed us to compare a number of results and extricate useful conclusions to any project development.

1.1 Materials and Methods

A representative sample of the Ain Barbar deposit located in the east of Algeria received in the ENP laboratory, whose Mineralogical composition and chemical analysis are presented in table 1 and 3. The sample was previously crushed in a jaw crusher followed by grinding in an impact mill of Ain Barbar unit. In this work, we aim to produce the size fraction [-0.8+0.1] mm for the glass. In view of the glass market application, we screened the sample E0 in [0.8 mm] size, were extracted by sieving the fines [-0.1 mm] to avoid over-grinding. Grinding and sieving are carried out as shown in the following schematic.

The desired results are the production of three fractions sizes [-0.8+0.4], [-0.4+0.25] and [-0.250] mm taken as the basis for subsequent recovery treatments as shown on the Figure 1.

Table 1. Grain size distribution of sample

Size fraction (mm)	RP (%)	Fe2O3 (%)
[+0.8]	3.30	0.45
[-0.8+0.6]	19.23	0.46
[-0.6+0.250]	19.58	0.49
[-0.250+0.1]	23.35	0.56
[-0.1+0.04]	7.92	0.63
[-0.04]	28.42	0.77

Grain size distribution of sample is shown in table below Table2.

Table 2. Mineralogical composition of sample

Element	Percentage
Orthose	52.66
Quartz	37.42
Pyllites	7.02
Albite	1.70
Anorthite	0.58
Fe_2O_3	0.53
Apatite	0.38

In a second step, we conducted the high magnetic intensity separation trials of iron oxides content in feldspars. Slices prepared underwent magnetic separation into two passages on magnetic separator intensive CARPCO brand. The next step is to treat the treated particles by magnetic separation will be treated by flotation; the other party will be processed by leaching. The requirements for effective flotation: the first condition to obtain good flotation is to achieve a grinding of the maximum releasing minerals from each other; and a suitable release of the particles to float. In some cases, it is necessary to desliming pulp before the float and to avoid that the recovery of the mineral particles surfaces.

In our cases, dry milling was performed in a ball mill ceramic to avoid contamination with iron, the milling time and the grinding mass are determined on the basis of tests. For this work, the grinding time is estimated about 8min, with a mass gain of 300 g. After grinding, we conducted a screening to remove particulates, which are smaller than -0.04 mm dimensions. The purpose of the grinding is to achieve the size less than 0.250 mm, to release the most of the mixed iron oxide particles, whose operation is controlled with a sieve whose opening is smaller -0.250 mm. At the end of the operation desliming refusals and passersby were dried and weighed.

A pulp containing between 5 and 50% solids mixture with water, the pulp is stirred in a conditioning tank to ensure the homogeneity of the medium. In a first time, dispersants AP 801 and AP 840 are added to avoid any kind of agglomeration before floating the concentrate (feldspar), then the collector Dodycelamine agent and hydrofluoric acid are added to modify the surface feldspar particles to be driven to the surface by the air bubbles. This process is repeated every time before flotation concentrate. In this work, the flotation operation is repeated 3 times. After flotation, we washed, dried filtered and concentrated and the discharges.

Table 3. Chemical analysis of sample

Element	Pourcentage
SiO2	75
Al_2O_3	12.45
Fe_2O_3	0.57
TiO_2	<0.05
CaO	0.30
MgO	0.20
Na_2O	0.30
K2O	<0.20
MnO	<0.20
P.F	0.70
P_2O_5	0.20

2 RESULTS AND DISCUSSION

Feldspar fragments having a maximum dimension of [150] mm are first crushed with a mass to be able to place in a laboratory jaw crusher, whose maximum aperture is [50] mm adjustable. A sample of forty pounds is inserted into the jaw crusher for a first step. The crushed product is recycled again after reducing the outlet opening of the crusher without sieving. Refusal to [0.8] are ground mm [0.8] mm in a FORPLEX grinder to reduce to [0.8] mm, the [+0.8] mm go over 3 times in FORPLEX mill.

We have taken after thorough mixing three samples we screened separately. The results are shown in the following schematic. A granular-chemical analysis was performed for all three screening. The level of the fine [-0.04] mm from the power decreases with the increase in recycling, this finding can be explained by the fact that the fragile particles crumble at the first passage on the crusher and mill, the hardest produce fewer fines remaining. [+ 0.25 -0.4] mm slice is produced with a rate that varies little regardless of the number of recycles, this rate varies between 10 and 12%, this is due to the fact that all comers has a good degree of homogeneity of hardness and perspective structure. The pattern of grinding applied in this study responds to market demand. Knowledge of the physical properties of size fractions required by customers, help in choosing based on the results of this study the quality and types of equipment that would be most suitable for the production unit projected. Knowing the results of weight crushing / screening assessment is used to size the facilities of a production unit based on size fractions required and demand.

2.1 High Intensity Magnetic Separator of Iron Oxides

Size fractions prepared underwent two passages on a laboratory magnetic separator intensive (mark CARPCO). Initially, we vary the magnetic field keeping the other factors fixed. The results obtained are shown in the following figure. The magnetic purification reduces the iron oxide content of feldspar to the value of 0.34% to 99.62% by performance weight relative to food, treating the size fractions [-0.8+0.1], [-0.6+0.1], [-0.6+0.250] and [-0.250+0.1] mm separately, except size fraction [-0.8 +0.1] mm which the iron oxide content is reduced from 0.50 to 0.39%. For a better release of iron oxides generated by a finer grinding, there is a better treatment for size fractions greater than 0.1 [mm]. For particle size fractions [-0.1] mm, removal of iron oxides is needless, caused by the ultra-fine particles that the magnetic field strength is no longer able to attracted and retain them on the drum machine Figure 2. These ferrous dust mixed with those of finely ground feldspar, which cover the receivable oxides, they reduce the driving forces generated by the magnetic field on these oxides, however favorable to their extraction feldspar dimensions [11–13]. Purification of the particle size range [-0.8 +0.1] mm by high gradient or high intensity magnetic field resulted in only a iron residual of 0.34 and 0.39 % values very close who do not justify the high investment in the use of high gradient separator. For products used in the ceramic industry, the high intensity magnetic purification gives contents oxide iron 0.34

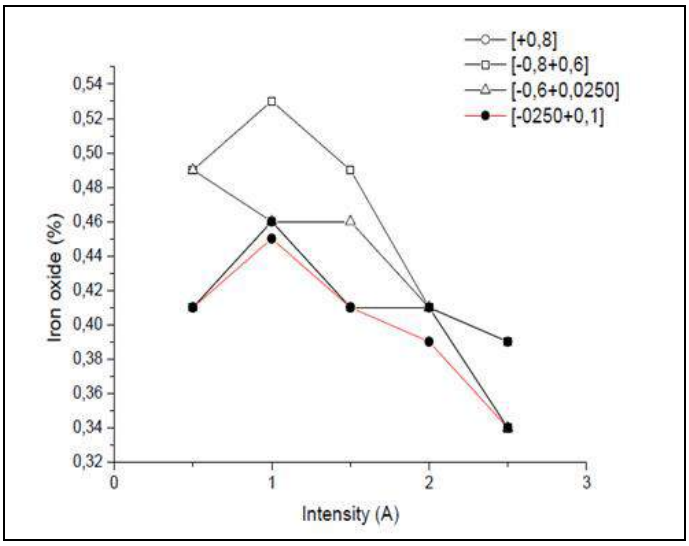

Figure 2. iron oxides (%) vs high intensity magnetic values

0.31% for size fractions [-0.2+ 0.080] ; [-0.25+0.1] mm. It is best to treat several size fractions separately and then mix them to reconstruct the portion that meets the required criteria for use.

2.2 Flotation Purification

A part of the size fractions treated by magnetic separation will be processed by flotation, followed by leaching, the other part will be treated by leaching. Dry grinding was carried out in a ball mill ceramic to avoid contamination with iron, the milling time and the grinding mass are determined on the basis of tests. In our case the grinding time is 8minutes to slice 0.1-0.8 mm and 6 minutes for the portion 0.1-0.6m.

2.2.1 The feldspars preparation scheme for flotation

After grinding, we conducted a screening to remove particles whose dimensions are less than [-0.04] mm using sieve whose opening is [-4mm].

The purpose of the grinding is to achieve fractions sizes less than [0.250] mm, to release the most of the iron oxide particles mixed, so the operation is always controlled with a sieve whose opening is less than [-0250] mm. The ore is desliming in [-0.04] mm with an opening sieve of [0.04] mm. At the end of the operation desliming refusals and passersby were dried and weighed to calculate the yield weight [14]. The weight average yield is 60.49 % for the group [-0.8 + 0.1] mm, that for [-0.6 + 0.1] mm is 64.80 %, these results are very close to those of the BRGM study. The schematic process of flotation is given in the following figure Figure 3.

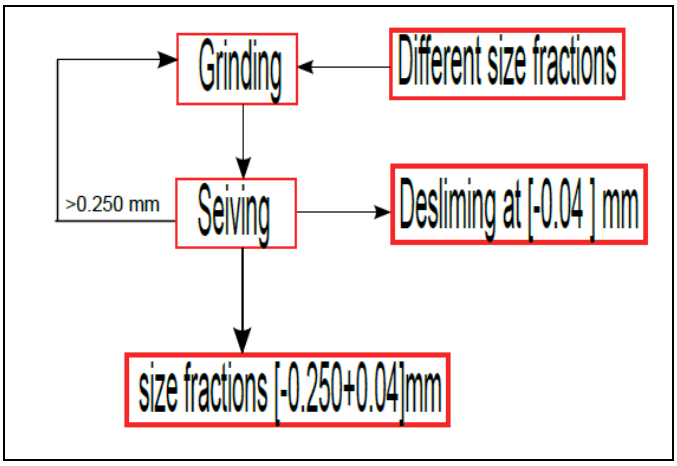

Figure 3. Grinding feldspar scheme for flotation application

Whatever the size fractions treated by magnetic separation, purification limited stops at
0.34% iron oxide, value already encountered in the BRGM study, who recoveries exceed 99%. Flotation applied for the size fractions treated with high intensity magnetic separation improves the purification by lowering content of Fe2O3 for about a third collector consumption 3ml, 4 ml or 5 ml and 0.05 kg/t, and 0.1 0,200Kg/t respectively. Fine particles were removed upper size fractions [-0.8 + 0.1] mm and [-0.6 + 0.1] mm, where more concentrated iron oxides, so they are less rich in oxides.

The contents of these oxides in the rough particles are released by grinding at [0.250] mm and removed by flotation. The final content of the concentrates is lower than in the case of thinner fractions sizes flotation ([-0.6 +0.25] mm [-0.25 + 0.1] mm [0.04 +- 0.1] mm). The results that we can reasonably extricate from these flotation tests carried out under the specified conditions, show that the decrease in content of the samples removed iron by magnetic purification, reached a rate of 40% to 50%.

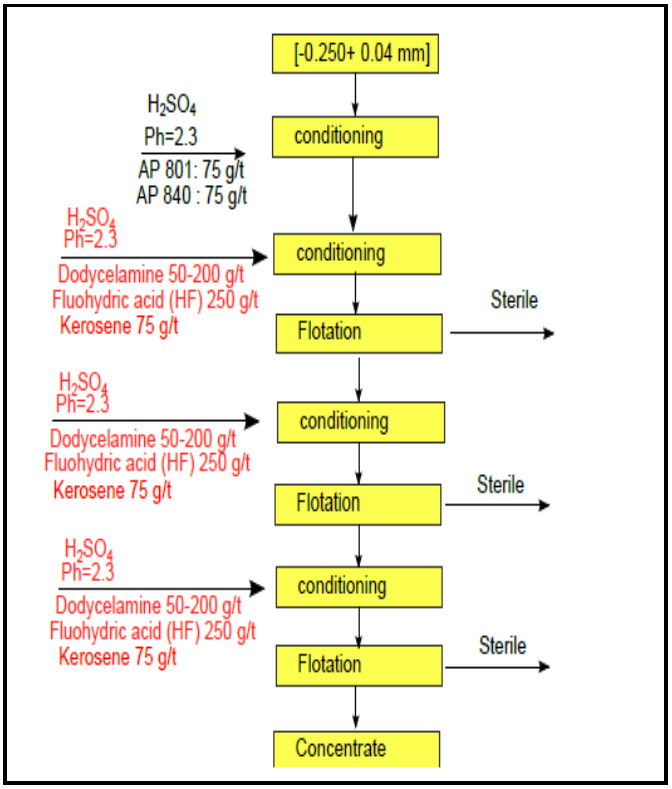

Figure 4. Flotation flowheet for feldspar purification

The final content of feldspar removed iron by magnetic purification and floated into the optimal conditions will be : Feldspar grinding to [0.8]mm where the fractions less than [-0.1] mm is extracted we have 54.85% yield weight with 0.23% a content of iron oxide.

For the size fractions [-0.6 + 0.1] mm subtracted from all comers crushed to [0.8] mm, we have 38.56% yield weight with iron oxide content of 0.20%, a decrease of 40% to 50%. The uncrushed size fractions to [0.25] mm and purified by magnetic separation, flotation gave weight yields very similar to those given in the two previous cases with iron oxides content ranging between 0.31 and 0.34%. The lower level of this impurity is only 0.18%. This result is explained by the fact that the non-grinding does not release encrusted oxides (mixed grains) in the grains of feldspar. For other thinner size fractions, the final content of iron oxide after flotation does not go lower than 30% with a drop that is around 11% for [-0.6 + 0.25] mm and [-0.25 +0.1] mm fractions and 50% for [-0.1 + 0.04] mm fractions. We note that the content of iron oxide is the least important in the upper size fractions, the more we go down to the fine, the content more increases ; this is due to the oxides physical characteristics, in particular oxides friability and connection nature which is associated with mineral feldspar, where it is finely disseminated. The size fraction [-0.6+ 0.1] mm contains more fines than [-0.6 0250]mm, hence the explanation that the Fe2O3 content of [-0.6 + 0.1] mm is higher (0.51%) than [-0.6 0250] mm (0.49%), which got rid of the fine [-0250 +0.1] mm richer in Fe2O3. The levels between 0.2% and 0.23% Fe2O3 with respective weight yields of 38.56% and 54.85% is commercial feldspar for ceramics for high consumption Figure 5.

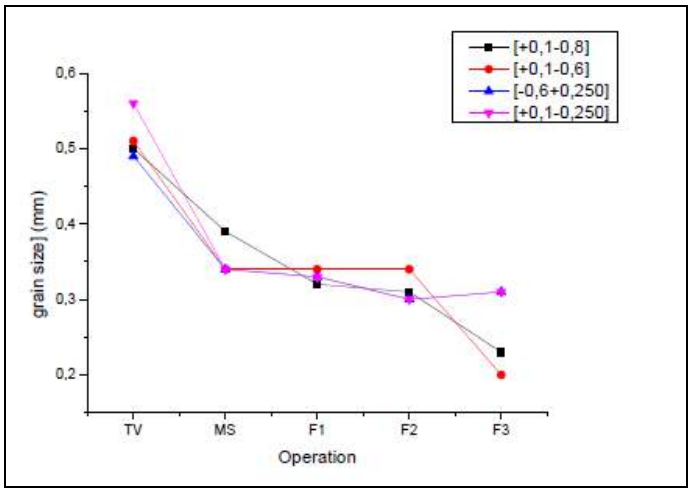

Figure 5. Flotation purification results compared with MS and TV

Table 4. Iron oxide composition for different sizes before and after grinding

Size fraction	Initial weight (g)	Fe2O3 (%)	Concentrate weight (g)	Fe2O3 (%)	Rp (%)
[-0.8+0.1]	300	0.39	149.2	0.32	49.73
[-0.8+0.1]*			276.9	0.23	92.30
[-0.6+0.1]	300	0.34	281.3	0.34	92.30

[0.1-0.250]	300	0.34	283.5	0.33	96.10
			267.0	0.30	94.50
[-0.14+0.04]	300	0.36	245.9	0.30	81.97
			285.6	0.30	89.83
[-0.6+0.250]	300	0.34	284.4	0.31	95.20
				0.30	94.80

2.3 Leaching Purification

In what follows, a hydrometallurgical process is applied. It consists of the selective dissolution of the metals present in the feldspar ore by a suitable reagent in aqueous solution. In our case, ferric iron oxides are reduced to ferrous iron. The experimental protocol consists of a beaker equipped with a heatproof cover and limiting the evaporation of the etching solution. The lid is provided with three ports, one to inject the acid, the second port is to fix a thermometer for measuring the pulp temperature and the third port serve as a location for refrigerant tube of the cooling gas which evaporates due to etching solution evaporation. The stirring and heating the mixture of the etching solution and ore are made using magnetic bars and a hot plate Figure 6.

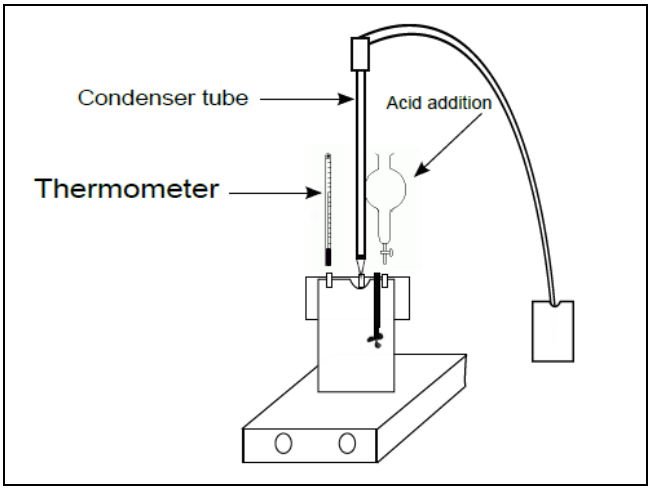

Figure 6. Leaching purification scheme for feldspar ore

To get some results for orientation, we performed some preliminary tests based on the three parameters influence with respect to the iron oxide recovery. Theses parameters are: consumption of nitric acid and ammonium bifluoride, the temperature with magnetic stirring bar and liquid/solid ratio. Initially, we vary the quantity of nitric acid, we noticed that for a quantity of 280 kg/ton of nitric acid, coloring and feldspar is remarkable that the iron oxide was reduced rate 0.06%. In a second step, we varied the ammonium bifluoride in consumption, the rate of iron oxide is reduced to 0.04%. This result shows already good feldspar that does not require to further purification except for special cases such as enameling high quality or manufacture of glassware. To achieve a concentration of 0.06% iron oxide, it will be necessary to use 40 kg/ton and ammonium bifluoride and 280 Kg/ton of nitric acid without prior purification. For a feldspar processed by high intensity magnetic separation to achieve iron oxide residual content equivalent to (0.06%), the consumption of the same reagents are reduced up to 100 kg/ton of acid and 20kg /ton of ammonium bifluoride. The optimum treatment conditions found above are applied to the different size fractions previously treated by magnetic separation at high intensity. Subsequently, we applied the same conditions to the same size fractions purified by magnetic separation followed by flotation. We noticed that the effect of flotation resulted in a gain of the iron oxide content down 0.05%.

3 CONCLUSION

As part of this work, to achieve the optimal conditions of ain barbar feldspar chemical purification requirements, using nitric acid in the presence of ammonium bifluoride as the reducing, we preferred to review the all tests results for characterization and recovery achieved in the past. This allowed us to compare a number of results and extricate conclusions for the development of the project. All chemical analyzes on all-comers or size fractions represent a panoply of iron oxides content, they give of a certain homogeneity in the sense that the majority are between 0.6- .7%. The origin of the iron oxide pollution comes largely from surface oxidation and water seeping into cracks veins. Feldspar is very homogeneous in terms alkaline oxide, silica and free silica. In conclusion, mainly potassium feldspar with 9% of K2O and 0.25% of Na2O, 12% Al2O3, 75% SiO2 and 0.59 to 0.7% Fe2O3, is part of very average feldspars. Improved quality requires high intensity magnetic epuration and free silica reduction achieved only by flotation. Purification of size fractions [-0.6 + 0.1] mm [-0.6 + 0.250] mm

[-0250 + 0.1] mm by high intensity magnetic separation, lowers the amount of iron oxide Fe2O3 until 0.34% with weight yields compared to all comers respectively 41.26%, 19.30% and 23.06%. As against the size fraction [-0.8 + 0.1] mm used by the glass industry, the rate of reduced iron is 0.39% with a weight of 60.89% yield. This purification yielded unsatisfactory results, the use of flotation purification of these same size fractions decreased the rate of iron oxides from 0.39% to 0.23 for [-0.8+ 0.1] mm and 0.34 to 0.20% for [-0.6 + 0.1] mm with a weight of 54.63% 38.40% yield respectively compared to all comers. These levels 0.20% and 0.23% iron oxide are appreciated by the glass and ceramics industry. For size fractions [- 0.6 + 0.250] mm, [-0250 +0.1] mm and [-0.1] mm, purification by flotation, pushes downward the iron oxide content of 0.34% to 0.30% only, does not meet the requirements of consumers. The application of hydrometallurgical process, excluding the effect of pressure in an autoclave and using sulfuric acid yielded poor results in the experimental conditions. The process using nitric acid in a reducing medium (HFNH4F) is effective and pushes the degree of removal of

Fe2O3 around 0.01%. This process applied to the glass-blower size fractions [-0.8 + 0.1] mm previously ironed by High Intensity a magnetic field reduces iron levels up to 0.054% with a weight of 58.32% compared to those all comers.

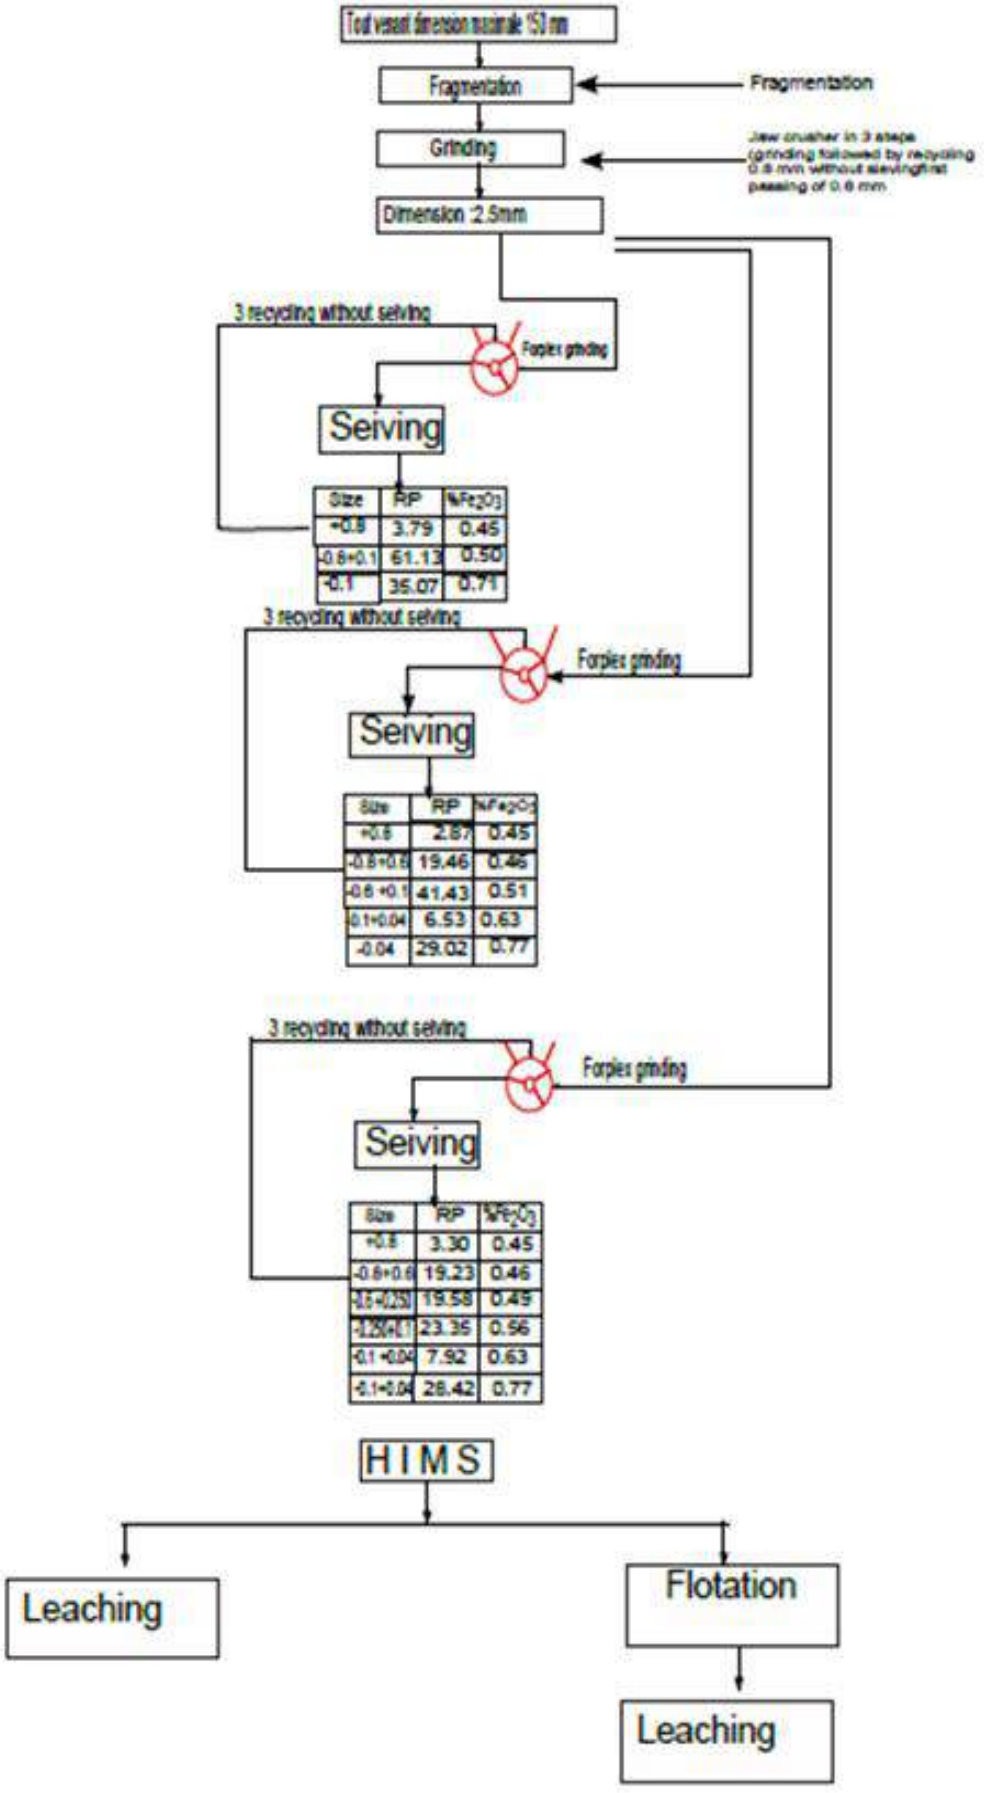

Figure 7. Grinding scheme

Effect of Calcination on the Grindability of Concentrated Phosphate of Djebel Onk Algeria

A. Bouzenzana
Laboratory of Mining, University of Tébessa. Faculty of Science and Technology, Department of Mining Engineering

ABSTRACT Grinding is a process essential for the preparation, is subjected to phosphate during treatment and especially their transformation. This is a very expensive operation because of its high energy consumption which is characterized by the grindability index « index Hardgrove and Bond »

The purpose of this study was to characterize different types of concentrated phosphate and determine their behavior during grinding (calculating indices Hardgrove and Bond) and compare them with other phosphates across the world

Keywords: concentrated phosphate, calcination, Grindability, Hardgove and Bond Indexes

1 INTRODUCTION:

The Djebel-Onk deposit is located in North-West of Algerian Sahara specifically in the East of mountains of Nememcha, 20 km from the Algerian-Tunisian boundaries.

The deposit belongs to Tahitian formation, which characterized by the appearance of the first substantial deposit of phosphate but it is highly clay strata succeed to its black marl and main phosphate deposition which is approximately 30 m deep with carbonated natural formation.

The total geological reserves of ore at our deposit are 317 Mt (P_2O_5 = 26.53% and MgO=2.16%). (FERPHOS)

The actually flow-sheet of Djebel-Onk is argued by the following two properties:

-*Texture (1st property):* The phosphate is formed by ooliths (grains) adjacent to 0.5 mm. Chemical analyzes of different tranches show that our phosphate is rich between 0.08 and 0.8 mm, the fragmentation and classification of this tranche with dry process gives us a concentrated phosphate (62% in TPL) approximately 28.5% of P_2O_5.

-*Structure (2nd property):* Phosphate contains a carbonate gangue. A simple calcination at 900 to 950 °C reduces dolomite, magnesite, calcite and lime. The latter can be eliminated from the rich ore hydrometallurgical treatment after extinguishing in water, by this way and according to the demand of costumers, we can obtain two types of concentrated phosphate; (69 -72%in TPL and 73-75% TPL. (FERPHOS DOCUMENT)

1.2 Utilization of Phosphates

The fertilizer industry consumes about 90 % of phosphates world production (sulfuric acid, simple superphosphate (SSP), phosphoric acid, triple superphosphate (TSP), ammonium phosphate and NPK). Phosphate is also used in the fine industrial, to produce the animal feed supplements and foodstuffs.

Another important use is the production of elemental phosphorous and its derivatives particularly sodium tripolyphosphate, and the important component of the bleaching strong detergents.

For their transformations and their commercialization, phosphates must be a high content in P_2O_5 and have a low cost to their grinding (energy consumption)

The Grindability testes on different samples by different methods, show that if the phosphate is rich in P_2O_5, energy consumption of grinding will be high , this consumption shows that if the enrichment method by calcination gives a very rich ore

nevertheless energy consumption is very high

For the transformation of phosphates into phosphoric acid we use the pushed grinding until the complete liberation of constituent.

The grinding costs represent a big expense for the treatment process [2]; they can reach more than 50% of treatment energizing costs. [THE CEMENT GRINDING OFFICE]

1.3 Production Process of Phosphoric Acid

The production process of phosphoric acid is obtained by the direct attack of phosphate with utilization of sulphuric acid.

The three main phases include:

- *Grinding*

Grinding of raw phosphate is designed to increase the attack surface of the mineral by sulfuric acid.

- *The attack filtration*

Grinded phosphate is attacked by concentrated sulphuric acid 98.5% and medium phosphoric acid (18-22% P_2O_5) in aqueous milieus, this mixture gives porridge.

The filtration of this porridge (goop) consists to separate phosphoric acid 29% in P_2O_5 of phosphogypsum via a rotary filter. The product is stored in decanting ferries.

- *Concentration*

The concentration objective of acid phosphoric is to allow the water evaporation to obtain an acid pulling 54% in P_2O_5.

1.4 Grinding Operation

Grinding of phosphate is one of the decisive steps in the process of acid phosphoric production, because in this level the consumption of energy reaches its maximum. Grinding of phosphate is one of the decisive stages of the manufacturing process of phosphoric acid because this energy reaches its maximum consumption level.

Grinding objective is to increase the attack surface of ore, the chemical reaction is especially easy than the surface offered the reactive is large; for this reason, the grinding is an operation that presents a particular importance in fact:

- An insufficient grinding, driven to a very difficult attack, a very elevated reaction time, and a lower efficiency.

- An over grinded of phosphate driven in contrary to the elevated decomposition degree, which drives to increase the temperature and to obtain a stable semi-hydrated phosphate.

The grinding could be optimized by good acquaintance of the spatial distribution of the phosphates Hardgrove.

In order, to increase the energizing efficiency and to avoid the over-grinding, we eliminates since the grinder's exit the sufficient fineness of grains. [BOUCHAIS S]

1.5 Balls Grinder

The grinder's choice to cannonballs must authorize to reach fineness in the order of millimeters to a few score of micrometers.

The balls grinder choice must authorize to reach fineness in the order of a few millimeters to some tens of micrometers. The grinder represents a very heavy investment; his operative cost is very elevated, either by the usury of its pieces or by its consumption in energy.

1.6 Grinding Energy Law

The performances of grinding installation depend between physical and mechanical characteristics of the product to grind. The determination of some physical properties of materials to grind permits a judicious choice of fragmentation devices and gives us an idea on the energizing consumption and the costs of the grinding operation for a given substance.

These properties are characterized by the fragility (friability) of Grindability Index and Bond energy Index

1.6.1 Bond energizing index

➢ Bond energizing Index: or grinding Index, Wi of material is defined as the consumed energy in kwh/t to obtain the total reduction of this material, since a theoretically infinite

initial dimension, until 80% passing through a sieve of 100 µm

- It may be calculated from any wet grinding by the relation:

$$W = Wi\ (10/\sqrt{P} - 10/\sqrt{F})$$

Where:

W: net energy consumption in kWh/t
Wi: Bond Index (in imperial or metric units of measure)
P: the passing size of 80% of the product grinds in µm.
F: the passing size of 80% of the diet in µm.

This test is a Hardgrove test performed in a standard ball grinder. It can be performed at the openings of meshes ranging from 28 to 40 meshes. The normal finish size is 100 meshes.

Table 1. Multiplier Coefficient of W for special cases

Coefficient multiplier of w for particular cases		
General case of Formula application	Particular case	Multiplier Coefficient
Wet grinding	Dry Grinding	1.3
Ø of grinder ≈ 2.45 m	Ø of grinder ≠ 2.45 m	$(2.45/\ Ø)^{0.2}$
Fragmentation report I= da/dp ≥ 4	i≤4	$\frac{i - 1,2}{i - 1.35}$
Closed circuit	Open circuit with passing through a sieve of 100 µm	
	50 %	1.035
	60 %	1.05
	70 %.	1.10
	80 %	1.20
	90 %	1.40
	95 %.	1.57
	98 %	1.70

1.6.2 Friability grindability index

This measure is based on the Rittinger law, which expresses an evaluation of the necessary energy E for grinding can be obtained by writing that the value of this energy is proportional to the difference between the specific surfaces of the grains before and after grinding.

$$E = K(S_f - S_i)$$

With;
S_f and S_i: initial and final specific grain surfaces
K: Constant energy that must be spends to make appear a new surface unit which depends on the nature of the material and the mode of fragmentation.

The objective of this method was to measure empirically the relative difficulty of coal to get the grain-size requisite for a complete combustion inside a home of furnace to pulverized coal. Thereafter, the use of Hargrove Grindability test (Index) (HGI) has been extended to other materials.

1.6.2.1 Procedure

A sample of 50 g was introduced into a ball grinder with fixed vertical grinding track.

Eight balls are placed above the material and the ring that the united pressure of a rotating shaft is disposed above the balls .the grinder makes 60 rotations.

The grinded material is sifted through a cell of 0.074 mm (200 meshes), the mass of passing (m) in grams, permit to determine Hardgrove Grindability Index (HGI) by the equation:

$$HGI = 13 + 6.93\ m$$

m: mass of the product passing through the sieve 0.074 mm (g).
For the transformation of the HGI Index into Bond Index we use the following formulas;

$$Wi = \frac{88}{HGI^{0,5}}$$ (Proposed by Bond, 1951)

$$Wi = \frac{435}{HGI^{0,91}}$$ (Modified by Bond, 1961)

In 1971, the Hardgrove Grindability Index was calculated with the ASTM norm using a linear equation. It has been prepared using quarter's standard samples of coal imported form the company in which the respective Index of Hardgrove (HGI) are: 43, 61, 80 and 103,

The weight Determination of passers at 74 microns after grinding, allows calibrating the experimented material with ASTM norms. [THE CEMENT GRINDING OFFICE,]

Table 2. HGI Values

Grindability Index (HGI)	Passing weight (m) at 74μm
43	4.89
61	7.04
80	9.52
103	13.05

- Linear equation:

HGI = f(P) is HGI = 8.13+ 7.35m

1.6.2.2 The used Grinder

- Type of grinder: ball grinder
- Rotation speed: 70 tr/min
- Engine power: 1.5 Kw / 380 V
- Ø of balls: (≈ 50 mm)
- Ø of Drum: 200 mm

2.3 Grains-Sizes Characteristics of the Three Concentrated Phosphate

The grains- sizes characteristics are represented in figure 1, 2 and 3:

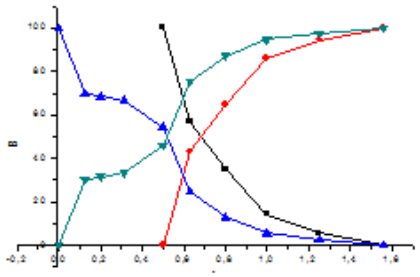

Figure 1.Grains- size characteristics of concentrated phosphate at 66-69% in TPL

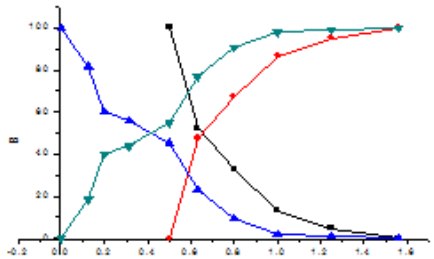

Figure 2.Grains -size characteristics of concentrated phosphate at 69-72% in TPL

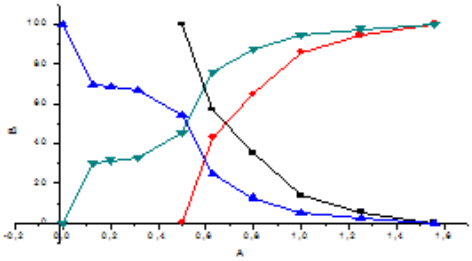

Figure 3.Grain-size characteristics of concentrated phosphate at 73-75% in TPL

Σγ↓% prior to grinding
Σγ↑% after to grinding
Σγ↑%
Σγ↑%

2.4XRD Analysis of Concentrated Phosphate

The XRD Analysis of concentrated phosphate is presented in figure 4, 5 and 6.

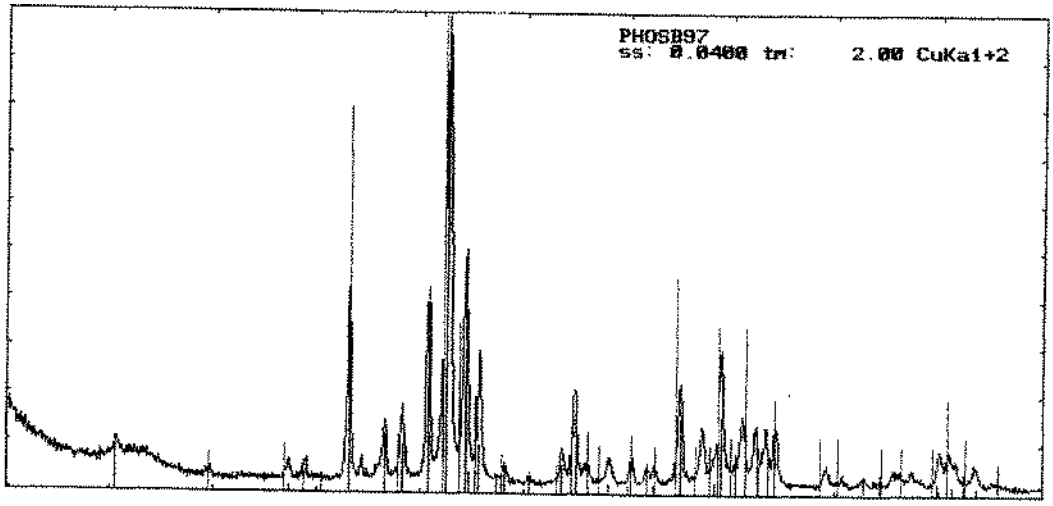

Figure 4. XRD of concentrated phosphate at 66-68% in TPL

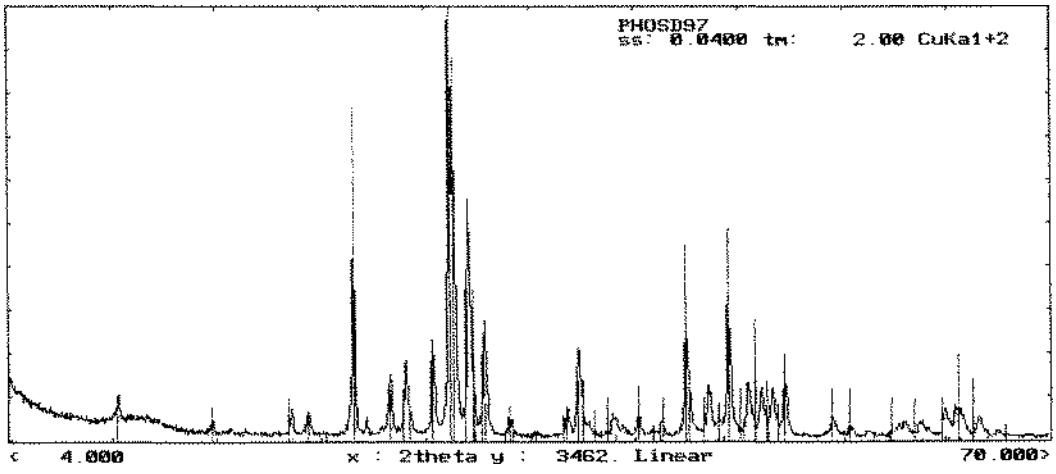

Figure 5. XRD of concentrated phosphate at 69 - 72% in TPL.

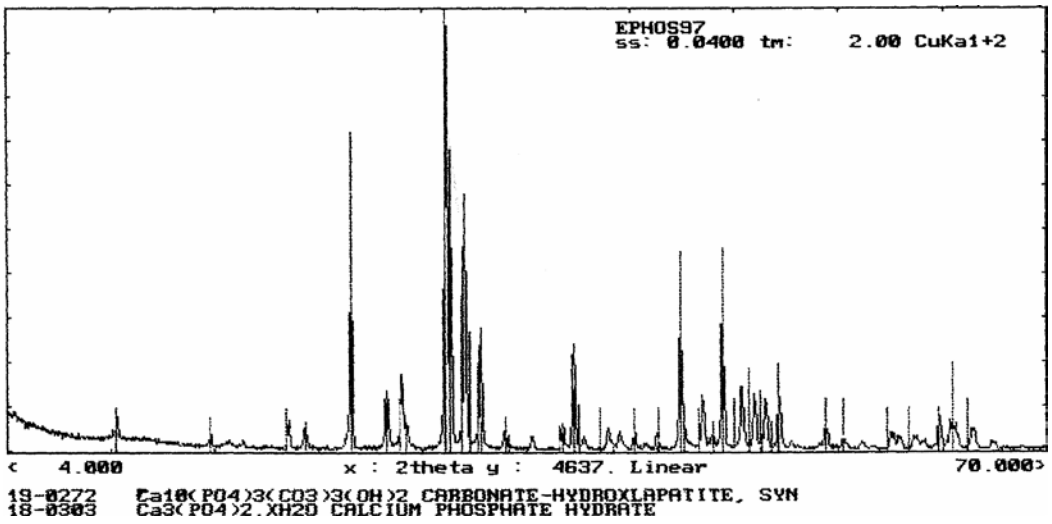

Figure 6. XRD of concentrated phosphate at 73 - 75% in TPL.

According to the peaks and the corresponding wavelengths in XRD patterns, we see that for phosphates:

- Concentrated at 66-68% and 69-72% in TPL Contain:
  - Magnesium carbonates (dolomite): Ca Mg $(CO_3)_2$.
  - Hydrated calcium phosphate: $Ca_3 (PO_4)_2$.
  - Carbonated hydroxyapatite: $Ca_{10} (PO_4)_3 (CO_3) 3 (OH)_2$.
- Concentrated at 73-75 % in TPL
-
  - Absence of magnesium carbonates: The absence of dolomite is due to the calcination and washing causing;
  - Enrichment of phosphates with increase of the content in TPL
  - The thermal destruction of carbonates (dolomite, calcite and magnesite), according to the reactions;

$$Ca\ Mg\ (CO_3)_2 \longrightarrow CaCO_3 + Mg\ CO_3$$
$$CaCO_3 \longrightarrow CaO + CO_2$$
$$Mg\ CO_3 \longrightarrow MgO + CO_2$$

After washing, we obtain:

$$MgO + H_2O \longrightarrow Mg\ (OH)_2$$
$$CaO + H_2O \longrightarrow Ca\ (OH)_2$$

3 CALCULATION

3.1 Calculation Formula

- ❖ Friability Grindability Index HGI = 8.13 + 7.35 m
- ❖ Bond Index $Wi = \frac{435}{HGI^{0,91}}$
- ❖ Multiplier of w for special cases
- Open Circuit: 80% passing (multiplier = 1.2)
- Ø of drum: 200 mm ($(2.45/ Ø)^{0.2}$ = 1.65)
- Dry Grinding (multiplier = 1)

Table 7. Values of HGI and Wi

Concentrated	Weight of passing at 74 µm(g)	HGI Index	Wi (KWh/t)	Wi (corrected) (KWh/t)
66 - 68 % in TPL	10.02	81.78	7.90	20.33
69 - 72 % in TPL	8.68	71.93	8.88	22.85
73 - 75 % in TPL	5.24	46.64	13.18	33.91

3.2 HGI Index Comparison Of Concentrated Phosphate With Other Indexes Around The World

Table 8. Values of HGI and Wi of phosphates around the world

Concentrated phosphate	HGI	Wi
Florida USA	49	12.6
Youssoufia (66/68% in TPL) Morocco	49	12.6
Phosphate of Togo	80	8.1
KalaaDjardaTunisie	81	8
Khouribga 75 Marocco	92	7.1
MoularesRedeyefTunisie	96	6.9
M'DillaTunisia	96	6.9
Khouribga 72 Morocco	100	6.6
M'Rata Tunisia	113	5.6

3.3 Usual HGI Values of Some Materials

Table 9. Values of HGI of some materials [4]

Materials	HGI
Clay	97
Clinker	30-50
Anthracite	30-50
Bituminous coal	45-85
Feldspar	45
Iron ore	38
Sand (Quartz)	25-55
Lime	105
Calcite	54 - 78
Iron oxide	57
Manganese	45-65

4 CONCLUSION

According to the results obtained we remark that more phosphate is richer, the grinding resistance is increased.

The phosphates of Djebel-Onk are composed of apatite that represents the useful mineral with gangue constituted mainly of carbonate (Calcite, dolomite, Quartz...etc.). All these materials cause a heavy resistance to the grinding according to the table 9 such as the quartz, that is very hard and the clays that promote the agglomeration of phosphate ooliths.

We remark that our phosphates which has been calcined at high temperature (concentrated 73-75% in TPL)show the Grindability more increased than that those of which the calcination temperature is lower (concentrated 69-72% in TPL) or cleaned phosphate (concentrated 66 - 68% in TPL).

The Grindability tests show that if phosphate has a high content in P_2O_5, the energy consumption of grinding will be big.

This observation shows that if the calcination permits to give a very rich phosphate, she participates at the same time to make the grinding more difficult.

From the results obtained after that we see for the Algerians concentrated energitiques and grindability index have average values compared to other concentrates around the world

The values types of induced HGI are consisted between 30 (increased resistance to

the pulverization) and 100 (pulverized more easily).

A. Refahi
Department of Mining Engineering, Zanjan University, Zanjan, Iran

ABSTRACT Material comminution by crushers and mills is an essential stage in mineral processing. Because of low energy consuming in crushers in competition with mills, it is better to crush materials by crushers as far as possible. Particle size distribution in any stages of comminution is one of the most important issues, but takes a lot of time and cost. Therefore, numerical simulating for predicting of product particle size distribution can be useful. PFC3D that is a three-dimensional particle flow code software that models the movement and interaction of particles by the discrete element method (DEM) techniques was employed to simulate the particle movement and to product size distribution of jaw crusher.

In this paper, single spherical and cubic shape specimens were simulated in crushing process between two rigid jaws, after simulating jaw crusher, the sieving process was simulated and particle size distribution of product was predicted. For validating the results of simulation, they were compared with the experimental sieving tests. Particle size distribution plots of both approaches had fairly good accordance.

Keywords: Particle size distribution, jaw crusher, discrete element modelling

1 INTRODUCTION

The size reduction of brittle materials is the most essential mechanical operation within the raw material processing, i.e. mining, industry. The size reduction performs in crushing and grinding stages. Crushing is usually a dry process, and is performed in several stages, Particle size distribution in any stages is one of the most important issues, but takes a lot of time and cost. Therefore, numerical simulating for predicting of product particle size distribution can be useful.

Many researches have been done for predicting of product particle size distribution. In previous works size distribution often was determined for mill product and they used numerical methods for this purpose. The discrete element method (DEM) has been adopted by many researchers as a tool for simulating and understanding comminution devices and was employed in the present work to study the particle breakage within the jaw crushers.

The DEM has been used to model many industrial applications over the past decade and was first proposed by Cundall and Strack (1979) to model the behavior of soil particles subject to dynamic loading conditions. Mishra (1991) pioneered the application of DEM in mineral processing and modelled grinding mills.

Mishra (1991) by using the 2Dmill code predicted the size distribution of mill product from the knowledge of energy distribution inside the charge, breakage behavior of the particles, and the transport properties of the charge. Djordjevic et al (2003) modelled two types of impact crushers: the vertical- and horizontal-shaft impact crusher. They calculated the distribution of collision energies was then converted into a product size distribution for a particular ore type using JKMRC impact

breakage test data. Moreover other methods has been used, Donovan (2003) used fracture toughness and develops models for the prediction of power consumption, breakage function/product size, and volumetric capacity have been developed based on fracture toughness experimental result.

Refahi et al (2007, 2009) Used rock mechanical properties to predict the Bond crushing index and compared bond crushing energy and fracture energy. Refahi et al (2010) was applied DEM to model the fracture behavior of a single spherical and cubic rock in a laboratory jaw crusher. In this study we used that model of jaw crusher.

This article presents a numerical model based on the discrete element method to describe crushing and sieving process. Because of the discontinuous nature of rocks, a distinct element code, PFC, developed by Itasca Consulting Group, Inc. was used for this purpose. PFC3D represents a model as an assemblage of spheres bonded together by parallel bonds. In this paper, the modelling steps will be described first. Then the numerical Results of product size distribution will be compared to the experimental measurements. The goal of this research is to use both numerical modelling and laboratory product size distribution to compare and show if numerical modelling can be used for predicting product size distribution.

2 MATERIALS AND METHODS

In this work, crushing and sieving process for two rock types with different mechanical properties, limestone and granite, were simulated, and the results were verified by comparison with the experimental data. Rock blocks were obtained from mine transmitted to the laboratory and where samples prepared by coring and cylindrical cores were prepared at the laboratory. Uniaxial compressive tests were conducted on cylindrical samples. The mechanical properties (elasticity modulus, uniaxial compressive strength) were experimentally evaluated. For this purpose a standard compression test was carried out on ten cylindrical specimens with 54 mm in diameter and 135 mm in height. To measure the modulus of elasticity, five strain gauges were used in the compression test. The dry density of the limestone and granite was estimated by the saturation and caliper technique, which was defined by the International Society for Rock Mechanics (ISRM). The obtained mechanical properties of the rocks studied are shown in Table 1.

Table 1. Mechanical properties of the rocks

Rocks	**Uniaxial compressive strength (MPa)**	**Elasticity modulus (GPa)**	**Density (tonne/m3)**
granite	49	104	2.52
limestone	30	35	2.40

From Table 1 it is seen that the strength and the elasticity modulus of limestone, which were determined from the simulated uniaxial compression test, are 30 MPa and 35 GPa, respectively and for granite are 49 MPa and 104 GPa, respectively.

Single cubic specimen with 5 cm in length and single spherical specimen with 6 cm diameter of limestone and granite were prepared. A laboratory jaw crusher was then used to crush the specimens. After sieving the jaw crusher product, Size distribution curves of the products emerging out of the crusher are determined that are shown in Figure 1

The curves demonstrate that the size distribution of the material in the product is independent of the size distribution in the feed and is primarily a function of the setting of the crusher and to a lesser extent of the nature of the material that is crushed (king, 2000). From Figure 1 the d_{80} is seen to be approximately 16.5 mm.

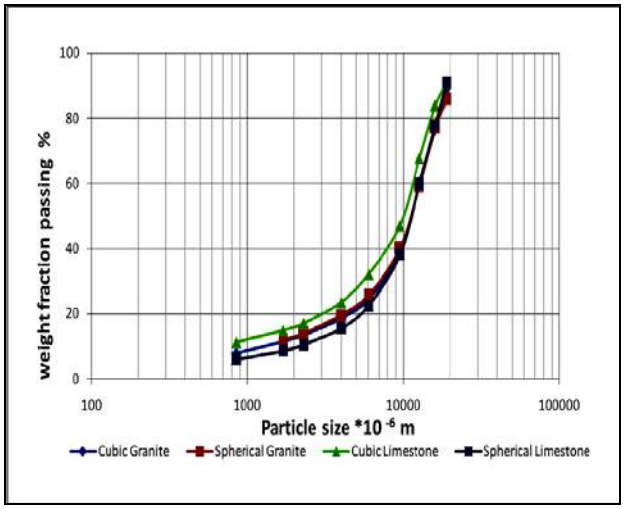

Figure 1. Size distribution of crushed products coming out of the jaw crusher for limestone and granite specimens

3 THE MODELLING STEPS

PFC3D Version 3.00 in which the particles are spheres was used to simulate these tests in the computer. The simulation process for predicting size distribution of jaw crusher product has been developed in several steps, each step being described in the following sections.

3.1 Conversion of Macro to Micro Properties

The input properties (such as modulus and strength) can be derived directly from measurements performed on laboratory specimens. PFC synthesizes macro-scale material behavior from the interactions of micro scale components, the input properties of the microscopic constituents are usually not known. In this case, we must first determine the relevant behaviors (and response set that best characterizes these behaviors) of our intended physical material, and then choose the appropriate microproperties by means of a calibration process in which the responses of the synthetic material are compared directly with the relevant measured responses of the intended material. On the other hand an inverse modelling method is used to determine the correct micro-mechanical properties of the numerical models from the macro-mechanical properties of the rock obtained during laboratory testing. This was performed by comparing simulated uniaxial compression test by PFC3D and laboratory tests. The Young's modulus, peak load and the fracture mode were matched to that obtained in the laboratory using the micro-mechanical modeling. (Itasca 1999) Also according to the properties of parallel and contact bonds, the parallel bond could completely nominate the feature of rock materials. The strength and the elasticity modulus of limestone and granite, which were determined from the simulated uniaxial compression test, are shown in Table 2.

Table 2. Mechanical properties of the rocks obtained from PFC3D model.

Rocks	Uniaxial compressive strength (MPa)	Elasticity modulus (GPa)
granite	106.60	49.20
limestone	30.20	35.10

Table 3 gives the micromechanical properties and bond strengths of limestone and granite, which are determined by simulating the uniaxial compaction test.

Table 3. Micromechanical properties of particles and bond strengths used for modelling studied rocks (determined from simulated uniaxial compression test by PFC3D

Micromechanical properties	granite	limestone
Ball density (kg/m3)	2520	2400
Ball-ball contact modulus (GPa)	65	44
Ball stiffness ratio	2	2.525
Parallel-bond modulus (GPa)	65	44
Parallel-bond stiffness ratio	0.65	0.70
Ball friction coefficient	2	2.525
Parallel-bond normal strength (MPa)	135	48
Parallel-bond shear strength(MPa)	135	48

3.2 Modelling of Rock

To achieve the cubic and spherical specimen each of limestone and granite such as ones used in laboratory test were modelled. For the purpose of modelling, a cubic specimen of 5 cm in height and a spherical specimen of 6 cm in diameter were prepared from two rock types that were studied. The model is made up of approximately 3000–4000 randomly placed particles ranging in size from 1.5 to 3 mm (see Figure 2).

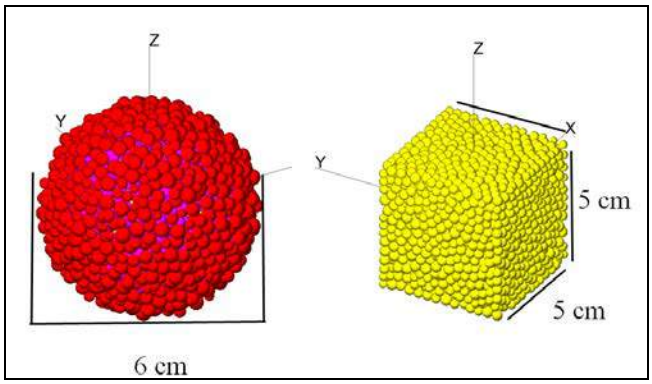

Figure 2. Models of spherical and cubic rocks studied displayed by PFC3D software

3.3 Modelling of Jaw Crusher

A laboratory jaw crusher was modelled using the PFC3D (Refahi et al, 2009). This model is based on single macroparticle simulation in a crusher, and multi-body interactions are ignored. The crushing process for a single cubic and/or a single spherical specimen in the jaw crusher is simulated using the PFC3D model. The jaw crusher has two plates (jaws), one of them is fixed and the other, swinging open and closed, trapping and crushing material between the two surfaces. The feeding entrance is 10 cm wide, and its maximum discharge aperture is 2.5 cm (open status). The minimum open space between the jaws during the crushing cycle is 17 mm (closed status). The rotational speed of the moving jaw is almost 300 rpm. The jaw surface is corrugated; the height and width of a corrugation is 0.5 cm (see Figure 3).

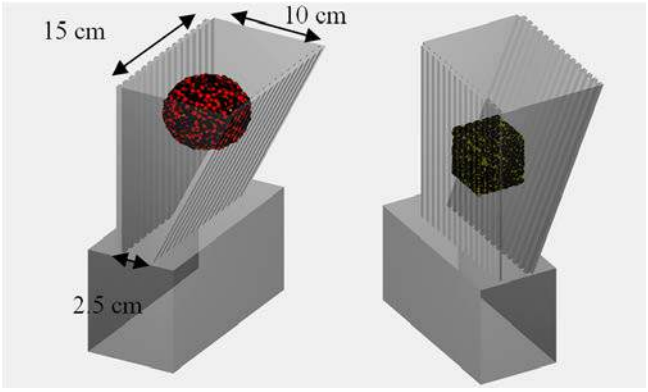

Figure 3. PFC3D model of a) a cubic and b) a spherical specimen between two rigid jaws (the black spots show parallel bonds).

3.4 Modelling of Sieving Process

In PFC3D by using walls and balls, materials and other shapes can be built. In order to build sieve using wall, one should use four coordinates and stiffness properties of walls. Table 4 show comparison between Geometrical parameters of sieves used in laboratory and simulation.

Table 4.comparison between Geometrical parameters of sieves used in laboratory and simulation

Rocks	**cross Section**	**Height (cm)**	**area (cm^2)**	**Diameter (or length) Of cross Section (cm)**
laboratory	Spherical	5	176.7	15
simulated	Cubic	5	170	13

As in Table 4 the sieves simulated are square and the sieves used in lab are gyrate, as the shape of sieves has a little effect on the result and also modelling of square sieves is easier it is acceptable to use square section sieves in instead of gyrate ones for modeling purpose. In order to model the wires of sieves one should be used perpendicular walls with different thickness. The diameter of wires was selected according to ASTM standards. When the shapes of sieves are ready then they should be vibrated. In order to vibrate the sieves define a velocity in special directives (x and

z direction).The sieves is oscillated upwards and to two side(x and z direction) with a frequency of 2 Hz, a amplitude of 10 mm, and a sideways amplitude of 8 mm. As sieves moves upwards, smaller particles move freely through the holes. The total number of sieves is 9. It should be noted that the smallest ball radius is 1.5 mm, so sieves with openings smaller than 3 mm is avoided. The sieve with openings equal to 2.8 mm acts as a pan (see Figure 4).

3.5 Calculation of the Cumulative Percentage of Material Passing

After the screening of crushed material (the material was crushed using jaw crusher). It is essential to measure the weight of materials on each fraction, first the volume of balls should be calculated (material is modelling using balls with different radius) and sum of these volumes is the total volume of crushed material in each fraction. It should be noted that the density of balls is equal, so by using volumes of ball in each fraction and total volumes of balls be calculated. After this by using the cumulative percentage of material passing, d_{80} can be calculated.

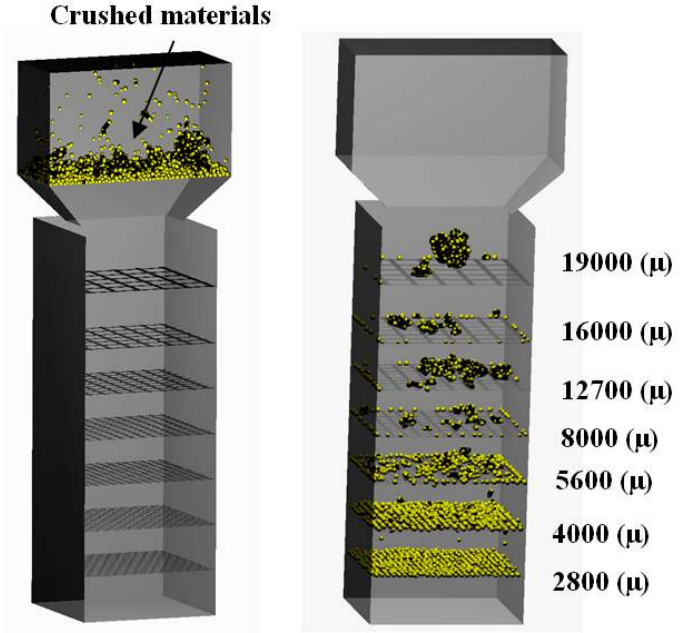

Figure 4.PFC3D model of sieving process a) before sieving b) after sieving

4 RESULTS AND DISCUSSION

Simulations are conducted for granite and limestone specimens and Figure 5 & Figure 6 show the distribution curves obtained from experiment and simulation for the two rock types studied in two modes (spherical, cube). The results of the simulation match the experimental results acceptably, especially for spherical shaped. d_{80} for both experimental and modelling results were almost similar(see Table 5). It is necessary to noted that because of limits of computers capability the radius of particles cannot be decreased. As the number of particles increases, the resolution, which is defined as the number of particles across the model diameter will be greater. Thus, greater the number of particles, the better the resolution and hence better results are expected to be obtained. However, with the Increase in the number of particles, there is increase in the computation time. (Mitra, 2006)

Table 5. Comparison between d_{80} result from DEM and laboratory

Specimen	Spherical granite	Cubic granite	Spherical limestone	Cubic limestone
d_{80} simulation(µ)	16900	16800	16700	16400
d_{80} laboratory(µ)	16700	15900	16400	15700

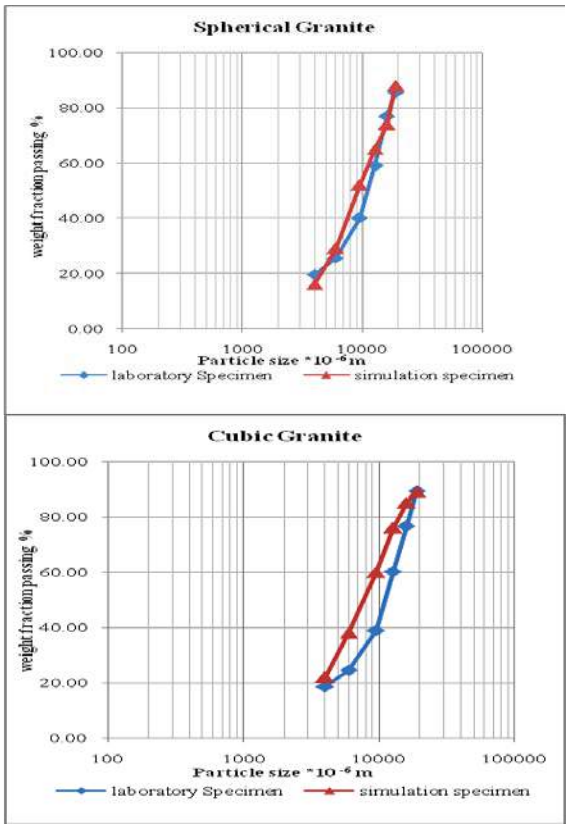

Figure 5.Comparison between Size distributions of crushed products coming out of the jaw crusher and simulation for granite specimens

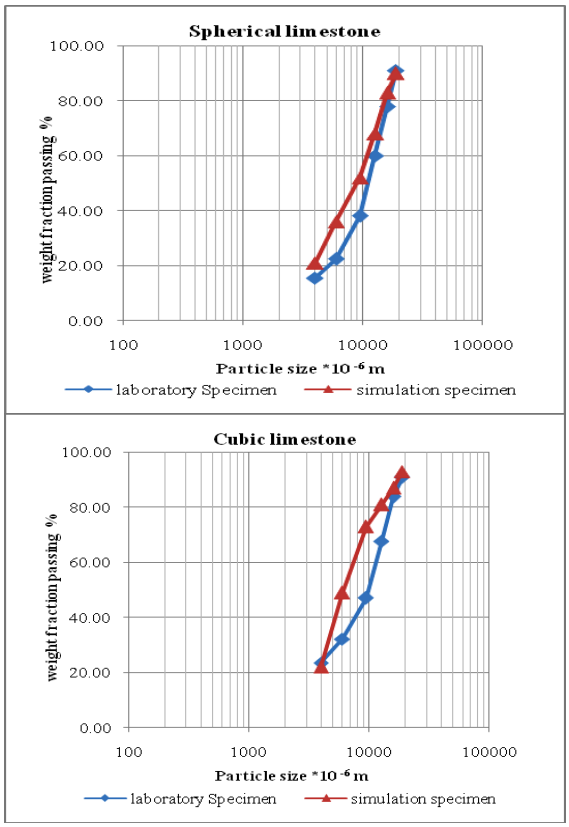

Figure 6.Comparison between Size distributions of crushed products coming out of the jaw crusher and simulation for limestone specimens

5 CONCLUSION

A PFC3D model within the framework of the discrete element method has used to simulate sieving process of jaw crusher product. In order to confirm the modelling results, Laboratory test has performed. Particle size distribution of crushed products coming out of the jaw crusher for granites and limestone specimens in laboratory showed that product size distribution of jaw crusher is independent from shape of feeds and the nature of material is lesser effect on particle size distribution. Comparing the results of simulating and the experimental sieving tests showed the particle size distribution plots of both approaches have good accordance, especially for spherical shape specimens. The increase in computer power can enable the creation specimens with greater the number of particles and make the use of discontinue models to simulate rock behavior more feasible. The ability of DEM to simulate sieves demonstrates this method has potential for use as a design tool for such equipment in mineral processing.

Examination of Albanian Chromite Ores In Terms of Liberation Size and Ratio Problem

Arnavutluk Krom Cevherlerinin Tane Serbestleşmesi ve Rasyo Sorunu Acısından İncelenmesi

H. Bastürkcü, B. Aydin, M. Özer, A.E. Yüce
Istanbul Teknik Üniversitesi Cevher Hazirlama Mühendisligi Bölümü

ÖZET Krom cevherlerinin gravite yöntemleriyle zenginleştirilmesinde temel yaklaşım, olabildiğince iri boyutlarda konsantre ürünler alabilmektir. Bazı cevher türleri iri boyutlarda zenginleştirilebilirken bazı cevherlerde çok ince boyutlara kadar öğütme gerekli olabilmektedir. Diğer yandan elde edilen krom konsantrelerinin rasyo değerleri de satış koşulları için önemli bir parametredir. Bu araştırma kapsamında Arnavutluk'tan ayrı bölgelerden alınan iki cevher numunesinin zenginleştirilme özellikleri incelenmiştir. KJM kodlu cevherde, iri boyutlarda (-25+1 mm) jig ile; ince boyutlarda ise (-1 mm) sarsıntılı masa ile satılabilir nitelikli konsantrelerin elde edilebileceği belirlenmiştir. Bu cevherlerden elde edilen konsantrelerin rasyo değeri ise 2,5 civarındandır. KM kodlu cevher ancak 0,6 mm'nin altında yeterli serbestleşme derecesine ulaşabilmektedir. Bu nedenle iri boyutlarda bir konsantre üretimi mümkün olmamıştır. Bu cevherlerden elde edilen konsantrelerin rasyo değerleri ise 2,18-2,41 arasında değişmektedir. Yapılan incelemelerde, çok ince boyutlara kadar öğütülmüş olmasına ragmen kromit tanelerinin yapısında çok ince dağılımlı manyetit bulunmuştur. Bu araştırma kapsamında; elde edilen sonuçlara göre her iki cevhere ait en uygun zenginleştirme koşulları belirlenerek proses akım şemaları oluşturulmuştur.

Anahtar Kelimeler: Rasyo sorunu, serbestleşme, kromit, akım şeması

ABSTRACT In beneficiation of chromite ores using gravity methods, the basic approach is to obtain concentrates with coarse sizes as long as possible. While some type of ores respond to this approach, some type of the ores needs very fine grinding. On the other hand, ratio values have importance in determining the quality of the marketable product. In this study, beneficiation properties and ratio values of two different chromite ores taken from Albania were investigated. On the KJM coded sample, jig tests (-25+1 mm) and shaking table tests (-1 mm) were performed. The ratio of the concentrate was determined as nearly 2.5. Besides, the liberation of the other sample – coded as KM – was provided below 0.6 mm. The concentrates of this sample had ratios varying from 2.18 to 2.41, since finely disseminated magnetite particles existed in chromite particles. In addition, magnetic separation tests were conducted in order to reduce the iron content. According to the optimized test results, appropriate process flow-sheets were established for both of the chromite samples.

Keywords: Ratio problem, liberation size, chromite, flow chart

1 INTRODUCTION

Chromium is one of the indispensable element and a raw material for steel industry. Different grades of ferrochrome are produced from the chromite ores by using metallurgical methods. While 90% of the chromite reserves is evaluated in ferrochrome production, 80% of ferrochrome is consumed in stainless steel industry (Murthy et al., 2011).

Depending on the deposit differences, different amounts of iron, aluminum, magnesium, and chromium exist in the

spinel structure of the mineral. During the formation of the mineralogical structure, iron is replaced by magnesium and aluminum resulting in higher Cr:Fe ratios in chromite. On the other hand, major gangue minerals can be pronounced as talc, quartz, hematite, goethite, limonite, gabbro, serpentine, anorthosite, dunite, and pyroxinite (Murthy et al., 2011).

Chromite ore is generally beneficiated using several methods, owing to the ore source and the end use requirements. Coarse clean ore is hand sorted, while the fine clean ore is subjected to gravity separation. Lumpy ore associated with host rock may require heavy medium separation. If chromite minerals occur in fine grains, then crushing, gravity separation and magnetic separation may be used (Papp, 1994).

It is difficult to obtain pure chromium, since it is contaminated by many other elements. Therefore, efforts have been made to produce cleaner chromite concentrates (Atalay and Ozbayoglu, 1992; Guney et al., 1992, 1994, 2009; Gul et al., 1995; Cicek et al., 2000; Yüce et al., 2003; Mohan et al., 2006; Önal et al., 2009).

Since a comparison cannot be made based on the effect of operating conditions alone, Pascoe et al. (2007) showed that it is possible to make a sensible selection of gravity separation in terms of the data obtained from particle size and the mineralogy of the ore.

In this study, beneficiation properties and ratio values of two different chromite ores taken from Albania were investigated. According to the optimum test results, appropriate process flow-sheets were established for both of the chromite samples

2 MATERIAL AND METHODS

The tests were performed on two different chromite samples taken from Albania. The disseminated chromite sample, which was suitable for shaking table tests, was coded as “KM”. While the other sample was coded as “KJM”, jig and shaking table tests were conducted on it.

The chemical analyses of both of the samples are given in Table 1. After the beneficiation tests, the concentrates were evaluated in mineralogical aspects.

Table 1. The Chemical Analyses of the Samples

Analyze	KJM, %	KM, %
Cr_2O_3	28.32	22.71
Fe	8.77	8.30
SiO_2	18.53	24.43
Al_2O_3	10.28	8.33
MgO	27.6	28.4
P	0.027	0.039
S	0.039	0.007
Ratio	2.21	1.87

3 RESULTS

3.1 Beneficiation Tests with KJM

3.1.1 Jig tests

The particle size of the sample was reduced below 25 mm and classified into size fractions such as (-25+19 mm, -19+13 mm, -13+9 mm, -9+6 mm, -6+3.36 mm, -3.36+1 mm) for the jig tests. Results obtained from different size fractions are given in Table 2, while combined and distributed results are shown in Table 3 and 4.

The jig tests provided a marketable concentrate containing 40.62% Cr_2O_3 with 53% of metal recovery. The next step was grinding the middling and tailings below 1 mm. The ground sample was combined with the -1 mm sample, which was classified before jig tests. The obtained sample was subjected to the shaking table tests.

3.1.2 Shaking table tests

The sample, which was obtained as middlings and -1 mm fraction from jigging process, ground and sized such as (-1+0.5 mm), (-0.5+0.212 mm), (-0.212+0.106 mm), and (-0.106 mm) and introduced to shaking table tests. Table 5 shows the results of shaking table tests in detail, while the combined and distributed test results are given in Table 6 and Table 7 respectively.

The results show that the particle liberation could be provided below 1 mm. In this way, a concentrate containing 48.58% Cr_2O_3 was obtained with 88% recovery.

When an evaluation in terms of a combined gravity separation processes including jig+shaking table, it was understood that final concentrate contents of 40.61% Cr_2O_3 and 48.58% Cr_2O_3 were achieved by using jig and shaking table, respectively. Besides, the chromite remained in the tailings was determined as 3.16%.

After application of the combined beneficiation process, 94.6% total efficiency was obtained as sum of 52.1% (using jig) and 42.5% (using shaking table). On the other hand, another important issue was considered as Cr:Fe ratio. Fe analyses were performed on the concentrates obtained from jigging and shaking table tests. The ratio values were determined as 2.67 and 2.59 respectively.

3.2 Beneficiation Tests with KM

3.2.1 Shaking Table Tests

The sample was prepared as -1 mm and classified into the size fractions of (-1+0.5 mm), (-0.5+0.212 mm), (-0.212+0.106 mm), and (-0.106 mm) for the tests. As it is possible to see the results in Table 10, the combined results are available in Table 11.

	Slime	10.5	10.93	4.9
	Feed	17.8	16.37	12.4
Total		100.0	23.53	100.0

According to the chemical analyses, a concentrate containing 48.97% Cr_2O_3 was obtained as 26.4% by weight. However,

when the contents of middling and tailings were considered, it can be concluded that particle liberation could not be provided with a particle size fraction at minus -1 mm. Therefore, it was decided to reduce the size fraction to -0.6 mm. The tests were carried out with the size fractions of (-0.600+0.300 mm), (-0.300+0.150 mm), and (-0.150 mm). The results of this group test were given in Table 12, 13 and 14

Table 11. Combined Shaking Table Test Results

Products	Weight, %	Cr_2O_3, %	Recv., %
Concentrate	26.4	49.97	55.1
Middling	44.1	19.60	36.7
Tailings	19.0	4.10	3.3
Slime	10.5	10.93	4.9
Feed	100.0	23.52	100.0

As result after distributing middling product, since it can be recycled in an operating plant, a concentrate of containing 48.90% Cr_2O_3 was obtained with 88.6% efficiency.

It was determined that the particle liberation was provided below 0.6 mm with the KM sample. When -0.6 mm sample was subjected to shaking table tests, marketable concentrate could be produced. In order to increase the efficiency of the process, as it was performed with the KJM sample, the middling could be recycled to the hydraulic classifier and beneficiated with shaking table in closed circuit.

3.3 Investigation of Magnetite Content and Ratio on the Concentrates and Middlings of the KM Sample

Some concentrates of the sample, whose particle size was reduced below 0.6 mm, was selected to determine their Fe content. In Table 15, Cr_2O_3, Fe and ratio values can be seen.

Table 15. Ratio Values of -0.6 mm Products

Size Fraction, mm	Product	Cr_2O_3, %	Fe, %	Ratio
-0.6+0.3	Conc. 1	51.41	14.62	2.41
	Conc. 3	44.42	13.43	2.26
-0.3+0.15	Conc. 1	53.63	15.39	2.38
	Conc. 4	49.33	14.73	2.29
	Conc. 5	44.61	13.99	2.18
-0.150	Conc. 3	50.55	15.88	2.18
	Conc. 5	34.52	12.81	1.84

Although the content of the concentrates reached up to 53% Cr_2O_3, ratio was found to be less than 2.38. Besides, it can be concluded that as Cr_2O_3 content increased, Fe content increased, too. These determinations can be explained in two ways:

- When the chromite concentrate content increased, the liberated magnetite particles existed in the mineralogical structure of the ore had a similar move in the chromite band.
- Even the sample was milled below 0.6 mm, it can be claimed that the liberation of chromite-magnetite could not be provided yet.

In order to determine which of these indications were true, the “Concentrate 1” of -0.150 size fraction with 53.61% Cr_2O_3 content was milled below 38 µm and fed to Davis Tube. Since this device can separate magnetite particles, it could be easy to understand the structure. As seen from Table 16, different ratios were obtained. After Davis Tube test, it can be indicated that the magnetite particles were associated with chromite particles.

Table 16. Davis Tube Test Results

Products	Weight, %	Cr_2O_3, %	Fe,%	Ratio
Non magnetic	86.4	53.95	15.0	2.46
Magnetic	13.6	48.08	21.8	1.51
Feed	100.0	53.15	15.93	2.33

Since the magnetite and chromite particles were thought to be associated together, then, it was decided to perform mineralogical analyses on these products.

3.4 Mineralogical Examinations

Basically, chromite and magnetite were found as expected. But olivine, serpentine minerals and less amounts of pyroxene could be counted as the gangue minerals. The related pictures were illustrated in Figure 1, 2, 3 and 4.

Chromite was found as an anhedral and fragmented structure. Only the sample demonstrated in Figure 4 had angled chromite particles. Also, the chromite and magnetite crystals showed fragmented morphology with twiggy and needle-shaped structure in the sample demonstrated in Figure 3.

According to the examinations, as long as the particle size decreased, the liberation of magnetite particles increased. Especially some part of magnetite was found in the fractures of chromite, which led to a decrease in ratio. This can be traced from Figure 1 and 2.

Magnetite particles had a disintegrative character and a part of it started to transform

to hematite. The size of the micro fractures the magnetite existed was nearly 30 µm. Besides, it was probable that the magnetite was formed as an alteration product of chromite.

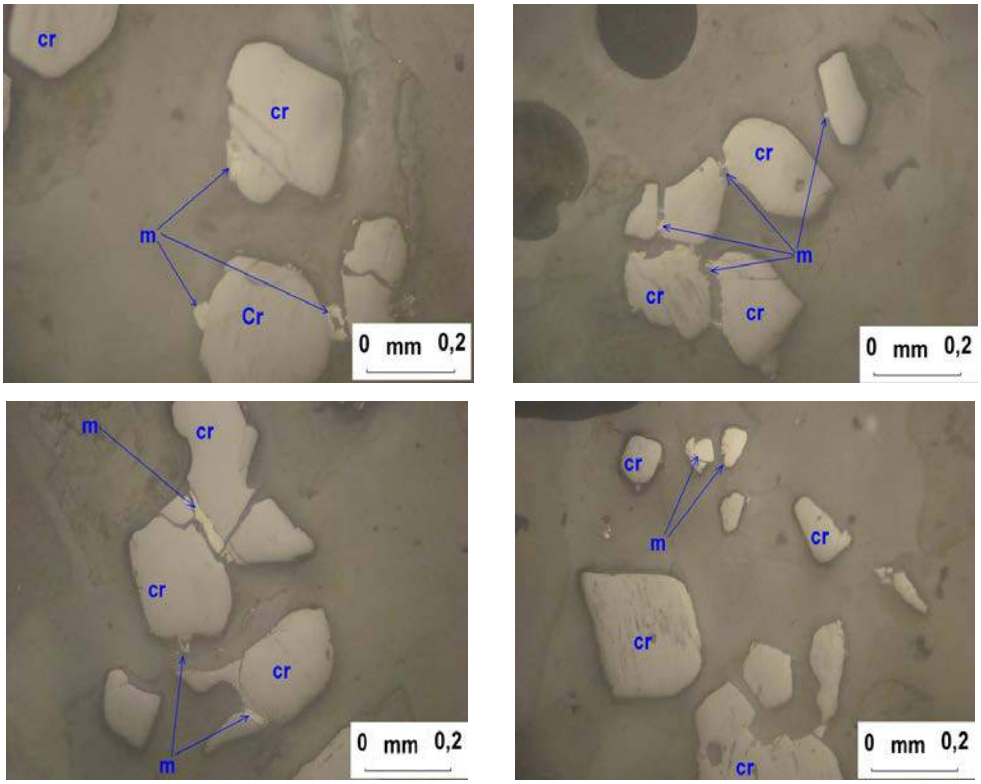

Figure 1. Chromite and magnetite crystals. Particles are euhedral and has clean surfaces. Magnetite is observed in the sides and fractures of chromite particles.

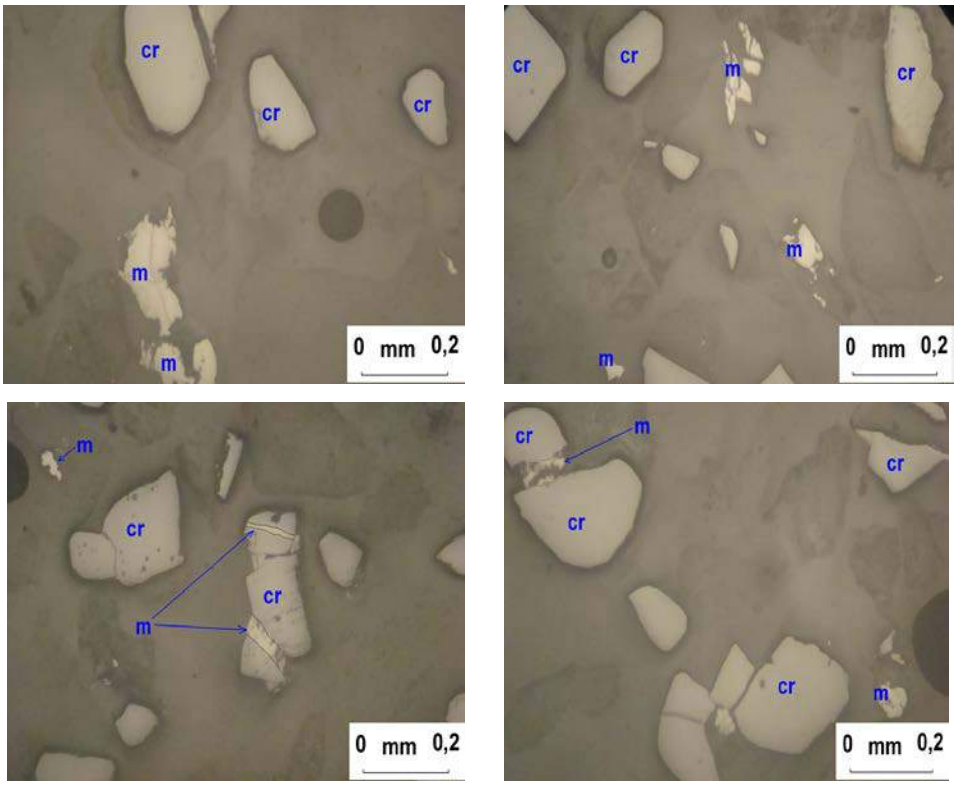

Figure 2. Euhedral and disseminated chromite particles. Fine grained magnetite exists in the fractures of chromite.

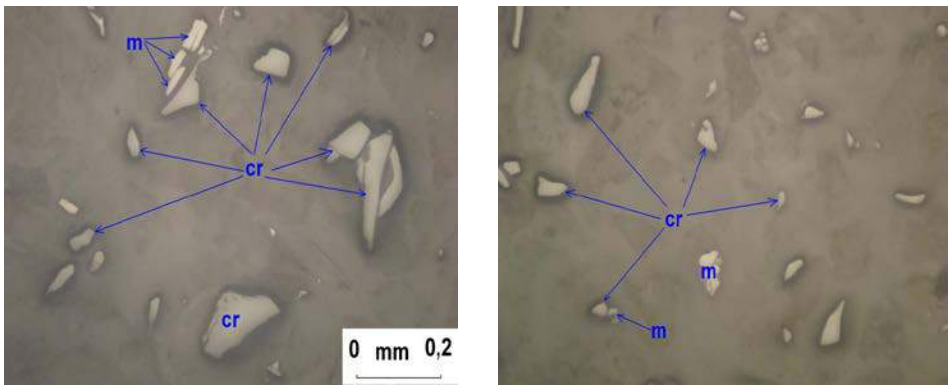

Figure 3. Fine grained and liberated chrmoite and magnetite crystals. Rarely associated. Mostly anhedral and fractured. Fine grained magnetites exist in the crystal matrix of silicates.

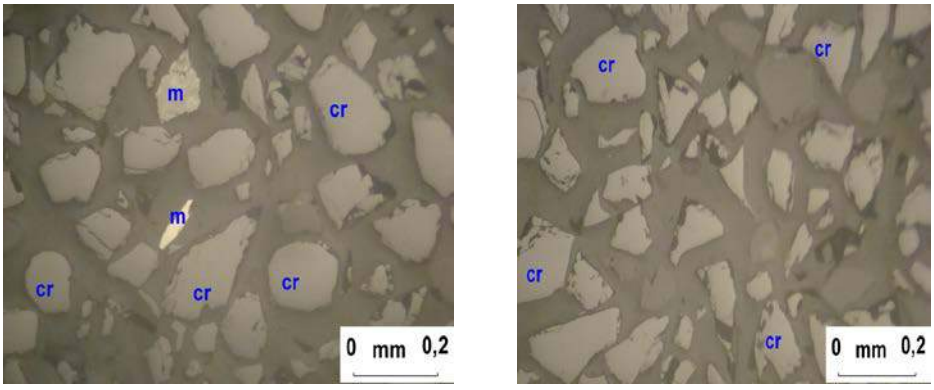

Figure 4. Relatively equidimensional, anhedral, locally needle shaped chromite and magnetite crystals. Not associated with silicates. Only a few magnetite particles exist.

4 RESULTS

In this study, examination of two different chromite samples taken from Albania in terms of particle liberation and ratio problem was investigated. With the KJM coded sample it was found that:

- Chromite concentrates containing nearly 40% Cr_2O_3 were possible with the size fraction of -25+1 mm using jig.
- When middling and residues of jig tests were milled below 1 mm, they could be subjected to shaking table tests resulted in 48.58% Cr_2O_3 content in concentrate.
- In a combined process of using jigging+shaking table, 80.9% of total metal recoveries were able to be achieved.
- If the middling of shaking table was recycled into the beneficiation system, then, it was seem to be possible to increase the efficiency.
- According to the chemical analyses, the ratio of the concentrates varied from 2.59 to 2.67.

With the KM coded sample it was found that:

- The particle liberation was provided below 0.6 mm.
- While the concentrate was obtained with 48.9% Cr_2O_3 content, the efficiency was calculated as 70.1%. However, the middling was obtained as 30% by weight, which could be recycled to the beneficiation unit in an operating plant. By applying this step, it was thought that 10-12% efficiency increases might be gained.
- The ratio values of these concentrates were found in a range of 2.29-2.41.
- Although Davis Tube tests were carried out, it was not found sufficient to

remove iron content. The reason for that situation was investigated utilizing mineralogical analyses.

- It was determined that the magnetite particles were associated with chromite particles.

Beneficiation of Dry Magnetic Separator Tailings Using Dense Medium Cyclones: A Simulation Study

A. Aghlmandi Harzanagh, Ş. L. Ergün
Hacettepe University, Department of Mining Engineering, 06800 Ankara, Turkey

ABSTRACT The aim of this research is to investigate the possibility of beneficiation of dry low intensity magnetic separator tailings of an iron ore concentration plant located in Malatya region of Turkey by using dense medium cyclones. After three stages of low intensity dry magnetic separation, there is a moderately high amount of iron (near 30% Fe) because of remaining hematite and goethite.

After taking samples from the tailings, size distribution analysis was performed. Then, the sample was divided into size fractions and sink-float tests were performed for each fractions. Using the size distributions and heavy liquid test results, simulation studies were performed to predict the performance of dense medium cyclone to recover iron minerals. The results showed that an iron ore concentrate containing 60.45% Fe with a 80% recovery could be obtained from the tailings using dense medium cyclones.

Keywords: Dense medium cyclones, Dry magnetic separator tailings, Tailing beneficiation

1 INTRODUCTION

Dense medium cyclones (DMCs) have been extensively used in coal preparation. Dense medium cyclone had been installed in over 25% of the coal preparation plants worldwide Reeves (2002). About 93% of 58 coal preparation plants in South Africa employes dense medium cyclones de Korte (2014). Large tonnages of iron ore and diamonds are also processed by dense medium cyclones Burt (1984). Dense medium cyclones (DMC) has several advantages such as ability to make sharp separations, ability to maintain controllable separation density, ability to handle a wide range of feed size, ability to remove products continuously, ability to change specific gravity of separation to meet varying market requirements and high capacity, comparing with other gravity separation methods (Aplan, 1985). Amenability of dense medium separation is usually evaluated by heavy liquid analysis. For the densities higher densities require organic liquids which are highly toxic.

Aqueous solutions of sodium polytungstate (SPT) or lithium polytungstate have certain safety advantages over organic liquids for the densities up to 3.1 g/cm^3. Koroznikova et al (2007) have developed a technique using finely ground tungsten carbide (TC) suspension in SPT to obtain densities upto 4 g/cm3.

Due to the relative simplicity of heavy liquid testing for coal and later development of density tracers, modelling and simulation studies have started earlier and matured to use reliable predictions for design and optimization of coal preparation plants Davis (1987). These have been applied to high density separations like diamond and lead-zinc Scott (1988).

Although a few earlier applications in chromite and magnesite, currently application of dense medium cyclones is limited to coal washing in Turkey, although its application would be beneficial for some problematic ores Aghlmandi Harzanagh (2014).

The aim of this paper is to investigate the possibility of using dense medium cyclone for the tailings of low intensity magnetic separator by using simulation as a tool.

2 EXPERIMENTAL STUDIES

2.1 Material and Method Used

The sample is the tailing of three stages of dry low intensity magnetic separation. The size of the sample is 100% passing 9.5mm. Figure 1 shows the size distribution of the sample.

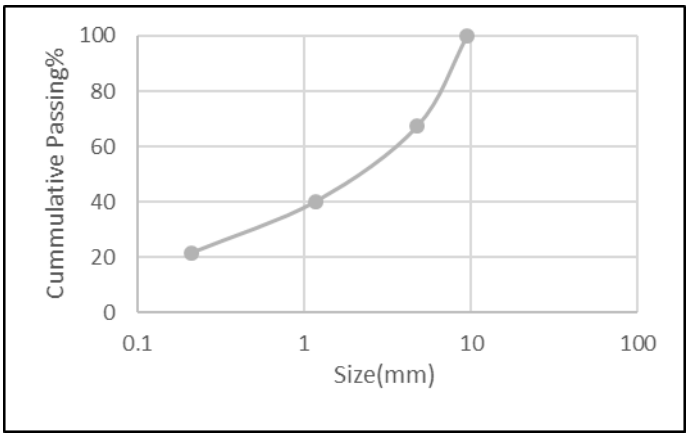

Figure 1. Size distribution of iron ore sample

Chemical analysis showed that Fe content of the sample is 31.9% and according to the results of the XRD analysis, Fe element mostly related to Hematite (Fe2O3) with specific gravity of 5.26 and Goethite (FeO (OH)) with specific gravity of 3.3-4.3. Also Specific gravity of the sample was measured as 3.18. After size distribution analysis of the sample, the sample was divided to -9.5+4.75 mm, 4.75+1.18mm, -1.18+0.212mm and -0.212mm size fractions for sink-float tests (Figure 2).

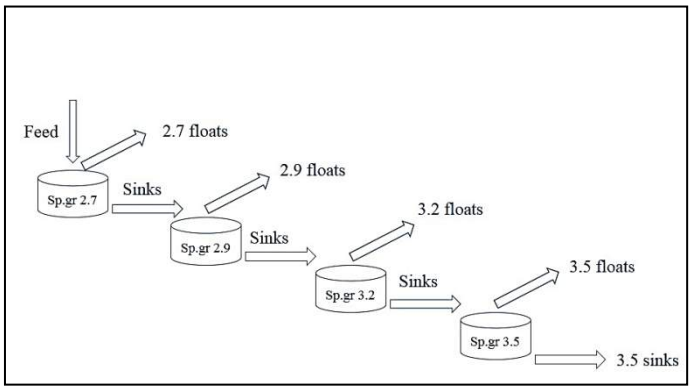

Figure 2. Schematic illustration of sink-float test

In this study, tetrabromoethane and acetone combination were used for preparing heavy liquids with specific gravies of 2.7 and 2.9 and suspensions of SPT and TC were used for preparing heavy suspensions with specific gravities of 3.2 and 3.5.

Preparing heavy suspension of SPT and TC consists of four steps:

- Preparation of SPT solution with 2.5 g/ml density (by this way the viscosity will not be high to separate fine particles).
- Pouring 20-30% of SPT solution into a separate container on a magnetic stirrer.
- Slow addition of the TC powder to form a homogenous suspension.
- Addition of this suspension to the SPT solution and stirring it very slowly until the desired density is obtained.

Then, sink-float tests were performed for all of the samples. In the case of coarse samples (+1mm) a normal beaker was used for fine size fraction (-1mm) special funnel (Figure 3) was used.

Figure 3. Modified separation funnel

2.2 Results

Figure 4-6 show the results of the sink-float tests for different size fractions of the sample.

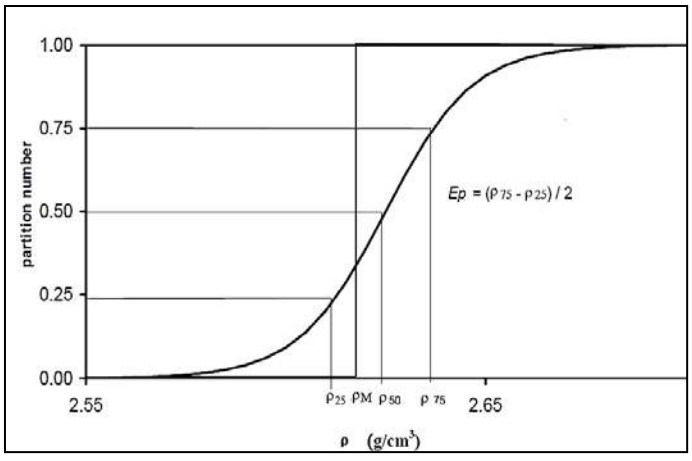

Figure 6. Heavy liquid density vs Fe grade (%), Fe recovery (%) and weight of the sink products (%) for -1.18mm+0.212mm size fraction

3 SIMULATION STUDIES

Any sink and float process can be described by a partition curve. Partition curve reports the amount (weight fraction) reported to the sinks versus solid density. If α is the partition coefficient, (1-α) is the amount of material reported to the floats.

The partition curve depends on: Feed properties (particle size distribution and density weight distribution), employed device and settings and dense medium stability and viscosity. In Figure 7 a typical partition curve is reported. The main important parameters describing the partition curve are Bevilacqua and Zanin (2002) :

- efficiency of separation (Ep): gives a measure of the curve slope
- Cut density (ρ50): is the density of the solids reported 50 % to the sinks and 50 % to the floats
- Offset: is the density difference between cut density and medium density (ρ50 – ρm).

Better separation occurs in low Ep values. Ideal separation has Ep = 0 and offset = 0. Ep and offset values depend on both feed and operational conditions like cyclone geometry, head pressure, separation density, medium stability and viscosity and flow rate. Coarser particles have smaller Ep and offset values than fine particles.

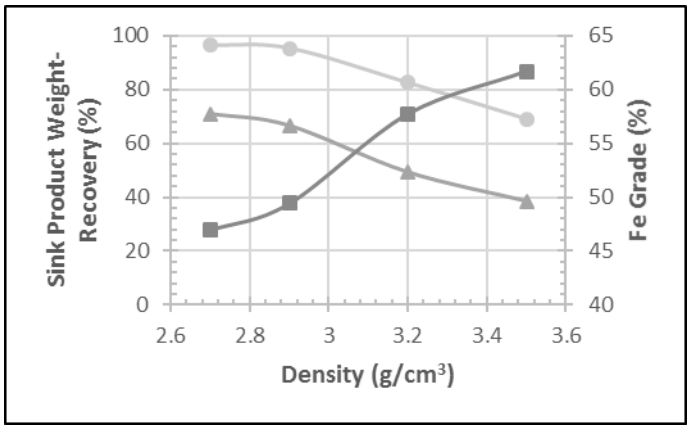

Figure 7. Partition curve and main parameters

According to Scott (1988), one of the simplest empirical efficiency curve expressions, Equation 3.1 is attributable to Whiten (1966) and has been used extensively by other workers. Where the partition number (Yj) is defined as the weight fraction

of density species (ρj) in the feed which reports to the underflow, (ρ50) is separation density and (∝) is a measure of the reduced efficiency curve slope.

Scott (1988) reported that Equation (3.1) could be presented by equation (3.2) and in case of high density separation, Ep value could be calculated by the following equations:

$$Y_{j=}\frac{exp\left(\propto\frac{\rho_j}{\rho_{50}}\right)-1}{\exp\left(\propto\frac{\rho_j}{\rho_{50}}\right)+\exp(\alpha)-2} \quad (3.1)$$

$$Y_j=\frac{1}{1+\exp\left[\frac{1.099(\rho_{50}-\rho_j)}{Ep}\right]} \quad (3.2)$$

$$Ep=Z+K.d^n \quad (3.3)$$

$$Z=19.6+0.16\Delta\rho-6.3Vmo \quad (3.4)$$

$$\ln(k)=6.87+0.59\ln(\mu)+0.30\ln(D_c) \quad (3.5)$$

Where, $\Delta\rho$ is the density differential in the cyclone, Vmo is the volumetric medium to ore ratio, μ is heavy medium viscosity and D_c is cyclone diameter. It is apparent from the equation that Ep value increases with all this parameters and high Ep values represent inefficient separation.

Because of similarity between the density and size distribution used in this study and diamond ore, the values of Z and K which was calculated for 400mm dense medium cyclone in Argyle diamond plant was used to predict Ep values in different size fractions Scott (1988).

$$Z=4+52d^{-1} \quad (3.6)$$

Lave 1.0 program was used to simulate the performance of the HMC plant. This computer program has been developed at the Department of Mining Engineering of Hacettepe University by Orhan, Gülsoy, and Ergün (2010) and it uses JKMRC model based on Whiten equation (Equation 3.2).

Lave 1.0 is able to run with minimal information that listed below:

- Particle size distribution of feed
- Heavy liquid analysis on each size range
- Separation density
- Ecart probable of separation (Ep)

As mentioned above, separation Ep changes for different size fractions of the feed so we have to calculate it for each size fraction then import them to the simulator program. Equation (3.6) was used to calculate Ep values for different size fractions. Figure 8 shows the principle of working with Lave 1.0 simulator.

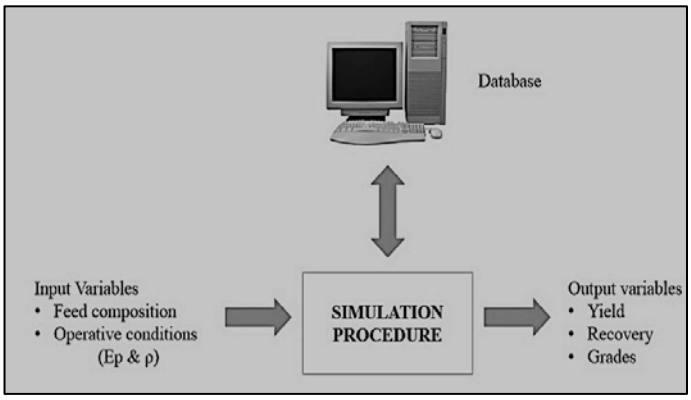

Figure 8. Principle of working with Lave 1.0 separator

For simulations the performance of HMC a simple circuit, including one screen and one HMC was considered. Using equation (3.6), Ep values were calculated for different size fractions and then these values were inputted to Lave 1.0 simulator. As a second variable pulp densities from 2.5 gr/cm3 to 3.5 gr/cm3 were entered to the simulator and simulation outputs were listed to select the best separation density (saleable concentrate grade with maximum recovery). Table 1 shows the calculated Ep values for different size fractions of ores and Figure 9 shows the grade and recovery changes according to separation density for iron ore sample. Figure 10 also shows grade-recovery curve.

Table 1. Calculated Ep values for different size fractions

Size fractions (mm)	Mean Size (mm)	Calculated Ep
-9.5+4.75	7.12	0.011
-4.75+1.18	2.96	0.021
-1.18+0.212	0.70	0.091

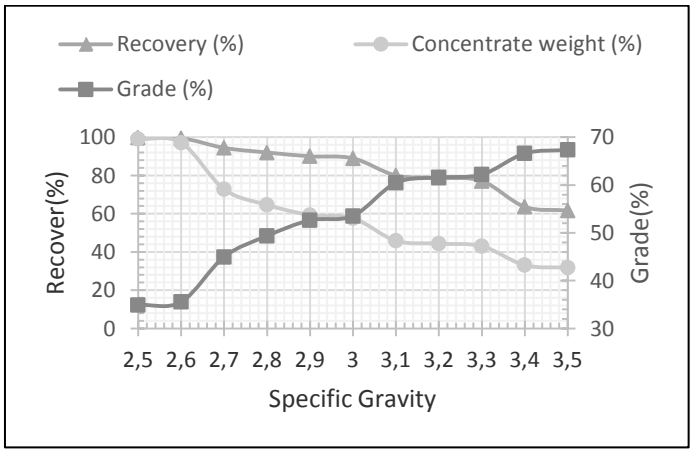

Figure 9. Grade, recovery and concentrate weight for different separation densities (based on simulation results)

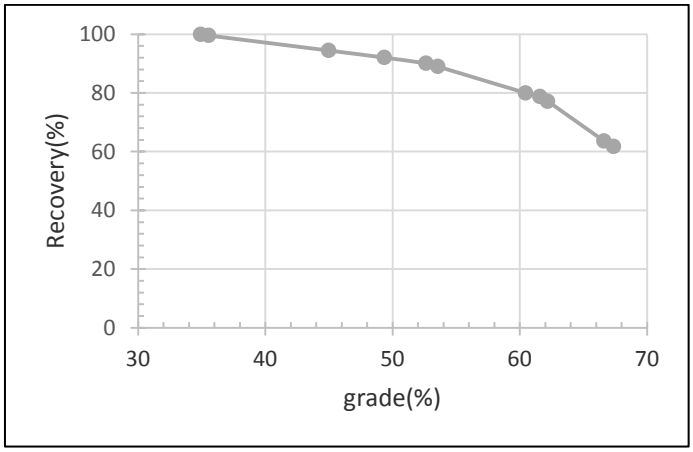

Figure 10. Grade-recovery relationship for iron ore sample based on simulation results

4 RESULTS AND DISCUSSIONS

According to the results of the simulations, Separation density of 3.1 gr/cm^3 is the most favorable density for the İron ore circuit. In this separation density it is possible to obtain concentrate with 60.45% Fe grade and 80% Fe recovery. Figure 11 shows the simulated flowsheet for iron ore with 100 t/h feed capacity and separation density of 3.1 gr/cm3.

The difficulty in gravity concentration processes can be evaluated using heavy liquid test results. according to Wills and Napier-Munn (2006) when the amount of near gravity particles is higher than 10%, it is really hard to obtain good results with jigs, tables, spirals and other gravity methods and the only efficient gravity method is dense medium separation. Table 2 shows the amount of near gravity particles for difference size fractions which calculated based on sink-float test results.

Table 2. Amount of near gravity materials for different size fractions

Size Fraction (mm)	Cum. Sinks Weight (%)		Difference
	- 0.1 of Separation Density	+0.1 of Separation Density	
-9.5+4.75	51.5	40.78	10.63
-4.75+1.18	54	45	9
-1.18+0.21	61	49.36	11.64

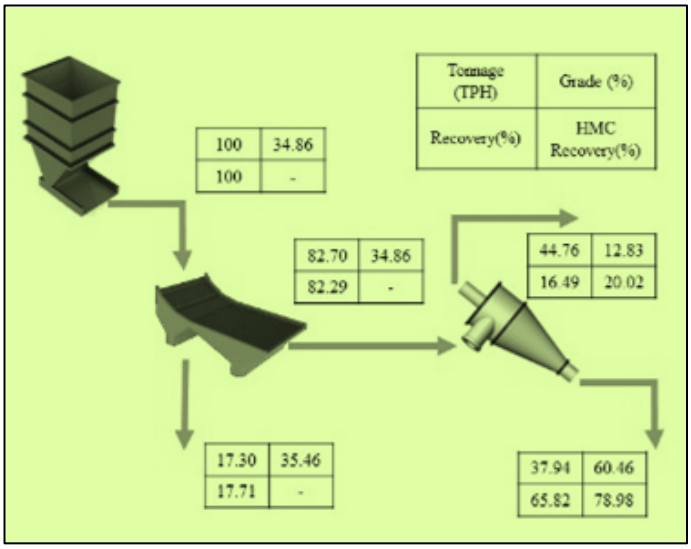

Figure 11. Schematic flowsheet of HMC plant for iron ore in separation density of 3.1 gr/cm^3

It is apparent from the Table 2 that, the amount of near gravity particles in most of size fractions are more than 10%. Therefore, this ore can not be beneficiated with the other gravity methods efficiently and using of dense medium cyclone is inevitable for this application.

5 CONCLUSIONS

Mineralogical analysis showed that hematite and goethite are the major iron minerals in the ore. Following sink-float tests, simulation results showed that obtaining a concentrate with up to 60.45% Fe grade and about 80% Fe recovery is possible for a dense medium cyclone plant with 3.1 g/cm^3 separation density, -9.5mm +0.5mm feed size.

Flotation Circuit Efficiency Enhancement Regarding Increase of Rougher Cells Throughput

A. Hassanzadeh
Mineral Processing Department, Faculty of Mines, Istanbul Technical University, 34469 Istanbul, Turkey

A. Azizi
Department of Mining, Petroleum and Geophysics, University of Shahrood, Shahrood, Iran

ABSTRACT Rougher flotation cells of Sarcheshmeh copper concentrator are expected to produce a concentrate assaying 7.6% with 96% recovery. Due to some reasons its recovery was decreased to 90 % during last year. Moreover, its recovery is of great significant because 80% of the final tailings is disposed from this section. In this work, mineralogical surveying, size by size copper recovery analysis, reagents stage addition and dosage were investigated. It is shown that, in the +75 μm size fractions in rougher tailings most of the free particles were chalcopyrite and pyrite minerals. The maximum recovery of copper was observed in 25-75 μm fractions, while the major copper loss was in +105 μm size fractions. It was found that, stage addition of collector (75, 13, 12) could improve the rougher recovery up to 2 percent.

Keywords: Flotation, circuit efficiency, rougher cell, copper

1 INTRODUCTION

The industrial practice of froth flotation is widely recognized to be a complex and highly self-compensating system (Klimpel, 1993).

Sarcheshmeh deposit which is one of the largest copper ore body in the world contains 1 billion tonnes of ore averaging 0.90% copper and 0.03% molybdenum. It is located in the southeast of Iran processing 47000 t/d of ore since 1982. The mine produces 100000 tonnes of copper and 2200 tonnes of molybdenite concentrate per year (Wunder, 1979). The rougher flotation in Sarcheshmeh copper complex is comprised of two sections which consisting of four rows of fourteen 8.5 m^3, stepped 4-5-5, cells (Fig. 1).

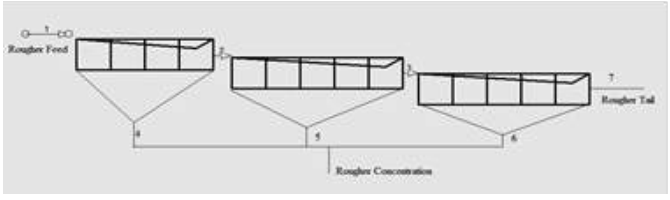

Figure 1. One of the selected rows of rougher cells and sampling points.

The relationship between particle size and flotation recovery has been the subject of several studies and it was shown that, the behaviour of fine and coarse particles in flotation follows different trends (Gaudin, Groh, 1931). In addition, the effect of reagent dosage and particle size on metallurgical performance has also been studied in detail (Shannon, 1986). Clearly, coarse and extremely fine particles are more difficult to be recovered by froth flotation compared to intermediate size particles (Gaudin, 1931). Also, mineral liberation plays an important role in flotation processes as demonstrated by studies on detachment of particles from bubbles during coalescence, or by comparing flotation kinetic constants of liberated and locked particles (Trahar, 1981).

In Sarcheshmeh concentrator, Banisi et al. showed that, 17% of copper was lost in tailings and the lowest copper recovery was corresponding with the particles coarser than 105 microns, while only one of the eight identical flotation banks was sampled (Banisi & Kargar, 2001). Furthermore,

focusing on mineralogical composition it was found that, 91.2% recovery could be obtained, while there was a reduction of 15% in the amount of free valuable minerals in the tailings stream, with chalcocite in the -38 microns size fraction having the highest contribution (Banisi & Iranmanesh, 2002). Since 80 percent of the final tailings was rejected from the rougher section the overall recovery was mainly dependent on the grade of rougher tailings (Banisi & Sarvi, 2003).

In this work, firstly the recorded performances of the past 6 month of the plant operations were compared with the design criteria. It was found that the final recovery was reduced to 86 from 90 percent, while the rougher recovery was decreased 8 percent. Increased throughput from 225 up to 280 and even 300 tph to each one of the 8 ball mills in circuit and consequently a coarser grind size and a shorter residence time in the cells, mineralogical variations due to the increased depth of the mine, major changes in the regime of reagent addition, could be responsible for the decrease in recovery. Thus, it was essential to investigate into the responsible factors to compensate for the loss of recovery.

2 METHODOLOGY

2.1 Determination of the performance of rougher cells

The rougher bank in Sarcheshmeh is divided into three units of 4, 5, and 5 cells. To analyze the flotation circuit, a section consisting of four of the rougher rows were selected for sampling and sampled at 7 points (Fig. 1). In a 3 hour period when the plant operation was in steady state six incremental samples were collected from each of the sampling points. Wet screenings of the samples were performed, while a -400 mesh fractions were classified by using the CSIRO cyclosizer. Eighty percent passing size of the feed to the flotation circuit was determined 62 µm in normal operation. Each size fraction was assayed for copper content. Flow rate of each stream was calculated and balanced by copper grade of the head samples using mass balancing software (Movazen 2.1) (Yarahmadi & Banisi, 1998).

It was determined that rougher and final recoveries are highly correlated (Fig. 2).

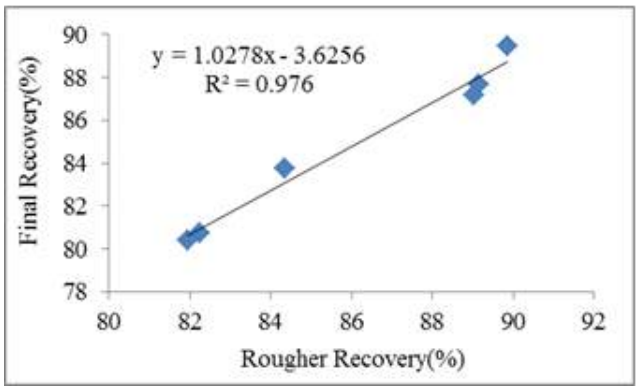

Figure 2. The correlation of final and rougher recoveries.

2.2 Mineralogical analysis

During a six-month period, the composite samples of each month of the feed and tailings streams of the flotation circuit were prepared. At first, polished samples were provided and the mineral counting procedures were executed through a detailed study. Liberation degrees and type of locking valuable minerals in both streams were determined. Grain sizes were measured manually and associate minerals for locked particles were also recorded routinely.

3 RESULTS AND DISCUSSION

3.1 Performance Monitoring

A six months survey of the flotation circuit revealed that the metallurgical objectives declined dramatically. According to design criteria, rougher and final recoveries must be 96 and 90%, respectively, while dropped to 88 and 86%, respectively. It was observed that, increased rate of throughput up to 280 led to the coarser grind size, 62% passing 74 µm (Table 1). Whereas, the average copper grade of rougher feed and rougher tailings streams were 0.83 and 0.10 during the period.

Reagent schemes used for the treatment of porphyry copper and copper-molybdenum ores are relatively simple and usually involve lime as a modifier, xanthate as the

primary collector and a secondary collector (Bulatovic, 2007). In practice, with a relatively coarser grind size, 62% passing 74 µm, an appropriate combination of collectors must be selected for flotation of coarse and middling particles.

Table 1. The results of monitoring rougher flotation circuit for 6 months

Month	rougher recovery, %	final recovery, %	rougher feed particle size, %	Cu%, rougher feed	Cu%, roughr tailings
Oct.	90	88	66	0.87	0.08
Nov.	88	86	63	0.82	0.10
Dec.	91	88	65	0.82	0.09
Jan.	88	85	61	0.81	0.10
Feb.	85	84	60	0.78	0.11
Mar.	87	85	62	0.86	0.10

The presence of valuable minerals in tailings and a subsequent decrease in recovery can be attributed to a deficient reagent regime in the circuit. Table 2 indicates a comparison between designed and operated condition of the type and dosages of collectors and frothres which were being consumed in the circuit. The average dosage of Z11 was 8.49 g/t which was very lower than the design criteria. Z11 is a strong collector that can improve the recovery of coarse particles. A low dosage of Z11 can contribute to a decrease in the recovery of coarse particles in the final cells of the bank. Table 2 shows a comparison between the layout values with operating dosage and type of surfactants in the concentrator plant.

Table 2. Designed and consumed reagents

Design layout			Current	
Reagent type		Dosage (g/t)	Reagent type	Dosage (g/t)
Collectors	Z11	56	Z11	9
	R404	18	Nascol-1451	20
	Z200	13	FlominC-4132	13
Frothers	MIBC	13	MIBC	15
	Fuel Oil	13	Fuel Oil	7
	Dowfroth250	13	A65	15

The degree of liberation is a determinant factor in mineral separation processes and can be used to estimate the selectivity of grinding and the sharpness of separation. Increasing throughout from 225 to 280 tph caused a decrease in the average residence time of material in primary ball mills. Consequently, the degree of liberation of the valuable minerals in rougher feed reached 72%. The result of residence time distribution (RTD) measurement with 280 tph throughput, showed that, MRT was about 5.75 min by the use of N-Mixers model, while according to the design criteria it should be 8 min.

Based on Agar theory the rougher split should be made at the flotation time where separation efficiency is maximized. At maximum separation efficiency, the grade of concentrate produced is equal to the flotation feed. Four stages of sampling were performed from the feed and products of different units of rougher flotation banks. The average copper grade of the concentrate of final unit copper concentration grade (cells 11-14) was 3.24, while copper grade in rougher feed was 0.71 (Figure 3).

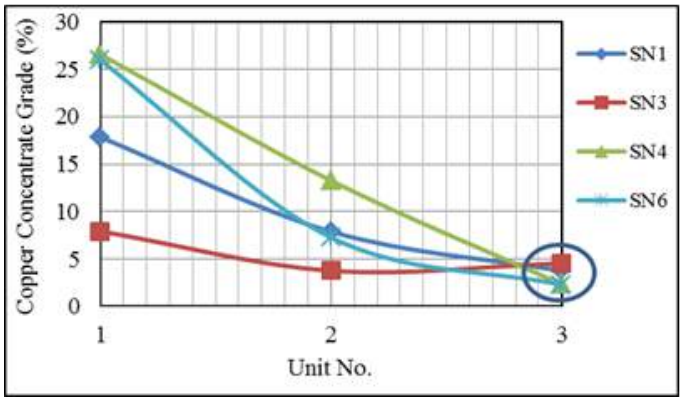

Figure 3. Copper grade in rougher cells in four sampling series vs. unit No. at a selected bank.

The observed results showed that, the mean residence time with 280 tph throughput was relatively 15% lower than with 225 tph.

3.2 Performance Evaluation of Rougher Cells by Size-by-Size Analysis

The recoveries of rougher cells in 10 size fractions were determined and are shown in Figure 4. As can be seen, the recoveries of +150 microns fractions in the last unit are zero that can be attributed to the deficiency and single stage addition of collectors. The

maximum and minimum recoveries in 3 units are corresponding to (15, 150), (33, 210) and (33, +150) microns, respectively.

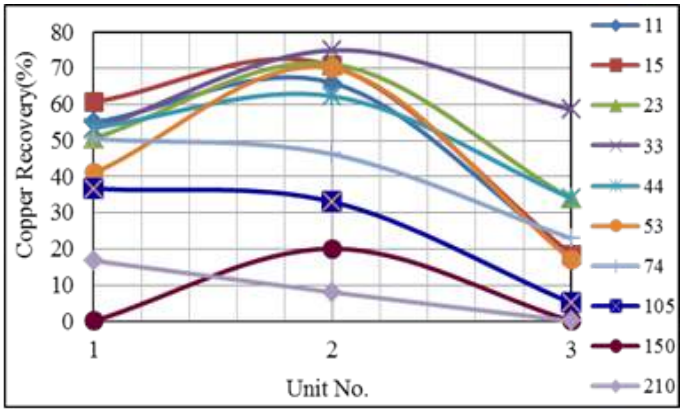

Figure 4. The size-by-size recovery at various units of the rougher bank.

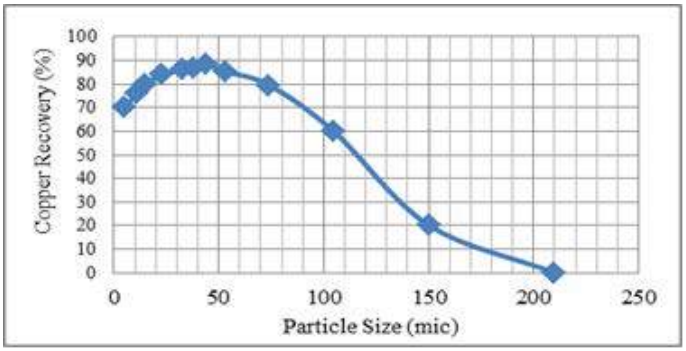

Figure 5. Copper recovery in different size fractions from rougher cells.

Copper losses from rougher cells were mostly related to the coarser particles (+105 μm). It can be seen from Figure 5 that, flotation recovery drops rapidly for the extremely fine fractions (<25 μm), and copper recovery also declines gradually for coarse particle size ranges (>105 μm). The maximum recovery was obtained for particles in the size range between about 25 to 75 μm, for which according to mineralogical study of the samples, the liberation of copper bearing minerals was maximized (>95%). This implies that, the lower recovery from out of this fraction size was mainly due to the locking of copper minerals and gangue.

3.3 Stage Addition of Z11 Into Rougher Cells

For small particles which have a larger specific surface area than coarse particles the dosage of collector required to render a given degree of particle coverage per unit mass is much higher than for coarse particles (Tucker, 1984). Since in the flotation circuit at Sarcheshmeh collector was merely added at the top of the bank (100-0-0), it would mostly be consumed by fine particles which in fact needed a little coverage to be efficiently floated. Thus, there would not be sufficient collector available to produce the hydrophobic coverage required to float the coarse particles, particularly, in the third unit (cell number of 10 to 14). Where, the d_{80} of concentrate and tailings were very higher than the first and second units (Fig. 6) Implying that coarse particles had not been floated in primary cells. For example cumulative percent finer than 200 mesh for RC1, RC2 and RC3 were 76, 65 and 53, respectively.

To avoid loss of valuable minerals as coarse particles in rougher tailings, stage addition of Z11 was implemented in different units of rougher cells. It was revealed that, the copper grade of rougher tailings was around 0.1. From figure 7 it can be observed that, more than 80% of the particles in rougher tailings were coarser than 105 μm. Therefore, stage addition of Z11 was examined. Results indicated that, with stage addition of the collector at heads of the three units (75-13-12) of the rougher cells the copper grade of rougher tailings was decreased about 30% (Fig. 7). Furthermore, an enhancement of 2 percent in the recovery of the rougher section was observed.

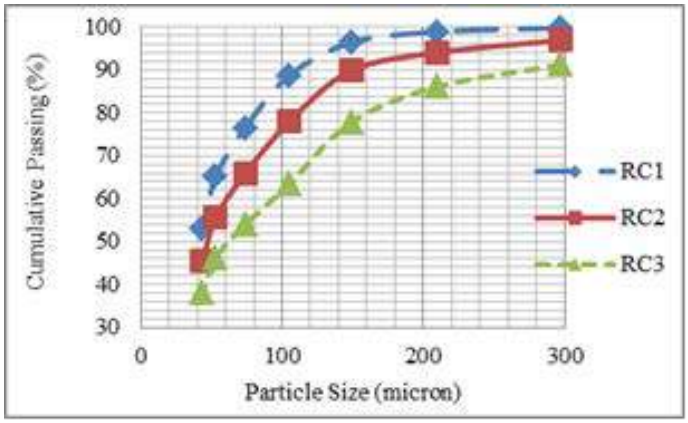

Figure 6. The size distribution of concentrates of the three rougher units.

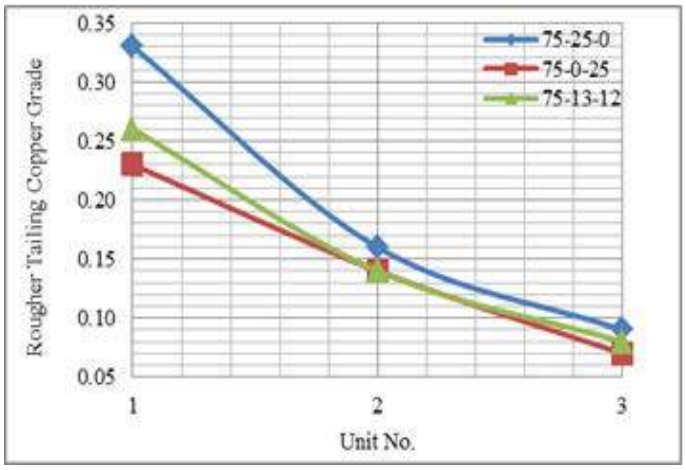

Figure 7. The effect of three methods of stage addition of Z11on the copper grade of rougher tailings.

4 CONCLUSION

Increased throughput into the concentration plant at Sarcheshmeh copper complex had led to a decrease in rougher cells recovery. The reduction in recovery was found to be due to the loss of coarse particles. Decreased MRT of 15 percent in rougher cells with increasing the throughput into each rougher row from 225 to 280 t/h was detected to be one of the major factors affecting the results. This was confirmed by lower separation efficiency in the last rougher cells (unit 3).

Results indicated that, the maximum recovery of rougher cells was achieved in the range of 25-75 μm size fractions. Stage addition of Z11 at heads of the three units (75-13-12) of the rougher cells contributed to about 30% decrease in copper grade in rougher tailings. In addition, the copper recovery of rougher cells was improved up to 2%.

Granulometric Separation in Laminar Flow

I. Grigorova, I. Nishkov
University of Mining and Geology "St. Ivan Rislki", Department of Mineral Processing and Recycling, 1700 Sofia, Bulgaria

ABSTRACT Research and development program was undertaken to develop a new generation of hydraulic separators which are more efficient and less costly to operate and maintain. Two methods of granulometric separation of fine particles in laminar flow have been tested. A method of hydraulic airlift size classification has been developed. For the laboratory experimental studies glass microspheres have been used. It has been shown that fine particles are dragged into the boundary layers of the rising bubbles and have been separated as an overflow (fines stream) product. The hydraulic Airlift separator has been tested in quartz-kaolin industry for recovery kaolin from technological waste. A method of particle size classification in a fluidized bed containing parallel inclined plates has been developed. The ballotini glass beads have been used in the laboratory experiments. The Reflux classifier has been tested for recovery of fine kaolin from technological waste. The data obtained from industrial tests illustrate the potential application of granulometric separation in laminar flow using AirLift and Reflux separators.

Keywords Granulometric separation, laminar flow

1 INTRODUCTION

In a variety of applications involving suspensions of small particles in fluids, it is desirable to classify or separate the particles based on differences in physical characteristics such size, shape and density. Common commercial equipment capable of effecting particle classification includes hydrocyclones, elutriators, centrifuges, cone classifiers, spiral classifiers and screens.

Particle classification may also be accomplished by hydrodynamic chromatography, field-flow fractionation, inertial deposition, filtration, and electrophoretic or magnetic mobility. An especially desirable classification method is the exploitation of differences in particle settling velocities undue the action of gravity. Gravitational classifiers are both simple in design and exert very little shear on the particles.

However, gravitational sedimentation may be quite slow, especially if the particles are very small.

Hydraulic classification is commonly used for particle size classification and gravity concentration of minerals and coal. Hydraulic separators are frequently used in mineral processing industry to classify fine particles according to size or density (Wills & Tim Napier-Munn 2006). Unfortunately, the efficiency of these processes can be quite low due to poor equipment design and variations in feed consistency. To help alleviate these problems, a research and development program was undertaken to develop a new generation of hydraulic separators which are more efficient and less costly to operate and maintain. Two methods of granulometric separation of fine particles in laminar flow have been tested in Bulgarian kaolin industry.

2 EXPERIMENTAL

2.1 Hydraulic Airlift Classification Laboratory Tests

It is known from the flotation theory and practice that although slime particles are hindered to form three-phase contact, due to thermodynamic (Scheludko, Toshev &

Bojadjiev 1976) and hydro dynamic (Derjaguin, Roulev & Dukhin 1977, Derjaguin & Dukhin 1959) barriers, they are nevertheless drawn into the froth product. The capture of fine particles in the froth is attributed to their small size and bears no relation to their surface properties. As a result the froth product is contaminated by fine particles of the non-floatable mineral. Gaudin (1957) has found that the amount of fine hydrophilic particles captured in the lower layers of the froth is linearly proportional to their concentration in the pulp.

The occurrence of this unwanted in the classical froth flotation secondary process of capture of fine particles has lead us to the idea of using it for separation by size of hydrophilic materials. Thus a method of hydraulic airlift size classification has been developed. The major goal of the method is to extract the finer fractions of a single mineral or the extraction of a mineral, the particles of which are known to be of smaller size than those of the other mineral components in the suspension.

The regime of motion of the gas bubbles corresponds to $Re_b \approx 1\text{-}150$. According to the theory at such values of Re_b the hydrodynamic field around the rising bubbles may be separated into two characteristic regions (Levich 1962): a boundary layer with an effective thickness δ_0 situated immediately at the bubble surface and potential flow extending from the boundary layer inside the liquid.

The hydrophilic mineral particles, which are not subjected to the "winnowing" effect of the flow, are dragged into the boundary layers around the floating air bubbles. The residence time of these particles in the boundary layer is different for various sizes and it is the determinant factor for their extraction into the upper layer. The residence time of the fine particles is much longer than that of the larger ones. This allows the fine particles drawn into the boundary layers to reach the upper layer and to form a separate upper product. The large particles remain in the bulk of the cell as a bottom product. The qualitative estimation of the forces acting on the particles shows that the main classifying effect is their radial migration in the boundary layer in a direction normal to the bubble surface.

The laboratory experiments were conducted in a glass cell with a porous bottom for dispersion of the gas phase. The cell volume was 150 cm^3. Glass micro spheres of radii: 1; 2; 5; 10; 25 and 50 μm products of Duke Scientific Co, were used. Weak inner circulation of the suspension in the bottom of the cell was generated by means of a magnetic stirrer.

The experiments were carried out under the following conditions: content of solid phase in the suspension – 2 g/dm^3; duration of the experiment - 20 min; consumption of gas phase (nitrogen) – 50 cm^3/min.

2.2 Steady-state Particle Classification Laboratory Tests

The work of Davis et al. (1982) suggests that lamella settlers may be used to classify particles according to differences in their settling velocities. This possibility for a single inclined settling channel is shown in Figure 1. A feed suspension containing a distribution of particle sizes is introduced into the channel. By use of the basic principle that larger particles settle more quickly than do smaller ones of the same density and shape, this feed suspension is classified into a coarse fraction (underflow) and a fine fraction (overflow). If the hold-up time in the inclined settler is larger than the required sedimentation time for a given particle size, then particles of that cutoff size and larger will settle onto the lower wall of the channel (and subsequently slide down it to the underflow) and will not be carried into the overflow. Thus, the overflow will be essentially devoid of particles larger than a certain cutoff size, which may be controlled by adjustment of the vessel geometry or the flow rate through the vessel. As a consequence, the underflow will be enriched in the faster settling, larger particles.

Several experiments were carried out in a single-channel inclined settler. The vessel has the dimensions L = 60 cm, b = 2.5 cm,

and w = 3.5 cm. Glass micro spheres of diameter from 0 to 60 μm products of Duke Scientific Co were used. The suspending fluid was water at room temperature. The reservoir volume was 4.0 L. Dry particles were weighed and added to the water so that the particle concentration was less than 1% by volume. The angle of inclination of the settler from the vertical was aired, although the value θ = 45° was used in all of the experiments. This choice was made because it allowed both for high settling rates and for the sediment to easily flow down the lower wall of the channel.

For the steady-state experiments, feed suspension was pumped from the magnetically stirred reservoir up through the bottom of the settler, as shown in Figure 1.

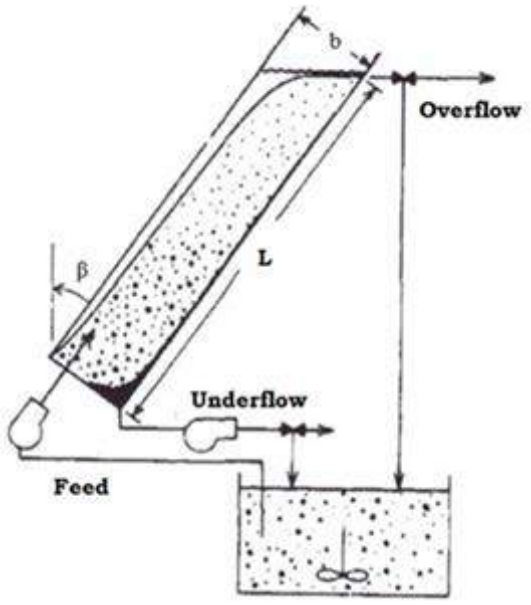

Figure 1. Continuous inclined settler for steady-state particle classification.

Concentrated sediment was withdrawn from the lowest corner of the settler and recycled to the reservoir. The bottom of the settler contained a machined insert with a splitter plate designed to separate the feed stream from the sediment and to prevent remixing of the sediment with the suspension. Both the feed rate and underflow rate were controlled with variable-speed peristaltic tubing pumps. The overflow rate was subject to level control and is simply the difference between the feed and underflow rates. The overflow was also recycled to the reservoir. A total of 20 steady-state experiments were performed by systematically varying the feed and underflow pump settings. For each experiment, approximately 1 h was required for steady state to be reached, with the slow step being the equilibrium formation of the thin layer of sediment deposit on the lower wall of the channel. Samples for later analysis were then taken from the feed, reservoir and from the underflow and overflow streams.

2.3 Technological Tails Characterization

A number of samplings in one mouth duration in Vetovo processing plant of Kaolin AD were performed. Sampling and performance evaluation was applied to final technological tails at two different feed capacities – 100 and 150 t/h. The samples were collected from each stream every one hour and were combined in a shift every time. The following characteristics of the sampling products were determined: particle size distribution and chemical composition. Particle size distribution of samples was determined by wet sieving: fraction "+45 μm" using vibratory sieve shaker Analysete 3, FRITSCH and fraction "- 45 μm" using SediGraph 5100. The chemical composition was determined using AES-ICP.

2.4. Pilot Plant Trial

Based on technological kaolin tails characterization and the hydraulic airlift classification experiments a hydraulic Airlift separator was developed. A schematic representation of the hydraulic Airlift separator is shown in Figure 2. The technological waste and additional water are introduced into classifier. Air flowed up through a distributor plate in the volume of the vessel, dispersing the gas phase into fine air bubbles. The fine particles are dragged into the boundary layers of the rising bubbles and have been separated as an overflow product. The large particles remain in the bulk of the Airlift separator as a chamber product and were separated as an underflow – final waste.

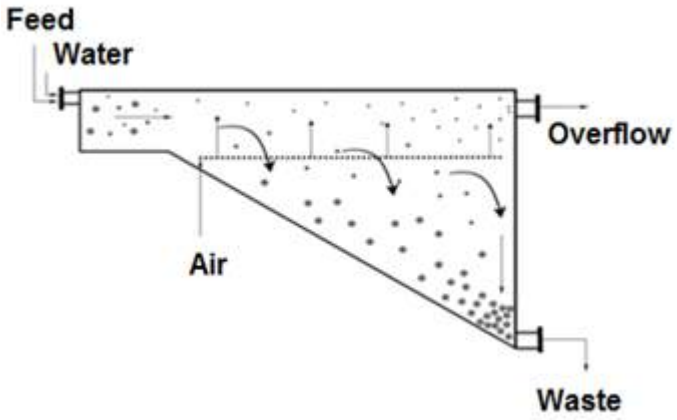

Figure 2. Schematic representation of the hydraulic Airlift separator.

Based on laboratory tests using a single-channel inclined settler a Reflux classifier was developed. A schematic representation of the Reflux classifier is shown in Figure 3. The feed slurry was delivered through the side of the vessel. Fluidization water flowed up through a distributor plate at the base of the vessel, suspending the particles within the vessel. Fluidized suspension passes up through the inclined channels, with the slower settling fine particles continuing on through to the overflow. Faster settling large particles segregate onto the inclined plates and slide back down as concentrated sediment to the fluidized zone below. A “reflux” action develops which in turn produces a sharper separation.

The both full scale units were trialed in Vetovo processing plant for recovery kaolin from technological waste. The technological waste treatment flowsheet is presented in Figure 4.

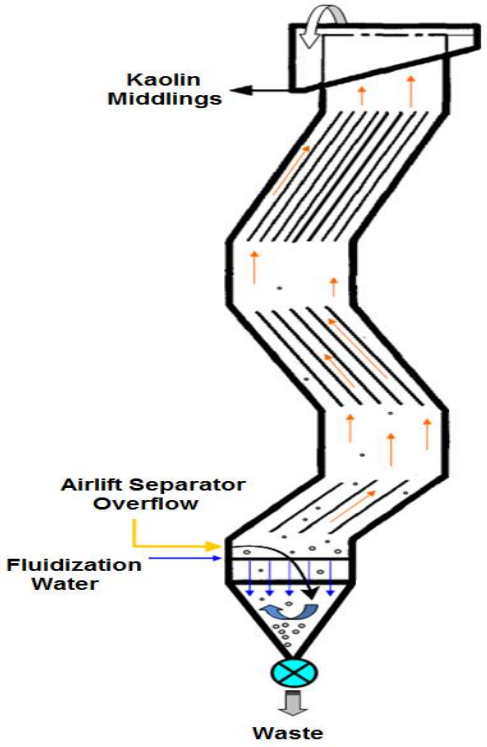

Figure 3. Schematic representation of the Reflux classifier

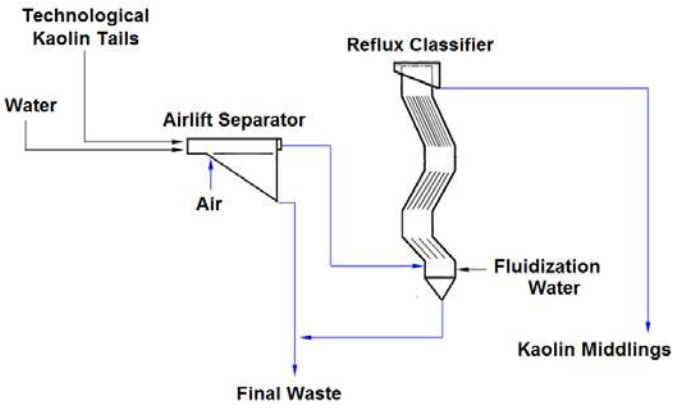

Figure 4. Two stages granulometric separation flowsheet.

The final tails are introduced into a hydraulic Airlift separator. The fine particles are dragged into the boundary layers of the rising air bubbles and have been separated as an independent product – overflow. This product is fed to the Reflux classifier where the fine particles are extracted as an overflow – kaolin middlings. The both underflows from Airlift separator and Reflux classifier were combined as final technological waste.

The pilot plant tests were carried out under the following conditions:

- Tailings slurry capacity – 21.15 m^3/h;
- Solids Mass Flow – 3.79 t/h;

The influence of the following variables is studied:

- Pressure air, bar;
- Ratio Overflow: Underflow of Airlift separator, %;
- Fluidization water, m^3/h;
- Ratio Overflow: Underflow of Reflux classifier, %.

3 RESULTS AND DISCUSSION

3.1 Hydraulic Airlift Classification Laboratory Tests

The results obtained in the laboratory experiments with glass micro spheres are presented in Figure 5. The dependence of recovery (mass yield of upper layer product) on particle size shows that mainly particles finer than 5 μm are extracted.

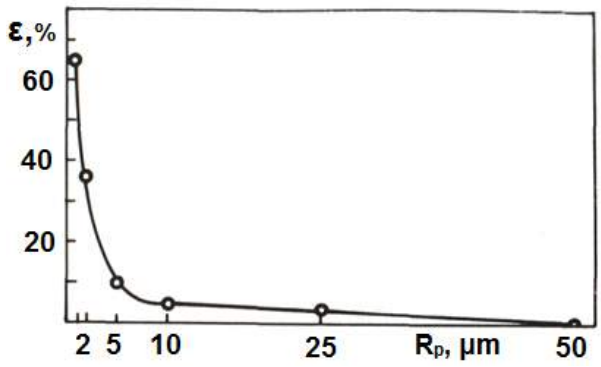

Figure 5. Dependence of recovery on particle size.

The theoretically calculated residence times for particles of various sizes in the boundary layer of a bubble of radius P_b = 250 μm are in good agreement with the experimental results (Grigorova & Nishkov 2008). Fine particles of sizes below *5* μm are mainly extracted in the upper layer product because their residence times are much greater than those for larger particles.

3.2 Steady-state Particle Classification Laboratory Tests

The results obtained in the laboratory experiments with single-channel inclined settler are presented in Figure 6. The cumulative size distributions of the particles in the feed, underflow and overflow streams for steady-state particle classification experiment are shown.

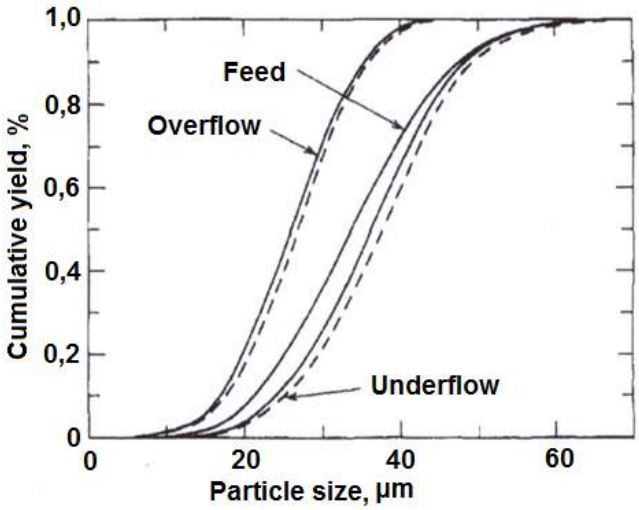

Figure 6. Cumulative size distribution of particles in the feed, underflow, and overflow steams for steady-state particle classification.

It is clear that a classification of particles by size was achieved; the overflow distribution is devoid of the larger particles, whereas the underflow distribution has a significantly reduced fraction of smaller particles.

3.3 Technological Kaolin Tails Characterization

The data from particle size distribution and chemical composition of final technological tails are presented in Table 1.

The performed analyses clearly demonstrate that the final kaolin tails is fine product – fewer than 56 μm. There are some losses of kaolin in final tails. The content of Al_2O_3 is in the frame of 6 - 9 %.

Table 1. Tails characterization data.

Parameters	Feed capacity, (100 t/h)			Feed capacity, (150 t/h)

3.4 Pilot Plant Trial

The results obtained in the pilot plant experiments with two stages granulometric separation are presented on Table 2 and 3.

The data clearly demonstrate that a classification of particles by size in laminar flow is achieved. The content of Al_2O_3 in overflow of Reflux classifier increases more than 2.3 times.

4 CONCLUSIONS

The two stages granulometric separation with Airlift separator and Reflux classifier is a new approach on recovery of kaolin from technological waste. The content of Al_2O_3 increases from 6 – 9 % in technological waste to over 21 % in the final product – kaolin middlings.

Evaluation of Spiral Chromite Tailings of South Africa
Güney Afrika Spiral Kromit Artıklarının Değerlendirilmesi

Ş. B. Aydın, M. Özer, A.E. Yüce
Mineral Processing Engineering Department, Faculty of Mines, Istanbul Technical University, Istanbul, Turkey

ABSTRACT In this study, beneficiation of the spiral chromite tailings taken from South Africa, which contains 22.5% Cr_2O_3, were investigated by using combination of gravity units. Shaking table tests were carried out at size fractions such as -0.841+0.355 mm; -0.355+0.212 mm; -0.212+0.074 mm and Mozley table was used for -0.074 mm, however, appropriate results were not obtained in terms of acceptable concentrate and tailing grade. Therefore, original material was ground under 0.355 mm in size, fractioned and subjected to gravity separation tests. Gravity separation tests were carried out at size fraction between -0.355+0,150 mm, -0.150+0.074 mm by using shaking table and at -0.074 mm using Mozley table. According to the overall gravity concentration test results under 0.355 mm; 34.6 % of feeding material can be obtained as a chromite concentrate having 41.52% Cr_2O_3 grade with 62.0% metal recovery. Final tailings having 6.24% Cr_2O_3 content can be separated with a 7.8% metal losses. Since Cr_2O_3 concentrate content of 40-42% is found sufficient in line with company's demand, 41.52% of Cr_2O_3 content is determined as the optimum value.

Keywords: Chromite, tailing, evaluation

ÖZET Bu çalışmada, Güney Afrika'dan alınan % 22.5 Cr_2O_3 içerikli spiral devresinden elde edilen kromit artıklarının gravite cihazlarının kullanımı ile zenginleştirilmesi incelenmiştir. -0.841+0.355 mm, -0.355+0.212 mm ve -0.212+0.074 mm boyut gruplarında sarsıntılı masa, -0.074 mm boyut grubunda ise Mozley masası kullanılmıştır. Ancak kabul edilebilir konsantre ve artık tenörleri açısından uygun sonuçlar elde edilmemiştir. Bu sebeple, orijinal numune 0.355 mm boyut altına öğütülmüş, boyut gruplarına ayrılmış ve gravite ile ayırma deneylerine tabi tutulmuştur. Gravite ile ayırma deneyleri -0.355+0.150 mm, -0.150+0.074 mm boyut gruplarında sarsıntılı masa, -0.074 mm boyut grubunda ise using Mozley masası kullanılarak gerçekleştirilmiştir. 0.355 mm altı malzeme ile yapılan gravite deneylerine göre, beslenen malzemenin %34.6'sı, % 41.52 Cr_2O_3 içeriğine ve %62'lik metal kazanımına sahip bir kromit konsantresi olarak elde edilmiştir. 6.24% Cr_2O_3 içerikli artık, %7.8' lik metal kaybı ile ayrılabilmiştir. Firmanın talebi doğrultusunda, konsantrede %40-42 Cr_2O_3 içeriği yeterli bulunduğundan dolayı, %41.52 Cr_2O_3 içerikli konsantre optimum değer olarak belirlenmiştir.

1. INTRODUCTION

Chromite is found in peridotite from the Earth's mantle. It also occurs in layered mafic and ultramafic intrusive rocks which contain olivine, pyroxenes and plagioclase.

Chromite varies widely in composition according to the chemical formula (Mg, Fe^{+2}) (Cr, Al, Fe^{+3})$_2O_4$. Chromium occurs as chromium spinel, a complex mineral containing magnesium, iron, aluminium and chromium in varying proportions depending upon the deposit (Rama et al., 2011).

Chromite is an important mineral due to its usage as alloying materials such as ferrochromium, ferrosilicochromium, and chromium compounds in the metallurgical industry. However, ferrochromium, which is used in making stainless steel, is the most

significant usage area of chromite (Kogel et al., 2006).

Chromite ores are usually concentrated by gravity concentration techniques such as shaking table, jig, spiral, and Reichert cone based on differences in specific gravity between chromite and the common associating gangue minerals and rocks such as serpentine and olivine (Yuce et al., 1998; Cicek, 2002; Onal et al., 2003) Another reason for selection gravity concentration techniques is their simplicity, low operating cost and easy to operate. Therefore, after crushing and grinding, the shaking tables and spirals generally are the basic separation units at chromite plants (Guney et al., 2009)

South Africa, with 80% of world chrome reserves having about 3.1 billion tonnes and a further estimated resource of 5.5 billion tonnes, is one of the major producers of ferrochrome. South Africa produces 75% of the world's ferrochrome for the local and export markets. (Xiaowei, 2013; SSI Holdings, 2014).

In South Africa, chromite concentrating plants generally use gravity separation. For gravity separation, mainly spiral concentrators are preferred, although shaking tables are used in few instances.

In this study, the gravity concentrator tests were carried out using shaking table (Wilfley) and Mozley table in order to evaluate spiral chromite tailings of South Africa. According to the tests results, process flow sheet including material balance was established.

2. MATERIAL AND METHODS

The chromite tailings samples below 2 mm (particle size passing of 80%) used in this study were obtained from the spiral concentrator plant of South Africa. According to the chemical analysis, the sample contains 22.5% Cr_2O_3.

The gravity tests were performed for enrichment of chromite by using gravitational units such as shaking table and mozley table. Due to company's request, it is aimed that final concentrate grades are acceptable between 40-42% Cr_2O_3.

2.1 Gravity Tests with -0.841 mm in Size Material

Original material was ground to below 0.841 mm and size fractions such as -0.841+0.355 mm; -0.355+0.212 mm; -0.212+0.074 mm and -0.074 mm were subjected to the gravity separation tests.

Wilfley and Mozley table tests were carried out for the each particle size fraction. The combined test results are given on Table 1.

Table 1. The combined result of tests carried out below 0.841 mm in size

Product	Weight, %	Cr_2O_3, %	Recovery,%
Concentrate	29.3	41.62	53.9
Middlings	48.6	18.81	40.4
Tailings	22.2	5.73	5.6
Total	100.0	22.59	100.0

According to the overall gravity concentration test results below 0.841 mm; 29.3 % of feeding material can be obtained as a chromite concentrate having 41.62% Cr_2O_3 grade and 53.9 % metal recovery.

As a result of tests at minus 0.841 mm in size, it is seen that the chromite concentrate recoveries are not acceptable. Also, it is understood that the liberation size is not adequate due to the fact that the significant amount of chromite remains in middling. Therefore it was decided to ground the sample to minus 0.355 mm in order to obtain the optimum particle liberation and so increase chromite recovery.

2.2 Gravity Tests with -0.355 mm in Size Material

According to the gravity concentration test results, it was evaluated that the reason for lower concentrate grades are obviously related with liberation of the materials at that size fraction. Therefore, original material was ground to minus 0.355 mm in size,

fractioned and subjected to gravity based concentration tests.

Gravity concentration tests were carried out at size fraction between -0.355+0.150 mm, -0.150+0.074 mm by using shaking table and at -0.074 mm in size by using Mozley table.

Wilfley and Mozley table tests with the different size fraction were performed. The combined test results are given in Table 2.

Table 2. The combined results of tests carried out below 0.355 mm in size

Products	Weight %	Cr_2O_3 %	Recovery %	Cr/Fe ratio
Concentrate	34.7	41.52	62.0	1.347/1
Middlings	36.2	19.27	30.2	1.012/1
Tailing	29.1	6.24	7.8	0.628/1
Total	100.0	23.18	100.0	

It can be seen in Table 2 that 34.6 % of feeding material can be obtained as a chromite concentrate having 41.52% Cr_2O_3 grade and 62.0% metal recovery. Final tailings having 6.24% Cr_2O_3 content can be separated with a 7.8% metal losses.

As a result of tests at minus 0.355 mm, final chromite concentrate grades could not be increased more than 43% of Cr_2O_3 content. According to preliminary estimates; Cr/Fe ratio for chromite concentrates could not be increased more than 1.347/1 due to possible high iron content of concentrates.

2.3. Magnetic Separation Test

In order to investigate the reason of lower ratio of chromite concentrates, belt type high intensity dry magnetic separation test was conducted on concentrate (42.64% Cr_2O_3) obtained from -0.150+0.074 mm size fraction.

In magnetic separation tests; four different magnetic field magnitutes were installed between 0.5 amper (6000 gauss) and 3.5 amper (11.500 gauss). Test result is presented in Table 3.As can be seen from Table 3, there is no significant change for both chromite grades and ratios.

Table 3. Magnetic separation test results on chromite concentrate

Product	Weight, %	Cr_2O_3, %	Cr/Fe ratio
MP1 (0.5 A)	5.2	42.54	1.30/1
MP.2 (1.0A)	16.3	43.47	1.35/1
MP.3 (2.5A)	7.6	43.38	1.36/1
MP.4 (3.5A)	33.7	43.21	1.35/1
NMP (3.5A)	37.2	41.78	1.36/1
Total	100.0	42.70	

MP: Magnetic product; NMP: Non magnetic product

2.4. Development of Process Flow Sheet

According to final test results on ground material below 0.355 mm, process flow sheet including material balance was developed and given in Figure 1.

3. CONCLUSION

The beneficiation of spiral chromite tailings taken from South Africa which contains 22.5% Cr_2O_3, were investigated using combination of gravity units. Gravity concentration tests were conducted on ground samples below 0.841 mm and 0.355 mm separately. At minus 0.841 mm in size, 29.3 % of feeding material can be obtained as a chromite concentrate having 41.62% Cr_2O_3 content and 53.9% metal recovery while 22.2% of feeds can be separated as a tailings containing 5.73% Cr_2O_3. As a result of tests, quite high amount of middlings with a high grade chromite values shows that the ore need adequate liberation and further beneficiation. In order to increase of chromite content and to decresase of middling amount, second group gravity tests on minus 0.355 mm ground material were carried out. According to test results, 34.6% of feeding material can be obtained as a chromite concentrate having 41.52% Cr_2O_3 grade and 62.0% metal recovery. Final tailings having 6.24% Cr_2O_3 content can be separated with a 7.8% metal losses. In that point, it is seen that appropriate liberation size of chromites are still lesser than 0.3 mm in size.

According to preliminary estimates, Cr/Fe ratio for chromite concentrates could not be

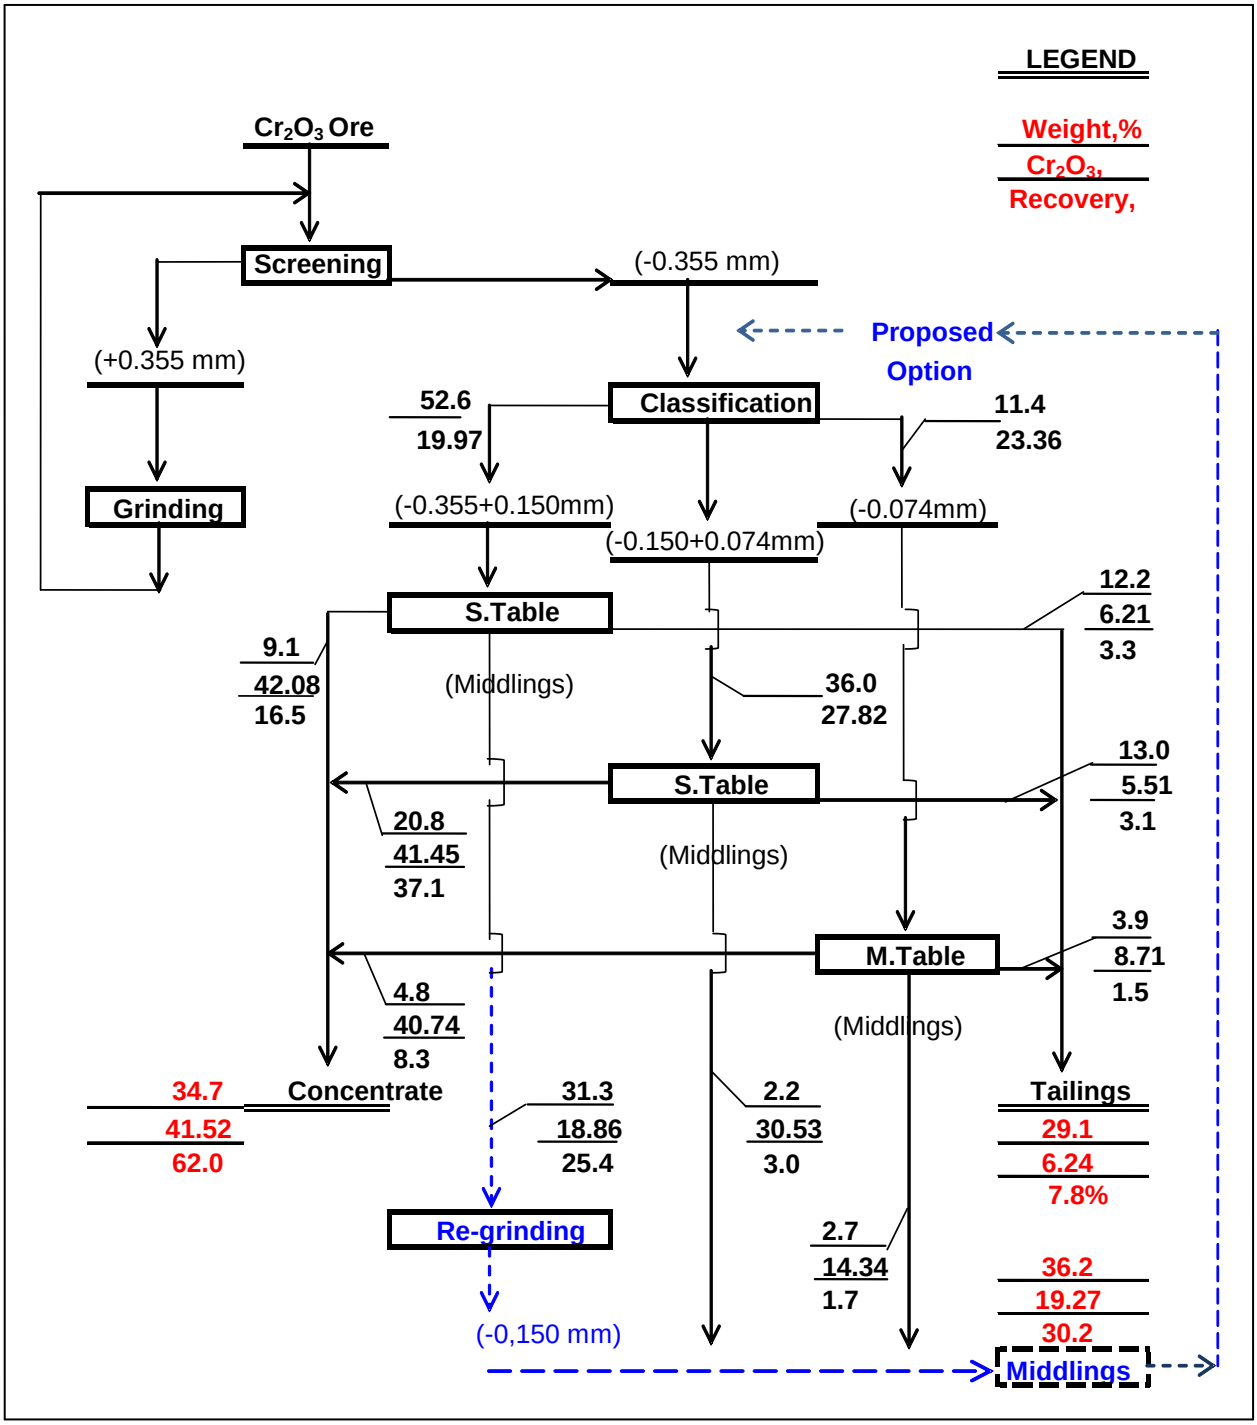

Figure 1. Process flow sheet for -0.355 mm

increased more than 1.347/1 due to possible high iron content of concentrates. Although the high intensity dry magnetic separation test is performed in order to investigate the reasons of lower Cr/Fe ratio, there are no significant changing both chromite grades and ratios.

Recovery of Silver From an Arsenical Silver Ore by Knelson Concentrator and Cyanide Leaching

O. Celep, P. Altınkaya, E.Y. Yazici, and H. Deveci
Hydromet B&PM Research Group, Department of Mining Engineering, Karadeniz Technical University, 61080, Trabzon

ABSTRACT In this study, the recovery of silver from an arsenical silver ore was investigated using a laboratory type Knelson Concentrator and cyanide leaching. Silver was found to be as acanthite, which occurs both as free grains and closely associated with other mineral phases such as quartz, barite, mica and the group of clay minerals. Gravity tests have demonstrated that the silver recovery tends to increase with increasing the rotation speed of bowl or decreasing the fluidizing water velocity. About 30% of the silver was recovered into a concentrate assaying 275 g/t Ag. Cyanide leaching tests have revealed that the silver extraction substantially improved from 60% up to 85% in cyanidation after ultra-fine grinding of the ore to <8 μm (d_{80}). These findings indicate that the ore is not particularly amenable to centrifugal gravity separation. It can be also deduced from cyanide leaching tests that the refractoriness of the ore is essentially physical in character apparently due to the physical encapsulation of silver phases.

Keywords: Arsenical silver, cyanide leaching, silver recovery

1 INTRODUCTION

Extraction of gold and silver from ores can be traditionally achieved using cyanidation method while gravity separation can be also used to recover free and coarse gold/silver particles (La Brooy et al., 1994; Marsden and House, 2006). Gravity separation can be utilized as an option with the possibility of maximizing the net smelter return and improving the overall precious metal recovery. Centrifugal gravity separators have been recently developed to recover even fine gold particles in the gold milling practice (Huang and Mejiab, 2005; Laplante and Nickoletopoulos, 2005).

In centrifugal separators, the application of centrifugal force allows effective capture of fine heavy minerals/metals. The centrifugal force acting on a particle can be equal to or even higher than 50 times the force of gravity. The size of particles that can be recovered becomes finer as the intensity of centrifugal forces generated is increased (Liu et al., 2006). The centrifugal force (Fc) in a centrifugal concentrator can be expressed as (Celep et al., 2006; Alp et al., 2008):

$$Fc = \left(\frac{\pi}{6}\right)(d_p)^3.(\delta_s - \delta_l).\vec{r}.\omega^2$$

Where ‘r’ is the displacement of the moving particle from the rotation axis to its present position, ‘dp’ is the diameter of the particle, ‘δ_s’ is density of the particle, ‘δ_l’is the density of the medium and ‘ω’ is the angular velocity of the particle (Huang, 1996).

The Knelson Concentrator is considered as essentially a hindered settling device with the application of a centrifugal force on particles instead of gravity force. Concentrator consists mainly of a rotating ribbed cone (bowl) and retention zones between the ribs where heavy concentrate is retained (Figure 1). Ore slurry is fed through a central feeding tube to the bottom of the cone and is dispersed outwards by the action of centrifugal force. Heavy (or large) particles are trapped in the retention zone between the ribs while the light particles (or fine particles) are washed away upward into the

tailings stream. Injection of water through small holes located in the retention zones leads to formation of a fluidized and penetrable concentrate bed consisting of heavier particles (Figure 1). The Knelson Concentrator has been successfully applied in the recovery of gold, platinum silver, mercury and native copper (http://www.flsmidth.com) (Figure 2).

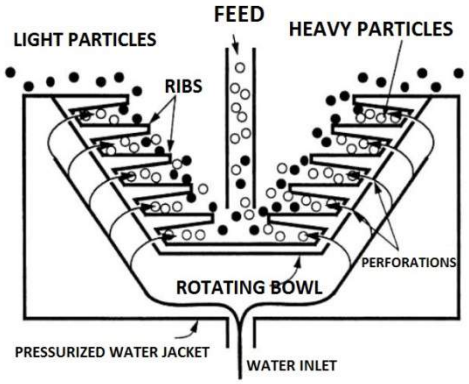

Figure 1. Schematic illustration of a Knelson Concentrator (Kawatra and Eisele, 2001)

In this study, the recovery of silver from an arsenical silver ore was investigated using a laboratory batch type Knelson Concentrator (KC-MD3). In experiments, the effects of fluidizing water pressure and rotation speed was investigated on silver recovery. Furthermore, cyanide leaching of the ore was also studied and effect of fine grinding on silver recovery in cyanide leaching was demonstrated.

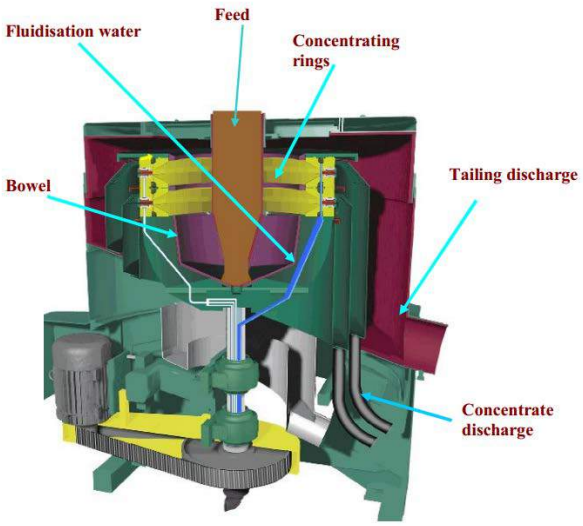

Figure 2. View of Continuous Knelson Concentrator (http://www.flsmidth.com).

2 MATERIAL AND METHOD

In this study, an arsenical silver ore (Turkey) were used. The ore sample was prepared for the experiments by crushing in a jaw crusher (-4 mm) and ground down to 106 µm in a rod mill at 50% pulp density (Figure 3). The chemical composition of the ore sample (Table 1) was determined using ICP-ES (Inductively Coupled Plasma-Emission Spectroscopy) after four acid digestion, fire assay fusion and X-ray fluoressans (XRF). Silver content of the ore was determined by fire assay method with a gravimetric finish. The ore contains 63.7% SiO_2, 11.7% Al_2O_3, 1.31% As and 127 g/t Ag.

Detailed mineralogical characterization of the ore sample with particular reference to the mode and occurrence of silver was also performed. The ground ore sample was split using a Quantachrome Mini-riffler to obtain representative sub-samples, which were used to prepare a number of resin mounts. Polished mounts were examined for MLA using an FEI Quanta 600F scanning electron microscope (SEM).

Table 1. Chemical composition of the ore sample used in the study

Compound	Content (%)	Element	Content (g/t)
SiO_2	63.7	Ag	127
Al_2O_3	11.7	As	1.31%
$BaSO_4$	5.5	Zn	7182
Fe_2O_3	5.19	Pb	7252
CaO	0.73	Sr	491
MgO	0.69	Sb	699
Na_2O	0.2	Ni	245
K_2O	4.14	V	86
TiO_2	0.47	Zr	148
P_2O_5	0.16	U	8
MnO	0.2	Cd	103
Cr_2O_3	0.068	Ga	13
Tot. S	0.99	Tot. C	0.21
LOI	7		

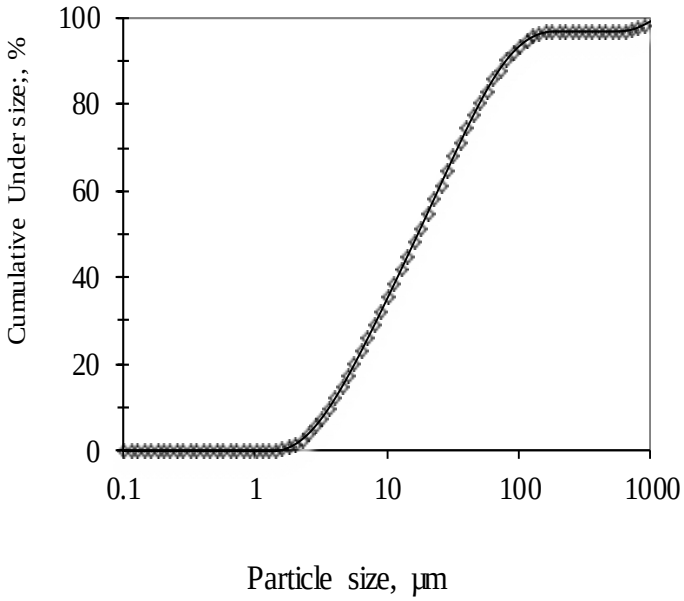

Figure 3. Particle size distribution of the ore sample used in gravity tests and in ultra-fine grinding

Ultra-fine grinding of the ore before cyanide leaching was conducted using 2 mm ceramic ball in a laboratory scale pin-type vertical stirred at 26%w/w solid-liquid ratio and 600 rpm stirring rate. The particle size analysis of sample was performed using the laser diffraction method by Malvern Mastersizer 2000 MU.

The ground ore samples (-106 µm) were subjected to Knelson gravity separation. The experiments were carried out using a laboratory batch type Knelson Concentrator (KC-MD3) (Figure 4). The operating conditions of Knelson Concentrator for the recovery of silver from the ore are presented at Table 2.

Table 2. Experimental conditions

Parameters	Unit	Value
Pulp density	%	6
Water flowrate	L/min.	1-3-5
Rotation Speed	rpm	500-1250-2000
Particle size	µm	106

Bowl rotation speed [500 rpm (11.2 G-force), 1200 rpm (28 G-force), 1500 rpm (100 G-force) and 2000 rpm (179 G-force)] and fluidizing water velocity (1 L/min., 3 L/min. and 5 L/min.) were investigated as parameters. Feed pulp was prepared at ≈6% solids by weight in volume of 500 mL. Agitation of pulp was performed using IKA RW-20 type overhead stirrer equipped with a 45° pitched blade turbine (four blade, 50 mm in diameter) for 15 min. The dispersed slurry was fed to the Knelson Concentrator at a rate of 15 g/min. Overflow (tailings) was collected in a bucket while concentrate remained in the bowl. The bowl content (i.e. the concentrate) and tailings were washed into beakers. After dewatering, the products were dried and weighed. Products were digested with aqua regia and analyzed for silver using Atomic Absorption Spectrometer (Perkin Elmer-AAS 400).

Figure 4. A photograph of Knelson Concentrator used in experiments

The cyanide leaching tests (1.5 g/L NaCN, 0.3 L/min air) were conducted in overhead-stirred glass reactors over a period of 24 h. The concentration of NaCN in solution was monitored by silver nitrate titration (0.02 mol/L $AgNO_3$) using p–dimethylamino–benzal–rhodanine (0.02% w/w in acetone) as the indicator. Sodium cyanide was added, if

required, to maintain the concentration of titratable NaCN at the predetermined level (1.5 g/L) over the leaching period. The consumption of cyanide was determined. pH was controlled at ≅10.5 by the addition of 1 M NaOH. Pulp (25% w/w) was stirred at 450 rpm.

3 RESULTS AND DISCUSSION

3.1 Mineralogical characterization

The mineralogical analysis indicated that the ore is composed of mainly quartz, barite, mica and the group of clay minerals. Silver (127 g/t) was found to be present mainly as acanthite, which occurs both as free grains (57 wt %) and closely associated with and/or encapsulated in other mineral phases that can restrict the contact of cyanide with silver (Figure 5).

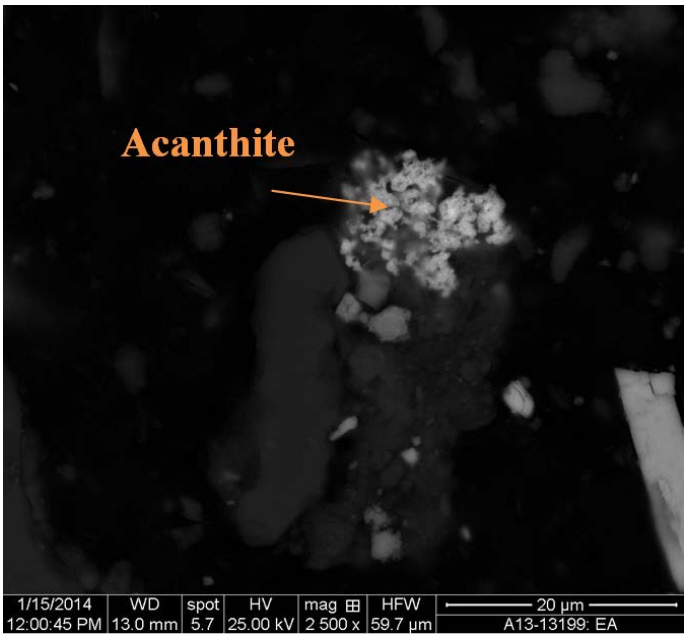

Figure 5. An acanthite grain in a particle that is composed of quartz, K-feldspar, Pb-Fe illite and muscovite

3.2 Gravity Recovery of Silver From Ore using a Knelson Concentrator

The silver recovery appears to increase with increasing the rotational speed of bowl or decreasing the fluidizing water velocity (Figure 6). Silver recovery was determined to be 30% into a concentrate that assayed 275 g/t Ag at 500 rpm rotation speed and 3L/min. fluidizing water velocity(Figures 6 and 7). Increasing bowl speed and flowrate of fluidization water improved silver recovery at the expense of reduced separation efficiency (e.g. 58.4% recovery, 150.6 g/t Ag grade and 10.1% mass yield at 2000 rpm bowl speed and 5 L/min fluidized water). High bowl speeds allows the recovery of even fine heavy particles. Increasing the flowrate of fluidizing water leads to the cleaning of concentrate in the retention zone.

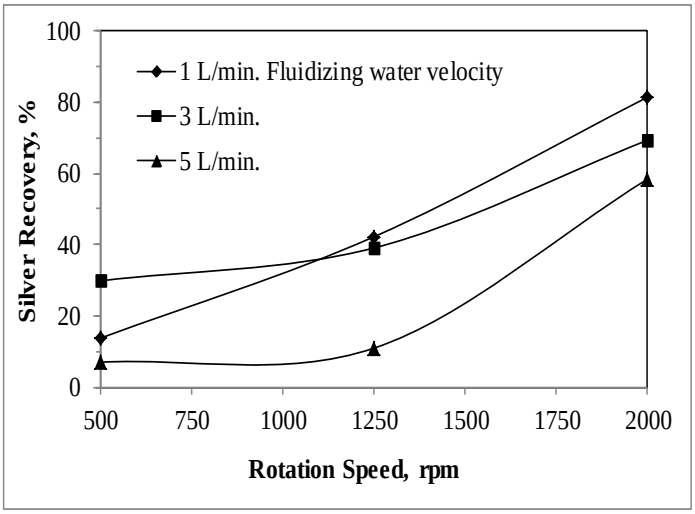

Figure 6. Effects of rotation speed and fluidizing water velocity on silver recovery

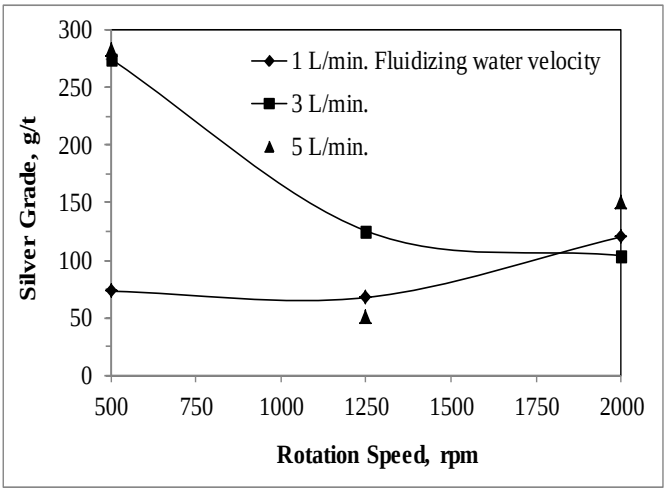

Figure 7. Effects of rotation speed and fluidizing water velocity on silver grade

3.3 Cyanidation of the ore

Effect of fineness of grind on silver extractions is shown in Figure 8. Silver extraction was observed to improve from 60% to 71% when the particle size was

decreased from 200 µm to 50 µm (d80) by conventional grinding. Similarly, silver extraction increased up to 85% after ultra-fine grinding of the ore down to 8 µm (d80) in the stirred mill. This enhancement in the level of silver extraction was attributed to the increased availability of silver for cyanide leaching. These findings also suggest that ultra–fine grinding is an appropriate pre–treatment method for the ore ahead of cyanide leaching. It can be also deduced that the refractoriness of the ore to cyanide leaching is partially physical in nature.

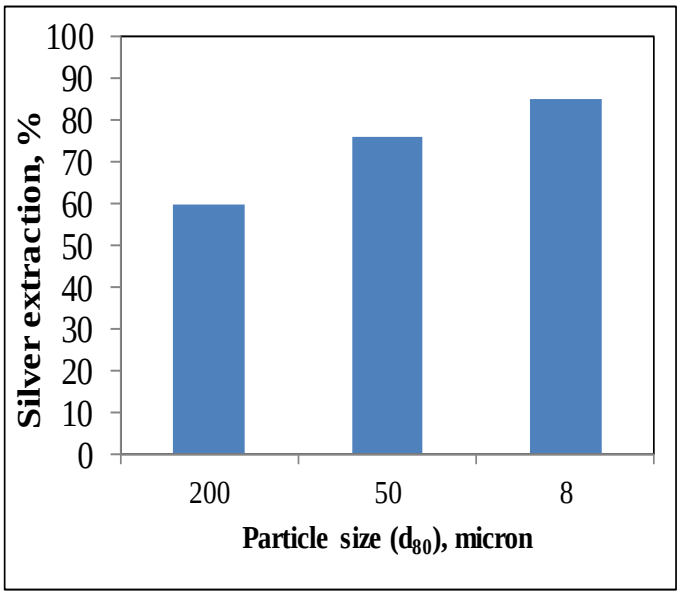

Figure 8. Extraction of silver from direct cyanidation of the ground ore (d_{80}: 50 µm and 200 µm) and after ultra-fine grinding (d_{80}: 8 µm)

4 CONCLUSIONS

In this study, the amenability of an arsenical silver ore to centrifugal gravity separation and cyanide leaching was demonstrated. Acanthite appears to be the main silver phase and occurs both as free grains and closely associated with and/or encapsulated in other mineral phases such as quartz, barite, mica and the group of clay minerals. Gravity separation tests have shown that bowl speed and fluidizing water flowrate are significant parameters affecting the recovery and grade. However, the findings suggest that the ore is not amenable to the gravity separation as indicated by low separation efficiency. Cyanide leaching tests have also revealed that silver extraction improves with decreasing the particle size of the ore apparently due to the increased availability of silver phases for cyanide. This indicates physical nature of refractoriness of the ore.

ACKNOWLEDGEMENTS

The authors would like to express their sincere thanks and appreciation to the Research Foundation of Karadeniz Technical University (Project No: 9200) and TUBITAK (Project No: 213M539) for the financial support and to Yıldızlar Holding for kindly providing the samples.

Effect of Hot Water Absorption on the Flexural Properties of Jute Mat Fiber Reinforced Polymer Matrix Composites

E. A. Elbadry
Mining and Metallurgical Engineering Department, Faculty of Engineering, Assiut University, Assiut 71515, Egypt

ABSTRACT Recycled needle punched natural jute fiber mats with 32 % by vol. fiber volume content were used as reinforcement for unsaturated polyester matrix composites. This study intended to study the durability of jute mat composites by investigating the flexural properties of jute mat composites including flexural strength and modulus under the effect of hot water absorption at 100oC for 96, 192, 384 h immersion times compared to the virgin specimens. The results showed that as the immersion time of the composites increases, the water absorbed by the composites increases and so the thickness swelling increases. As a result of that, the flexural strength and modulus of jute mats composites decrease compared to the virgin specimens. On the other hand, when the immersed specimens are dried for 6 hours, the flexural strength and modulus of the composites was recovered compared to the immersed specimens due to the decrease in the absorbed water content.

Keywords: Jute mat composites; Flexural properties; Water absorption; Swelling; Interface.

1 INTRODUCTION

Natural fiber composites are nowadays widely used instead of synthetic fibers due to their advantages like biodegradability, low weight, low cost and high specific mechanical properties, however the incompatibility with the hydrophobic polymer matrices and poor resistance to moisture absorption reduce significantly the mechanical properties of the natural fibers reinforced composite materials [1-5].

However, because of the hydrophilic nature of the fiber, the use of natural fiber reinforced composites requires to know their behavior in a wet environment including water and other chemical solutions. Research investigations showed that the exposure of vegetal fiber composites in a wet environment leads to a decrease of the mechanical properties when subjected to wet environment. Studies of the water absorption on the different mechanical properties of some natural fibers such as jute, palm, bamboo, flax, kenaf, and hemp composites have been reported in the literature [6–12].

Natural fiber composites can be used in indoor and outdoor applications and as a result of those natural fiber composites may be subjected to water, therefore the study of the effect of water on the mechanical properties of the composites became very urgent. In this work, the flexural properties of jute mat composites including flexural strength and modulus will be investigated in terms of hot water absorption and thickness swelling of the composites.

2 EXPERIMENTAL ROCEDURE

2.1 Materials

Jute fiber mats consisting of 50% jute slivers and 50% recycled jute were prepared by Yano Co.LTD, Japan with three jute mats layers with 32 % by vol. fiber volume content. Unsaturated polyester, RigoracTM was obtained from Showa Denko K.K., Japan and the curing agent is Methyl ethyl ketone peroxide (PERMEK® N) obtained from NOF Corporation, Japan.

2.2 Preparation of the Composites

Jute mats were dried for 6 h at 1000^{o} C and were completely submerged in unsaturated

polyester resin. The next step which differentiates the modified technique over the conventional technique is that the jute mats were degassed in a vacuum for 20 minutes at room temperature to remove the entrapped air bubbles and the details were mentioned in [13]. Sheets were prepared with 32 % by vol. fiber volume content and the specimens of required dimensions were cut from the sheets and used for testing.

2.3 Mechanical Characterization

2.3.1 Hot water absorption of the composites

Hot water absorption test of the composites was carried out by immersing the test sample in hot water in boiler at 100°C for 0, 96, 192, and 384 hours. After immersion, the specimens were taken out from the water and all surface water was removed with a clean dry cloth. The specimens were reweighed by sensitive digital balance. The moisture absorption was calculated by the weight difference. The percentage weight gain of the samples was measured at different time intervals and the moisture content and the weight excess versus the time was plotted. Six samples were selected for each time interval and three specimens were dried in a drying oven at 100°C and the other three specimens were lifted without drying. These specimens with and without drying were then tested under three point bending test for each case.

2.3.2 Three point bending test of the composites

Three-point bending test was also done using the same machine according to ASTM D 790-03 at a crosshead speed of 1mm/min. with sample dimensions of 140×18×6 mm and the span to depth ratio was 16:1 and three testing specimens were prepared for different cases and for the virgin specimens.

3 EXPERIMENTAL PROCEDURE

3.1 Hot Water Absorption Of The Composite

Water absorption of the composites after immersion in hot water at a specific time can be calculated by the following equation:

$$\Delta W(t) = \frac{w_t - w_o}{w_o} \times 100 \qquad (1)$$

Where $\Delta W(t)$ is the water absorption of the composites and w_t, w_o are the weight of the samples after immersion in hot water at time t and before immersion, respectively.

In order to show the water diffusion in jute mat composites, water absorption of the composites in terms of weight gain versus square root of soaking time is illustrated in Fig. 1. It can be observed that the weight of the composites increases as the time of immersion increases due to the increase of the water absorbed by the composites as shown in Fig. 1. Moreover, water sorption behavior of jute mat composites at 100oC displayed a pseudo-fickian behavior where a saturated moisture level had not been attained at the end of the 16 days aging period and initial uptake is rapid and characterized by linear dependency on square root of immersion time ($t^{1/2}$) followed by a slow approach to final true equilibrium, as shown in Fig. 1.

On the other hand, when the immersed specimens are dried for 6 h, the water absorbed by the composites was significantly decreased compared to the immersed specimens without drying as was shown in Fig. 1.

A plausible cause is that internal degradation of jute fiber and jute fiber-matrix interface continues to occur with soaking time. As the immersion time of the composites in hot water increases, the water absorbed by the composites increases and therefore this will have a high significant effect on internal degradation of jute fiber and jute fiber-matrix interface.

The resistance to absorb the water by these jute mat-unsaturated polyester composites is higher compared to that of hemp-unsaturated

polyester composites of the same nearly volume fraction prepared by [7] which hemp-unsaturated polyester composites reaches the same water absorption faster than jute mat-unsaturated polyester composites.

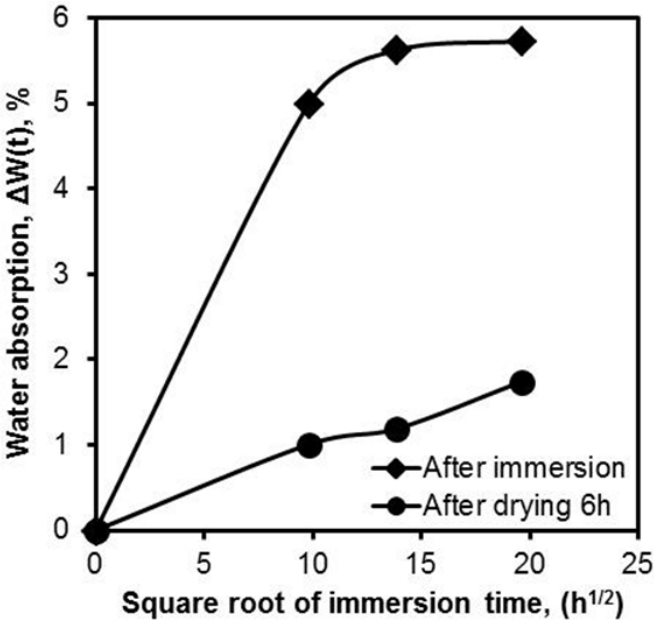

Figure 1. Water absorption at 100°C of jute fiber mats composites.

3.2 Changes Of Flexural Properties By Aging

$$\sigma_f = \frac{3PL}{2bd^2} \quad (2)$$

Where P is the load (N), L is the length of support span (mm), b is the specimen width (mm), and d is the specimen thickness (mm). The flexural modulus (E_f) was calculated using:

$$E_f = \frac{L^3 m}{4bd^3} \quad (3)$$

Where m is the slope of the initial straight line portion of the load-deflection curve.

According to Eldadry et al. [13] the flexural strength and modulus of Jute mat composites was improved at 32 % by vol. As a result of that the test of hot water absorption was carried out for the jute mat composites at 32 % by vol. to determine the mechanical efficiency of these composites when subjecting to hot water.

Stress-displacement curves of jute mat composites after immersion in hot water for different time of immersion compared to those of virgin composites are shown in Fig. 2.

It can be observed that all composites at different times of immersion exhibit the linear response and as the time of immersion increases, the flexural strength and modulus decrease compared to the virgin specimen are shown in Figure 2.

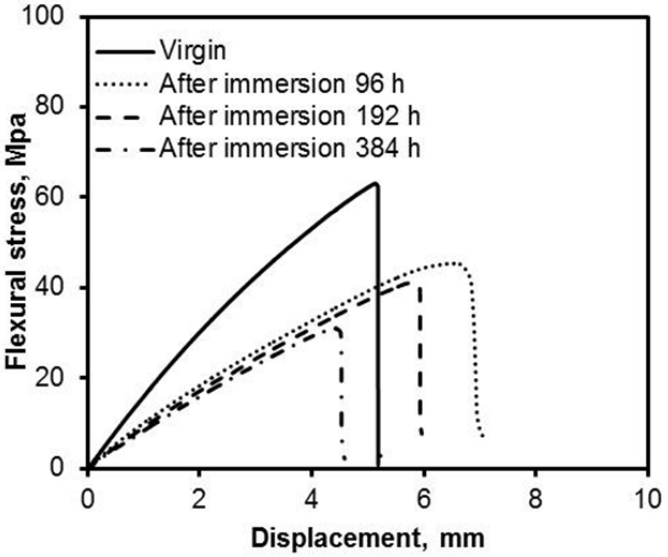

Figure 2. Stress-displacement curves of jute mats fiber composites after immersion for different immersion times.

On the other hand, Stress-displacement curves of immersed jute mat composites after drying for 6 hours compared to virgin composites are shown in Fig. 3. It can be observed that the same behavior as immersed specimens but the flexural strength and modulus were enhanced compared to those of immersed specimens as shown in Figure 3 compared to Figure 2.

Degradation of mechanical properties of jute mat composites depend on the amount of water uptake, soaking time, and temperature at which aging is carried out. The effect of immersion time on the flexural strength and modulus of jute mat composites compared to virgin specimen is displayed in Fig. 4 and 5, respectively. It can be observed that flexural properties decrease after water immersion which can be related to the weak fiber–matrix interface due to water absorption.

It can also be observed that the strength of the composites decreases when the composites were immersed in hot water for different immersion times compared to that of the virgin specimen as shown in Fig. 4. On the other hand, when the immersed specimens are dried for 6 hours, the strength of the composites was slightly recovered compared to the immersed specimens due to the decrease in the absorbed water content as was shown in Figure 1.

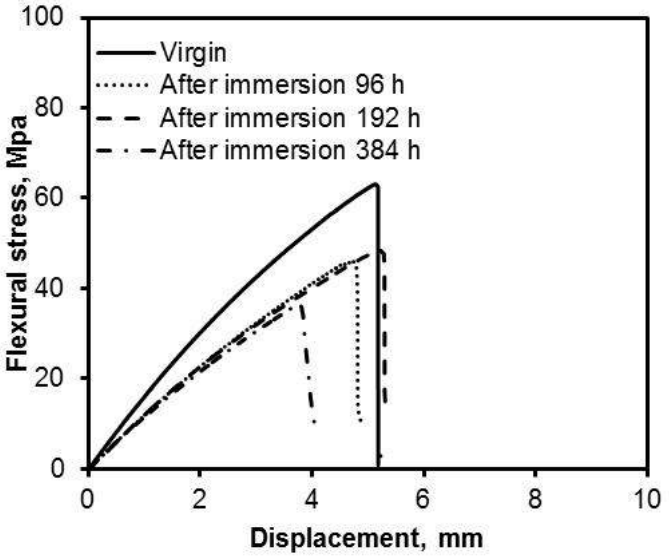

Figure 3. Stress-Displacement Curves Of The Immersed Jute Mats Fiber Composites After Drying For 6 H At 100^{o}c.

The effect of immersion time on the flexural modulus of jute mat composites compared to virgin specimen is displayed in Figure 5. It can be observed that the flexural modulus of the composites decreases compared to that of the virgin specimen when the composites were immersed in hot water for different immersion times as shown in Figure 5.

Moreover, as the time of immersion increases, the modulus of the composites has significantly decreased due to the higher absorption of hot water by the composites with longer immersion times as was shown in Figure 1. On the other hand, when the immersed specimens are dried for 6 hour, the modulus of the composites was recovered compared to the immersed specimens due to the decrease in the absorbed water content as was shown in Figure 5.

The thickness swelling of the composites after immersion in hot water at a specific time can be calculated by the following equations:

$$\Delta S(t) = \frac{s_t - s_o}{s_o} \times 100 \qquad (4)$$

Where ΔS(t) is the thickness swelling of the composites and s_t, s_o are the thickness of the samples after immersion in hot water at time t and before immersion, respectively.

The swelling of the composites as a result of hot water absorption versus square root of soaking time is illustrated in Figure 6. It can be observed that the swelling of the composites increases as the time of immersion increases due to the increase of the water absorbed by the composites.

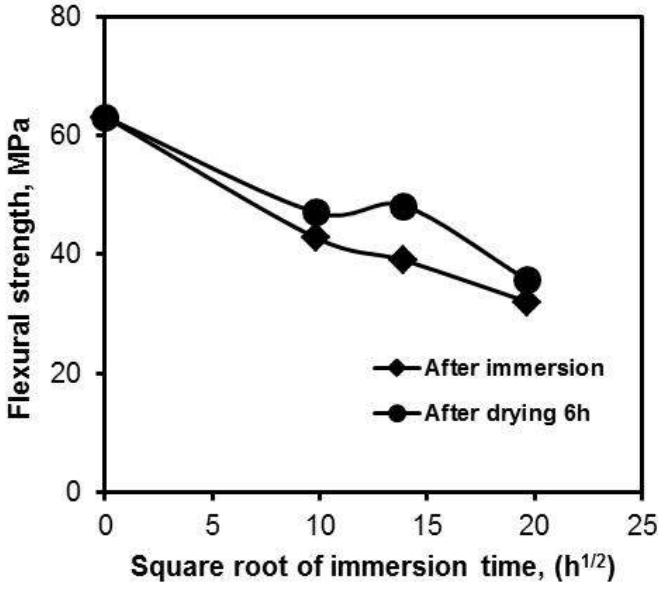

Figure 4. The effect of the immersion time on the flexural strength of jute fiber mats composites.

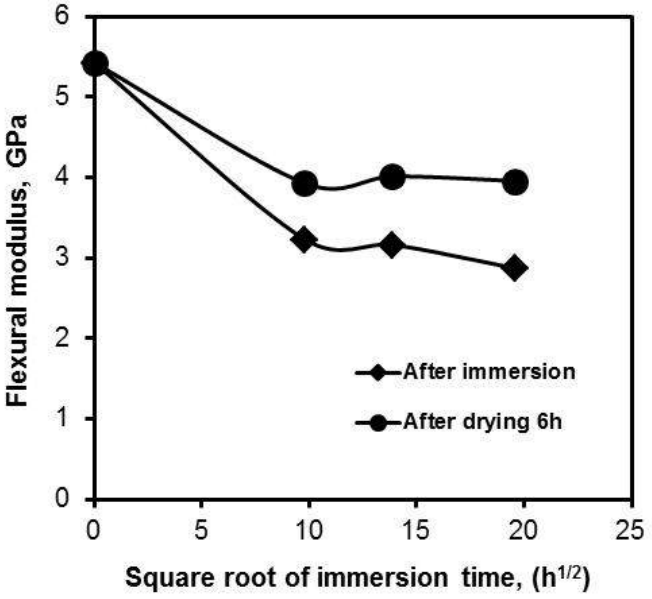

Figure 5. The effect of the immersion time on the flexural modulus of jute fiber mats composites.

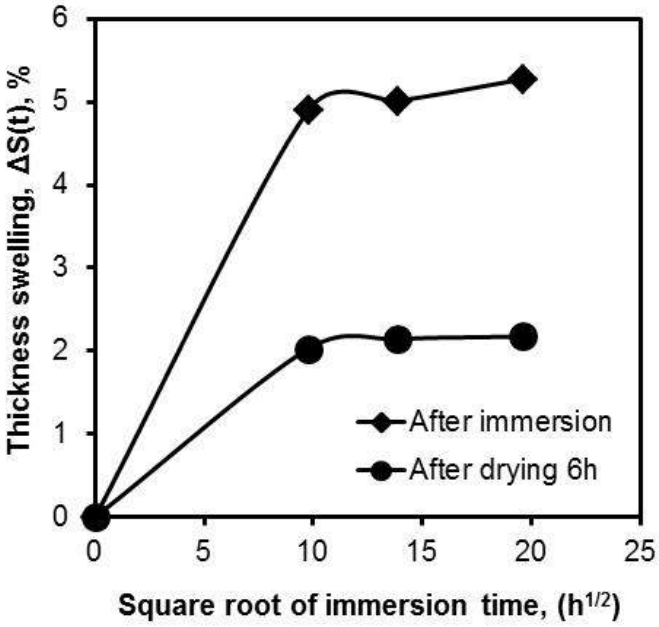

Figure 6. Thickness swelling of jute fiber mats composites.

The composite swelling of these jute mat reinforced polyester composites is lower than as that of jute and palm reinforced epoxy composites as reported by [9]. On the other hand, when the immersed specimens are dried for 6 h, the swelling of the composites was significantly decreased from around 2% to about 5% compared to the immersed specimens due to the decrease in the absorbed water content as was shown in Fig. 6.

The way in which the material absorbs water depends on many parameters, such as hygrometric rate, temperature, fiber fraction, fiber nature, porosity fraction, reinforcement geometry, matrix type. The transport of water can be facilitated by its diffusion inside the resin, by the presence of defects within the matrix, formed during the compounding process (micro-space, pores or cracks) or by capillarity along interfaces which present some defects between the fibers and the resin [14]. As the composite cracks and gets damaged, capillarity and transport via micro cracks become active. The capillarity mechanism involves the flow of water molecules along fiber–matrix interfaces and a process of diffusion through the bulk matrix. The water molecules are actively attack the interface, resulting in debonding of the fiber and the matrix [8].

The high cellulose content in jute fiber further contributes to absorb high amount of water and therefore, more water penetrating into the interface and the high water temperature enhance the dissolution of jute components which leads to a weak interfacial bonding between the fiber and the matrix and so this will lead to degradation of the flexural properties. Moreover, Differences in both thermal and moisture expansion coefficients of fibers and matrix also contribute to progressive debonding and therefore this will contribute in the weakening of the composites.

To understand deeply the detrimental effects of water on mechanical properties of the composite, the future work study may be concerned to study the effect on the constituents of the composites, the fiber, the matrix, and the fiber/matrix interphase region through microstructure examination at different immersion times.

4 CONCLUSIONS

The results showed that as the immersion time of the composites increases, the water absorbed by the composites increases and so the thickness swelling increases and therefore, the flexural strength and modulus of the composites decrease compared to the

virgin specimens. On the other hand, when the immersed specimens are dried for 6 hours, the flexural strength and modulus of the composites was recovered compared to the immersed specimens due to the decrease in the absorbed water content.

Influence of the Impurities on the Quality of Kaolin Collected From the Field of DjebelDebbagh, Algeria

M. Laraba
University of Tébessa, Tébessa city, Algeria

A. Roula
University of Jijel, Jijel city, Algeria

ABSTRACT Kaolin is a common clay mineral with general formula: Al2(OH)4Si2O5, discovered at the origin in China. Kaolin is characterized by high reflectivity, inertness, fine particle size and low fluid viscosity. Because of these properties, it has many industrial uses and applications: paper filling and coating, in the production of ceramics and porcelain as well as in fiberglass, paint and plastic industry.

The aim of this study was to determine the influence of the kaolins impurities on their quality. For this reason, we took 2 kaolins samples from the mine of DjebelDebbagh (DD2 and DD3), situated in the East of Algeria.

The chemical analysis with XRF, show the DD2 sample is a kaolin alumina-silicate of the first order, and very low (traces) impurities like Fe_2O_3 and TiO_2, and the whiteness is very high which places it among the kaolin most sought by various industries. The presence of MnO in DD3, gives a gray color to the kaolin.

The mineralogical analysis with XRD, show that the most peaks of DD2 present as kaolinite phases and there is no impurities, which is nearly in conformity with the structure of a halloysite. The sample DD3 contains as impurities phases; manganese and organic matters, therefore a valorization is necessary to eliminate these impurities.

Keywords: kaolin, impurities, chemical analysis, mineralogical analysis.

1 INTRODUCTION

Kaolinitic clay is a versatile industrial mineral. The oldest known use of the clay is as a ceramic raw material. Presently, the clay also finds application as a coating and filler pigment for paper, as a filler for paint, rubber, insecticide, formulation of medicine, cosmetics, etc. The main characteristic, which determines the utility of the clay for various applications, is its purity. Pure kaolinite ($Al_2O_3.2SiO_2.2H_2O$) is white in color and its chemical composition is 46.54% SiO2, 39.50% Al2O3 and 13.96% H2O (Grimshaw, 1971).

Presence of impurities, particularly iron- and titanium-bearing materials, imparts color to kaolin. The mined kaolin is usually associated with various impurities like quartz, anatase, rutile, pyrite, siderite, feldspar, etc., depending on the origin and depositional environment (Grimshaw, 1971). These impurities impair the characteristics of kaolin and affect its utility for various end applications.

Kaolin generally presents different features in the same deposit. This deposit has a hydrothermal formation and is close to the repute thermal sources (Lalmi Khier, 2008).

The quality of this kaolin change with the lodes of extractions, some lodes give an appearance very white, on the other hand, the others are characterized by a color, which varied between gray and blackish color.

The treatment method used for this kaolin is the manual sorting, where the workers select the good quality of kaolins and they leave the bad quality.

Kaolin marketed, satisfied generally the following conditions:

- To remain white after burning to 1400°C;
- To present a maximum diameter of the grains (generally 20µm), doesn't exceed 50 - 63µm;
- To contain at least 80% in weight of kaolinite (BelamriZehira, 2008).

Kaolin minerals depend on the amount and nature of the mineral impurities associated to it. Although these methods are quite useful in removing impurities, they are, at the same time, costly, complicated and environmentally hazardous (Rawlings D.E., 2004).

In this study we took 2 kaolin samples from Djebel Debbagh mine (DD2 and DD3), situated in the East of Algeria. To characterize these samples, XRF and XRD techniques have been used and then to study the influences of the impurities on the quality of our kaolin. .

1.1 Geographic Situation

The DjebelDebbagh mine is situated at 35 km to the Northwest of Guelma city and at 7 km in the N-NE of the thermal sources of HammamDebbagh (ex Meskhoutine) (Figure 1).

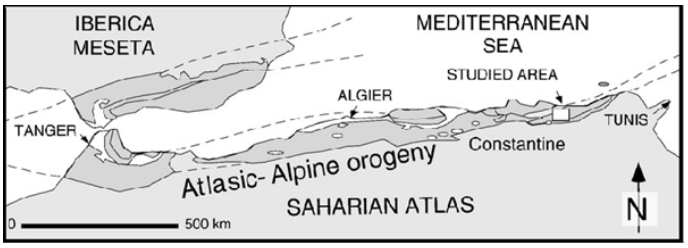

Figure 1.Geographic Situationof DjebelDebbagh(C. Renac et al, 2009)

This massif belongs to the most important chalky chains of the Constantinois neritic mole (marine sedimentation); it's lengthened on meadows of 10 km from east-west and large of 3 km from the North to the South(ENOF, 2004).

The Djebel Debbagh layer is located in the karstics cavities. Currently 74 karstics cavities exist on the whole layer (ENOF, 2008). He presents two parallel crest lines oriented East-west, His altitude varies from 700m to 1060 m (Soalka SPA, 2012).

2 MATERIALS AND METHODS

Two kaolins samples (labeled DD2 and DD3) have been collected from Djebel Debbagh mine, following criterion of different color, as raw materials, were accordingly characterized. These samples are presented in the below figures.

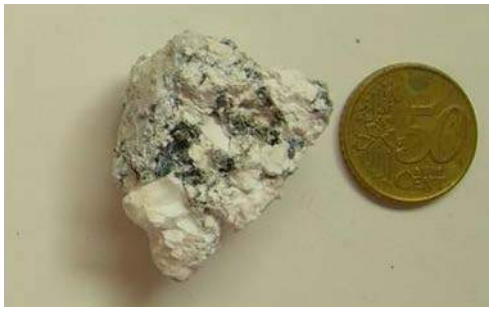

Figure 2. White-Gray kaolin D2

Figure 3. Blackish kaolin KDD3

We can see in the two figures that the colors are different between DD2 witches is white-gray and DD3 witches is blackish.

2.1 Characterization of Kaolin DD2 and DD3

Our kaolin has been characterized in order to have the necessary information for this research.

2.1.1 DRX Analysis

The nature of the present phases has been subtracted from the diagrams of diffraction X-rays (XRD) gotten in 30 min. of acquisition

The XRD diagrams of the different kaolin are presented in the figure 4 and 5.

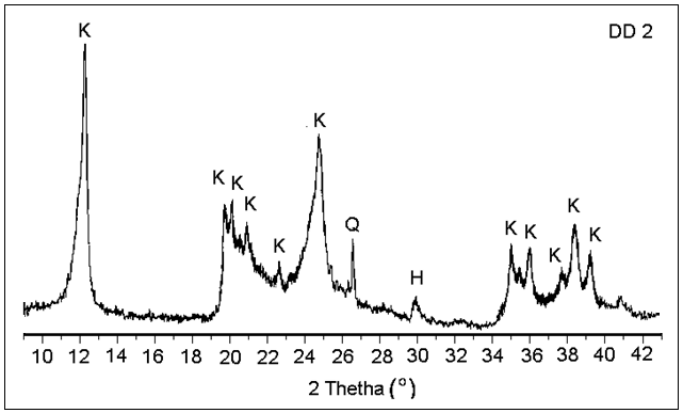

Figure 4. XRD Diagram of DD2; (K): Kaolinite, (Q): Quartz, (H): Henritermierite.

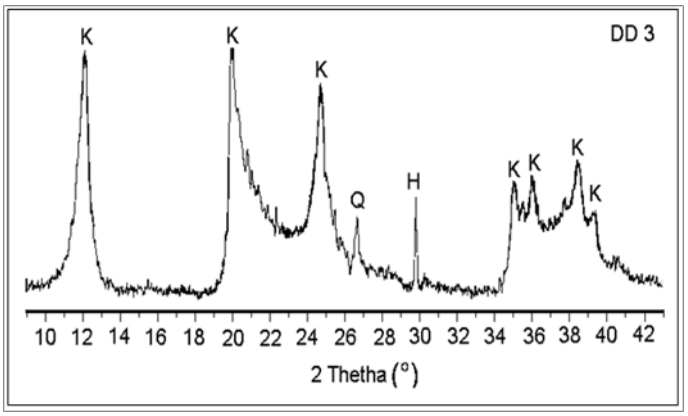

Figure 5. XRD Diagram of DD3; (K): Kaolinite, (Q): Quartz, (H): Henritermierite.

In the two cases, the most intense stripes are to 2θ = 12.30°, 19.85° and 24.85°, characteristics at a time of the kaolinite and the halloysite.

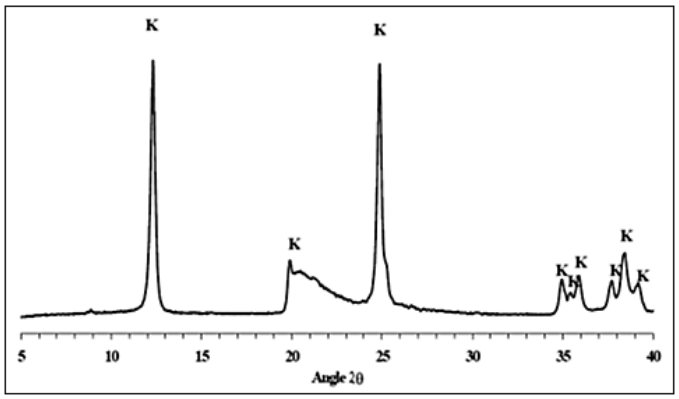

Figure 6. X RD Diagram of KGa-2 (K : Kaolinite)

2.2 Comparison of Kaolin DD2 and DD3 with Kga-2

2.2.1 Kaolin Cristallinity

The clayey minerals generally include crystalline default. For example, in the nature, the kaolinites exists under shape going very well of the crystallized to very disorganized. (D. N. Hinckley, 1962)

The XRD powder diagrams indicate the influence of crystalline state on the form of the diffraction stripes feature of kaolinite: some intense and fine stripes (peaks) become diffuse, and badly determined, with increasing of the structural disorder and stacking default of the kaolinite leaflets.

The physico-chemical properties of kaolinites are strongly dependent on the nature and the quantity of defaults.

Numerous empiric relations have been established in order to estimate this crystalline disorder. They are based on the intensity, the height and the form of diffraction peaks strips (hk0).

When the crystalline disorder increases in the plan (a, b), the corresponding stripes become larger and their intensities decrease. They can even constitute some wholes without distinct peaks.

The most used cristallinity indices is the one described by Hinckley (W. D. Kingery et al, 1076), sensitive to the defaults set presents in the plan (a, b), he is defined from the strips peaks (02*l*) and (11*l*) (figureII-2) while using the relation:

$$HI = \left(\frac{A+B}{At} \right)$$

Where

- A and B are respectively, the heights of strips (02*l*) et (11*l*)
- At : is the height of pic (110) measured from the continuous bottom existing in the outside of these strips.

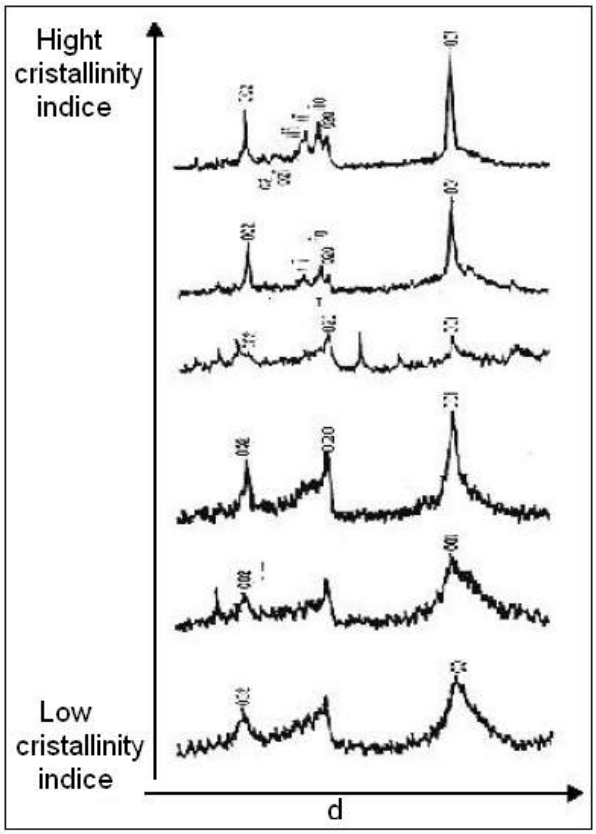

Figure 7. Variation form of stripes (001) and (002) of kaolinite with stacking defaults (J. M. Amigo, 1994)

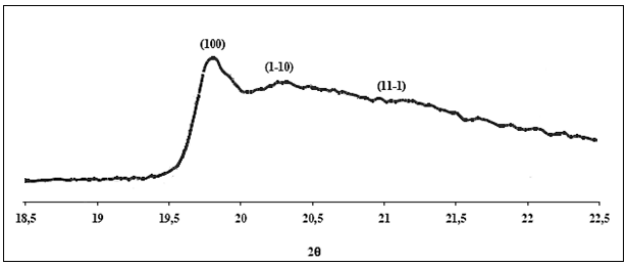

Figure 7. Strip (02) and (11) of XRD specter kaolin (KGa-2)

2.2.2 Chemical composition

Table 1 gives the contents of the different oxides present in the tow kaolins. We compared DD2 and DD3 with reference kaolin KGa-2, relatively pure, coming from the state of Georgia (USA). This kaolin was already the subject of many studies (B. Tchoubar, et al 1982), (Jean-Paul Legros, 2007), (N. S. Soro, 2003), its chemical composition has been determined by ICP (B. Tchoubar, et al 1982)..

Table 1: chemical composition of DD2, DD3 and the reference of KGa-2, (%).

Elements	KGa-2	DD2	DD3
SiO_2	43.90	43,58	42,57
Al_2O_3	38.5	38,14	37,84
TiO_2	2.02	--	--
Fe_2O_3	1.13	0.09	0, 14
K_2O	0.0065	--	--
Na_2O	0.005	--	--
MnO	0, 00	0, 59	1, 49
MgO	0, 03	0, 32	0, 11
CaO	--	0, 05	0, 21
LOI	13, 72	16, 18	16, 80
Whiteness /color	> 85%	withe-Gray	Blackish

The KGa-2 kaolin show that the Al2O3/SiO2 report is equal to 0.88, that the contents in TiO_2 and Fe_2O_3 are relatively important and that the loss in ignition is 13, 72%. While comparing these results with the results gotten for the DD2 and DD3, we remark that the Al_2O_3/SiO_2 reports are near; on the other hand the loss in ignition of the order of 16% are superior to those gotten with the KGa-2 kaolin.

2.2.2 Mineralogical composition

Table 2 presents the mineralogical composition of DD2, DD3 and the reference KGa-2

The research of minerals composing DD2 and DD3 kaolin is led by X-rays diffraction. The indexing of the peaks watches that three main crystalline phases constitute DD2 and DD3 kaolin, the first is represented by the kaolinite that is extensively present. The second phase is the Al $(OH)_3$ gibbsite, carrier of alumina, and Finally a third phase that is carrier of the manganese with elevated ratio in DD3.

We don't discover the presence of quartz, certainly; this kaolin is very little soiled by the free silica. Some peaks remain unidentifiable.

Table 2: Mineralogical composition of DD2, DD3 and the reference KGa-2 in (%)

Sample	Kaolinite	Illite	Quartz	Anatase	Organic matters
DD2	85	---	14	---	<1
DD3	60	---	35	---	<5
KGa-2	97	---	<1	< 2	---

The richest kaolin in kaolinite is DD2 (85%) compared with the DD3 kaolin (60%), at the same time the DD2 kaolin is close to the composition of KGa-2 kaolin.

The mineralogy of KGa-2 kaolin studied by the XRD, show that kaolin is essentially constituted of the kaolinite (97%).

3 RÉSULTS AND DISCUSSION

The silica and alumina are the majority constituent oxides in our sample.

The SiO_2/Al_2O_3 reports of DD2 is 1.14 instead of 1.1 for the pure kaolin, This gap suggests the presence of free silica (quartz), on the other hand for the DD3 is equal to 1.12 which also confirms the presence of the free silica. , these values indicate that the quality of our kaolins is varied, the DD2 characterized by a middle quality, the second DD3 characterized by a weak quality.

We remark that the percentage in impurities is not elevated in relation with kaolins used in the industry; however a small presence of the manganese oxide in DD3 made the difference compared with other kaolins, because this one gives a gray color to ores.

The calculations of Hinckleys indices values that calculated from these strips are: 0.409 and 0.214 for DD2 and DD3 respectively, and are different from the value Hinkley indices references of KGa-2 that equals to: 0.37 (B. Tchoubar, et al 1982), which confirms that our samples of kaolin are badly crystallized.

It is proved that a relation exists between the evolution of the Hinckley indices of the kaolinite and the increase of the number of structural defaults from the moment all diagrams are recorded on the same device and in the same conditions (O. Castelein, 2000)

The rates of the iron oxide are very low (0,09% for DD2 and 0,14% for DD3), in relation with the kaolin used in the industries of ceramics 0.6–1% , Paper coating and Paper filler 0,5 to 1 %.(Siddiqui et al., 2005).

As we know, the iron oxide is a harmful element for the kaolin and can give reddish, brown and brunette for kaolin.

We remark that the impurities percentage is not heighten, however a small presence of the manganese oxide made a compared difference with other kaolins, because this one gives a gray and blackish color to the kaolins.

The loss on ignition (LOI) for DD2 and DD3 is superior to 16%, in relation with KGa-2 kaolin, that due to the existence of structural water.

4 CONCLUSION

Our different kaolins are characterized by several aspects.

According to the chemical and mineralogical analysis, the essential mineral is always hydrated silica-alumina, under kaolinite or haloysite form; it is come accompanied except in DD2, by several impurities: micas and feldspars bring potassium.DD3 contains the manganese and the organic matters; DD2 is nearly in conformity with halloysite.

The SiO_2/Al_2O_3 reports of DD2 and DD3 are 1.14 and 1.12 respectively instead of 1.1 for the pure kaolin, This gap suggests and confirms the presence of free silica (quartz), these values indicate also that the quality of our kaolin is varied the middle quality to the second poor quality.

It is noted that DD3 contains non negligible contents in Fe2O3, K2O, CaO and MnO. These impurities present with traces in DD2, It is coherent with the white-gray color DD2, and the blackish color of DD3.

After comparison with the KGa-2 kaolin, it is appears that the DD2 and DD3 are not kaolinites ($2SiO_2,Al_2O_3,2H_2O$) but rather a

hydrated form that approaching to the halloysite ($2SiO_2,Al_2O_3,4H_2O$).

Microstructural Evolution of Consolidated and Unconsolidated Cemented Paste Backfills by SEM-EDS Analysis

E. Yilmaz
University of Quebec in Abitibi-Témiscamingue (UQAT), Department of Applied Sciences, 445 Boul. de l'Université, Rouyn-Noranda (Québec) J9X 5E4 Canada

ABSTRACT This paper investigates the microstructural characterization of consolidated and unconsolidated cemented paste backfill (CPB) by scanning electron microscopy coupled with energy dispersive X-ray spectroscopy (SEM/EDS). The two different pressure application during curing (i.e., unconsolidated samples cured under 0 kPa and consolidated samples cured under the pressure up to 400 kPa) were tested in the experiments. Samples were prepared with 100wt% general use Portland cement and subjected to unconfined compression tests after curing time of 28 days. Results show that the strengths of consolidated backfills are always higher than those obtained from unconsolidated ones because of removal of excess free water and an efficient curing process leading to a high grain density. SEM micrographs of polished and fractured sections have also revealed that consolidated backfills give more solid matrix than unconsolidated ones. This is due to hydration products filling up the interstitial space within CPB cured under pressure and create a stronger bridge between particles.

Keywords: Cemented paste backfill, scanning electron microscopy, energy dispersive x-ray spectroscopy

1 INTRODUCTION

Cemented paste backfill (CPB) is a relatively high density, low strength material, which consists of mill tailings (typically with more than 70% solids), hydraulic binder (typically 3-7% binder to total solids ratio), and mixing water (typically reflects a slump consistency of 15-25 cm (Bernier et al., 1999; Kesimal et al., 2003, 2004; Potvin et al., 2005; Tariq and Nehdi, 2007; Yilmaz, 2011). Mine fills may be delivered to underground stopes in several ways: either by truck, by pumping or gravity or paste by boreholes and pipelines (Belem and Benzaazoua, 2008; Ercikdi et al., 2010). CPBs are often used for backfilling stopes in underground mines. This may allow a safer management of potentially acid generating tailings, while at the same time offer ground support to the surrounding rock mass (Fall et al., 2004, Kesimal et al., 2005; Landriault, 2006; Bussiere, 2007; Yilmaz, 2010; Coussy et al., 2012; Wu et al., 2013).

In comparison with concrete and/or mortar mixtures (having typically a water-to-cement w/c ratio of <0.5), CPB reflects a very high w/c ratio of >2.5) which has a harmful effect on its micro-structure. Paste backfills mixed with high water contents cannot make higher strengths, slowing down cement hydration (Benzazoua et al., 2004; Ercikdi et al., 2008, 2013; Cihangir et al., 2011, 2014; Ghirian and Fall, 2014; Yilmaz et al., 2015a,b).

Investigators have published some works on CPB microstructure by scanning electron microscopy equipped with energy dispersive spectroscopy (Ouellet et al, 1998, 2004,2006, 2007, 2008; Belem et al., 2001; Benzaazoua et al., 1999, 2002, 2004; Mohamed et al., 2003; Ramlochan et al., 2004; El Aatar et al., 2007; Cihangir et al., 2008; Deschamps et al., 2008; Ercikdi et al., 2009). These works were done on fractured or polished samples and gave precious info. Using the polished sections also permitted quantitative analyses.

Although the microstructure of concretes or mortars is relatively well known (Poon et al., 1997; Diamond and Kjellsen, 2008; Choi et al., 2009; Thomas et al, 2013; Abd El Aleem et al., 2014; Grilo et al., 2014; Heikal et al., 2014; Hu, 2014; Huang et al., 2014; Manfroi et al., 2014; Vaitkevicius et al.,

2014), the micro-structural behavior of CPB thus needs to be further understood. It has been well documented that curing cemented materials under effective stress increases the strength gain, depending on cement type and ratio (Belem et al., 2007; Yilmaz et al., 2009, 2011, 2012, 2013, 2014a,b). It should be however noted that the time of application of stress plays a key role on the CPB strength. Fourie et al. (2006) showed that if effective stress is applied immediately before the start of curing, samples gain more strength than when the effective stress is applied after the hydration is complete. This is attributable to the cement bonds that form during hydration (Revell, 2004; Fall and Samb, 2009; Yilmaz, 2010). If CPB is subjected to curing stress after a couple of days, then the cement bonds that are forming may break down, therefore reducing the material's stiffness.

Consequently, the complete information of these aspects is needed to evaluate the micro-structural behaviour of CPB. The principal purpose of this paper is to present the results of the experimental testing undertaken for assessing the microstructure of consolidated and unconsolidated paste backfills. The two different pressure sequences were applied to backfills during curing. The unconsolidated samples were cured under zero pressure (0 kPa) while the consolidated samples were cured under a pressure sequence up to 400 kPa. The consolidation effect on the CPB microstructure was assessed after unconfined compression testing. CPB samples contained 100wt% general use Portland cement and tested for their microstructural analyses after curing time of 28 days alone.

The key interest of the present paper stems in part from the fact that this is one of the very original attempts, to the authors' best knowledge, to investigate the microstructural behaviour of CPB samples being cured under time-dependent consolidation loadings.

2 MATERIALS AND METHODS

2.1 Materials

Paste tailings were sampled as representative of the tailings streams from the paste plant of the LaRonde mine, located in the Abitibi region of northwestern Quebec, Canada. The samples were received in plastic containers and subjected to the material characterization tests. Based on American Society of Testing Materials standards testing procedures, lab experiments were done in triplicate and their average values are reported. Further details on paste tailings material characteristics can be found in Yilmaz (2010).

2.1.1 Physical Tests

The paste material used was analyzed using a Mastersizer (Malvern Instruments) laser diffraction particle size analyzer. The test procedure consists simply of mixing 0.2-0.4 g of powder in a dispersant contained in an ultrasonic bath operated until the grain size distribution curve stabilizes. The laboratory analysis results show that the tailings sample has an average water content w of 23.4 wt%, a specific gravity G_s of 3.7, a specific surface S_s of 2.2 m^2/g, a relative compaction R_c of 91 wt%, a liquid limit w_L of 23 wt%, a plastic limit w_P of 18 wt%, a liquidity index LI of 1 wt%, a plastic index PI of 5 wt%, and a clay activity A (simply defined as the PI divided by the percent of clay-sized particles present, < 2 µm) of 1. The Atterberg limit results showed that the paste tailings studied would be designated as ML.

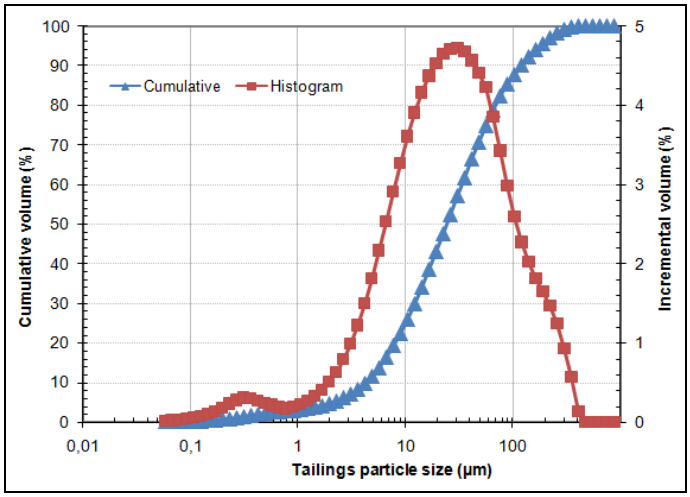

Figure 1. Cumulative and incremental GSD curves of paste tailings

2.1.2 Chemical Tests

X-ray diffraction (XRD) analysis and ICP-AES analysis show the results of the tailings

sample studied. It can be concluded from XRD analysis that the sample contains a high proportion of pyrite (47 wt%), mainly responsible for the high G_s of tailings (3.7). The other major minerals are quartz (31.6 wt%), chlorite (8.9 wt%), paragonite (7.3 wt%) and muscovite (4.6 wt%). The ICP-AES analysis also indicates iron Fe (27.4 wt%) and sulphur S (24.9 wt%) are the most abundant elements identified within tailings.

The binder used for CPB preparation was 100 wt% of general use ordinary Portland cement (GU). Chemical composition was listed in Table 1. Physical characterization shows that specific surface area and specific gravity are 1.6 m^2/g and 3.1, respectively.

Table 1. Physical and chemical properties of the cement used.

Parameter	Value
Specific gravity G_s	3.1
Specific surface area S_s (m^2/g)	1.6
Al_2O_3 (%)	4.9
CaO (%)	65.8
Fe_2O_3 (%)	2.5
MgO (%)	2.2
Na_2O (%)	2.1
SO_3 (%)	3.7
SiO_2 (%)	19.5
Hydraulic modulus	2.3

The mixing water used in the tests is very highly aggressive regarding sulphate content (4883 ppm) but also contains calcium Ca of 559 ppm because of addition of lime during milling. Tap water used within CPB contains a calcium concentration of 40.9 ppm and a magnesium concentration of 2.27 ppm.

2.1.3 Sample Preparation and Curing

The amounts of paste backfill ingredients such as mine tailings, cement and water were prepared in a Hobart mixer. The total mixing time for CPB materials was 12 minutes. Each CPB mixture has a solid concentration of 78 wt% and 4.5 wt% cement (corresponding to a water-to-cement ratio of 6.5).

Consolidated CPB samples were obtained by a transparent cylinder within the CUAPS apparatus while unconsolidated CPB samples were obtained by plastic moulds. Paste mixes were cast into both cylinders and moulds in one-third increments. After the cylinders or moulds were filled, the paste was rammed in 25 blows using a small steel rod to eliminate any large trapped air bubbles within sample. After sealing, the moulds were stored in a foggy room set at 80% humidity and 25 °C temperature over a curing time of 28 days. Please note that after the paste was poured into cylinders within the CUAPS apparatus, the top porous stone, the loading piston and platen connected with a pneumatic pressure line were placed in order to simulate in situ backfill conditions. Figure 2 illustrates the different test conditions of CPB samples.

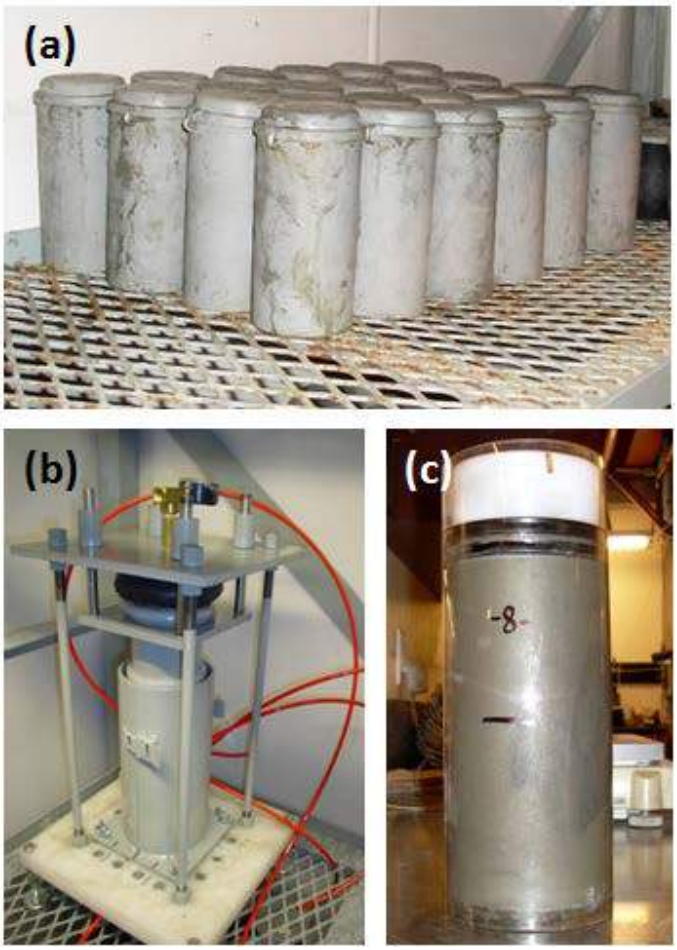

Figure 2. Photos illustrating the different test conditions: a) conventional moulds stored in the humidity room, b) the CUAPS apparatus allowing simulate field backfill conditions, and c) CUAPS cylinder filled with CPB.

2.2 Methods

2.2.1 Curing Under Applied Pressure Tests

These tests were run to simulate the strength behaviour of in situ paste backfill samples

and compare it to of paste backfill samples in standard laboratory conditions. The CUAPS setups were filled with freshly prepared paste backfill material. For the first half an hour, no pressure was applied to the CPB sample, with pressure gradually increased thereafter up to 400 kPa for a total duration of 35 h. Average compression rate was 11.4 kPa per hour, for a filling rate of 0.5 m per hour. A final pressure or stress application of 400 kPa corresponds to an equivalent overburden of 20 m in height of CPB in an underground stope. Each sample was left to cure under the final pressure of 400 kPa for a curing time of 28 days, chosen arbitrarily.

2.2.2 Unconfined Compression Tests

At the predetermined curing period (28-day), CPB samples were subjected to unconfined compression tests in order to determine their strength properties. Unconfined compressive strength (UCS) test was used because of its simplicity and reliability. A mechanical press (MTS 10/GL) with a normal loading capacity of 50 kN was used. The samples' two ends were first planed to get their surfaces normal to the plates of the mechanical press prior to the tests. Figure 3 shows a typical UCS test.

Figure 3. Photos of (a) MTS Sintech 10/GL mechanical press, (b) a sample rectification with typical results, and (c) the CPB sample under compression testing.

2.2.3 SEM-EDS Characterization Tests

The microstructure and texture of samples were characterized using a Hitachi 3500-N scanning electron microscopy with energy dispersive X-ray spectroscopy (Fig. 4).

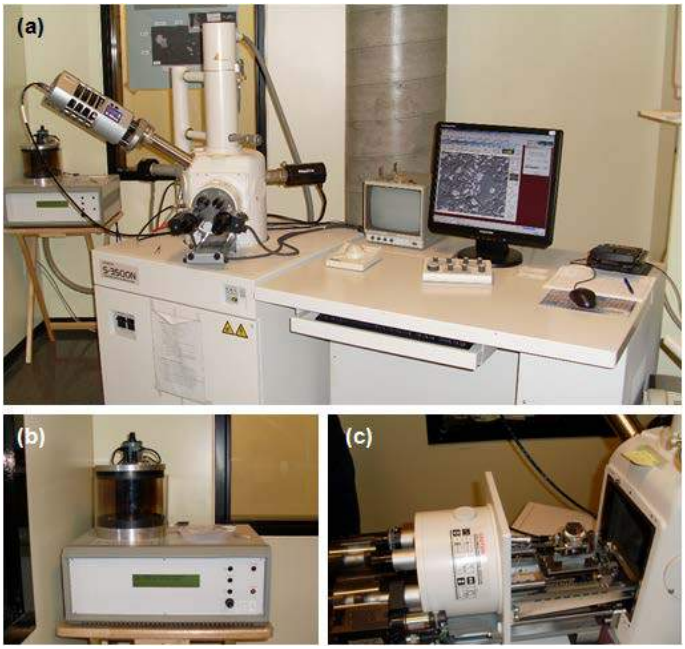

Figure 4. Photos of (a) the SEM-EDS tool, (b) impregnation unit and (c) internal section of sample placement in SEM equipment.

To examine both oxidized and unoxidized sections, a piece of sample was extracted gently from CPB and cut transversally. Once the sample was dried, vacuum impregnated with low viscosity epoxy, polished and gold coated, SEM observations were performed in the secondary electron mode at high vacuum (<0.1 Pa), using a primary voltage of 20 keV and a working distance of 15 mm. Figure 5 shows polished and fractured CPB samples.

Figure 5. Photos of polished and fractured paste backfill samples.

3 RESULTS AND DISCUSSION

To assess the variation in the conditions of the CPB placed in an underground mined out

stope, the two extreme points of the stope were simulated by choosing 0 kPa (reflects the top of the stope, Case I) and 400 kPa (reflects the bottom of the stope, Case II).

Case I allows us to better understand the information of CPB material close to the top of the stope, which is initially subjected to no consolidation, and thus represents a loose material). Case II allows us to better realize the information of CPB material close to the bottom of the stope, which is subjected heavily to self-weight and/or time-dependent consolidation, and thus represents a dense backfill. Please note that the stope height simulated is site-specific and limited to max stope height to 20 m.

3.1 Consolidation Effect on Strength Behaviour of CPB Samples

Figure 6 shows that consolidated backfills always provide higher mechanical strengths those obtained from unconsolidated samples. The stiffness of the samples cured under a stress of 400 kPa increases with increased cement hydration rate. When compared to the undrained backfills cured under 0 kPa, consolidated backfills provided a strength increase of 33%, 31%, and 26% after curing times of 7, 14, and 28 days at 4.5wt% binder, respectively.

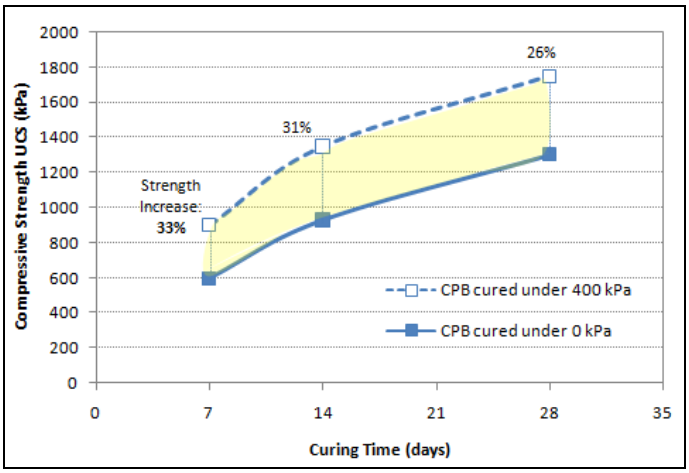

Figure 6. Change in the compressive strength with curing time for both consolidated (cured under 400 kPa) and unconsolidated (cured under 0 kPa) CPB samples.

Results indicate that consolidation process plays a key role in the strength development of CPB samples. The consolidated backfills display smaller degree of saturation than the unconsolidated ones because of the reduced pore size distribution in paste backfill being cured under stress. During cement hydration, the capillary voids present in the sample due to consolidation will be filled with hydrated products, thus increasing internal cohesion. This observation was confirmed by a variety of microstructure tests (MIP, SEM, etc) done on consolidated and undrained CPB samples (El Aatar et al., 2007; Yilmaz, 2010).

3.2 Scanning Electron Microscopy (SEM) Investigation of 'Polished' Samples

The polished section samples provide us the central information on quantitative chemical elemental analyses of CPB samples through SEM-EDS, based on the Ca/Si ratio. Please note that the polished section analyses might have some errors because the microstructure of the paste backfill samples is altered during sample preparation. There is not anything to recover this fact because it is based on the technique studied. On the other hand, it is a good analysis so that the information on the void ratio changes can be obtained.

Figure 7 demonstrates scanning electron microscopy (SEM) micrographs of polished section of paste tailings without cement. It is apparent that the void ratio of paste tailings (grey zone) is too much and need to be filled with the hydrated products when the cement is added to tailings. The microstructure of tailings was comprised of particles varying between 15 µm and 35 µm. The interstitial space between larger particles was loosely filled up with much smaller particles varying between 1 µm and 5 µm. The majority of the space present within paste tailings was empty and unrelated with one another. The image analysis of paste tailings confirmed that there were more than 50% void space within the material tested. This is in a good agreement with bulk measurements of the total porosity of similar uncemented paste tailings samples, which are obtained using mercury intrusion porosimetry (MIP) tests.

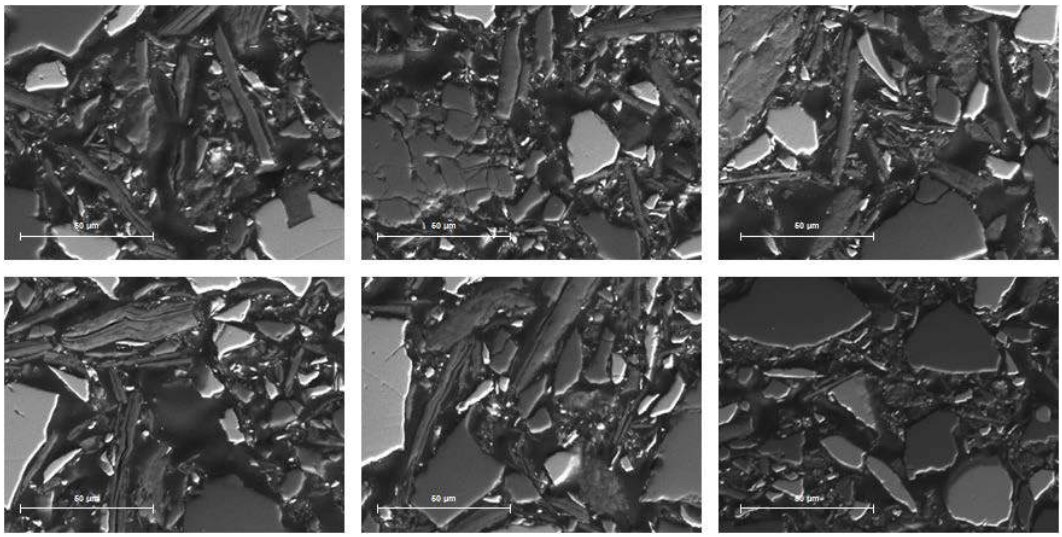

Figure 7. SEM micrographs of the polished section of uncemented mine tailings.

3.2.1 Effect of Curing Without Stress

Figure 8 shows the SEM micrographs of the polished section of unconsolidated backfill samples cured under 0 kPa. The structure of CPB samples consisted of a combination of fine particles and hydrated cement products. Even though the cemented material studied appeared very porous, the hydrated products could get in touch with the tailings particles, as expected. Due to the fact that there is no drainage from unconsolidated CPB samples (no holes perforated at the bottom of mould), there exists much more free water within the sample. This causes a sober delay of cement hydration, thereby resulting in larger voids.

Unlike mortars or concretes, there was no observation about a cementitious formation between tailings particles. It is well known that the application of pressure to the backfill during curing leads to a significant increase in the compressive strength of CPB samples. From Figure 8, it can be also inferred that the interstitial space between tailings particles was much greater than the space occupied by the hydrated products. This also confirmed that it was not created a bridge between the tailings particles in consequence of calcium silicate hydrate products. The microstructure of unconsolidated backfills is less dense than the one of consolidated ones.

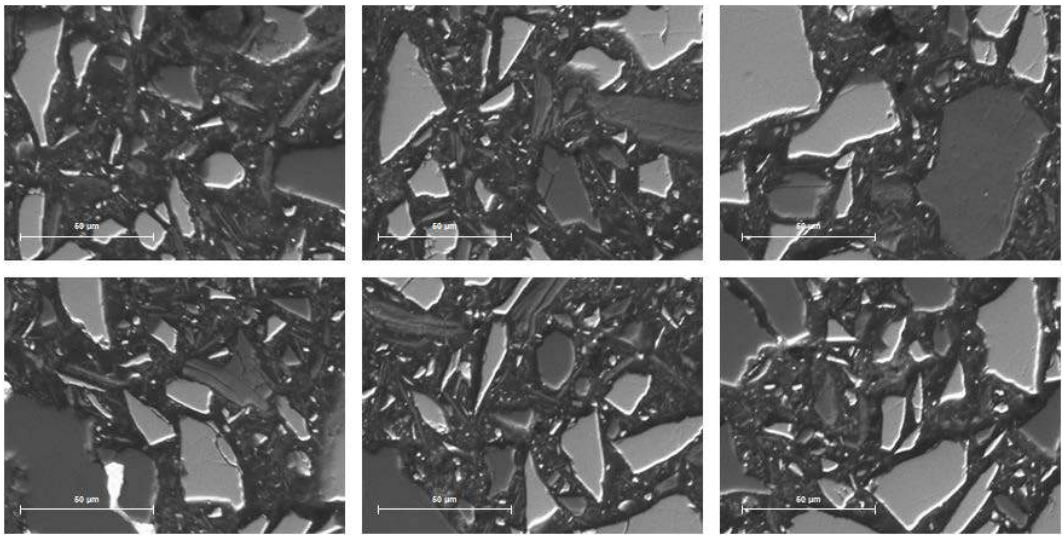

Figure 8. SEM micrographs of the polished section of unconsolidated CPB samples prepared with GU@100 wt% and cured under no applied pressure during curing. Samples contain a binder content of 4.5 wt% and show a curing time of 28 days.

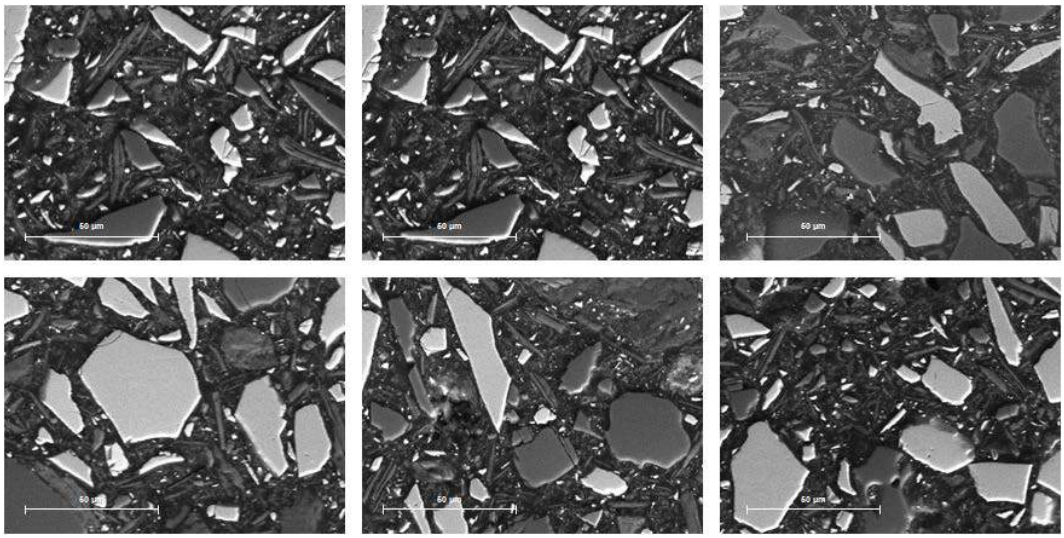

Figure 9. SEM micrographs of the polished section of consolidated CPB samples prepared with GU@100 wt% and cured under an applied pressure of 400 kPa during curing. Samples contain a binder content of 4.5 wt% and show a curing time of 28 days.

3.2.2 Effect of Curing Stress (400 kPa)

Figure 9 shows the SEM micrographs of the polished section of the consolidated backfill samples cured under a pressure of 400 kPa. The studied backfills appeared to embrace a larger proportion of fine-grained tailings than the unconsolidated backfills. As a result of the removal of free water within the backfill cured under the applied pressure (named as consolidation), the number of micro-cracks in the backfill sample reduces due to the fact that the tailings particles are pulled together under capillary forces. This may result in an increase of the CPB's rigidity, accelerating cement hydration and therefore, generating higher unconfined compressive strengths.

The amount of hydrated products within the consolidated CPB samples found infilling void spaces (Fig. 9). The microstructure also shows that precipitated secondary minerals contribute to the cohesion of paste backfill matrix by filling the granular voids. From the SEM micrographs, one can notice that the microtexture of consolidated CPB matrix is denser than the one of unconsolidated CPB samples (with void spaces).

The lab curing conditions (with or without stress during curing) seems to have an effect on the microstructure of CPB as we can see as comparing the images corresponding to paste fill samples with similar binder content at similar curing days.

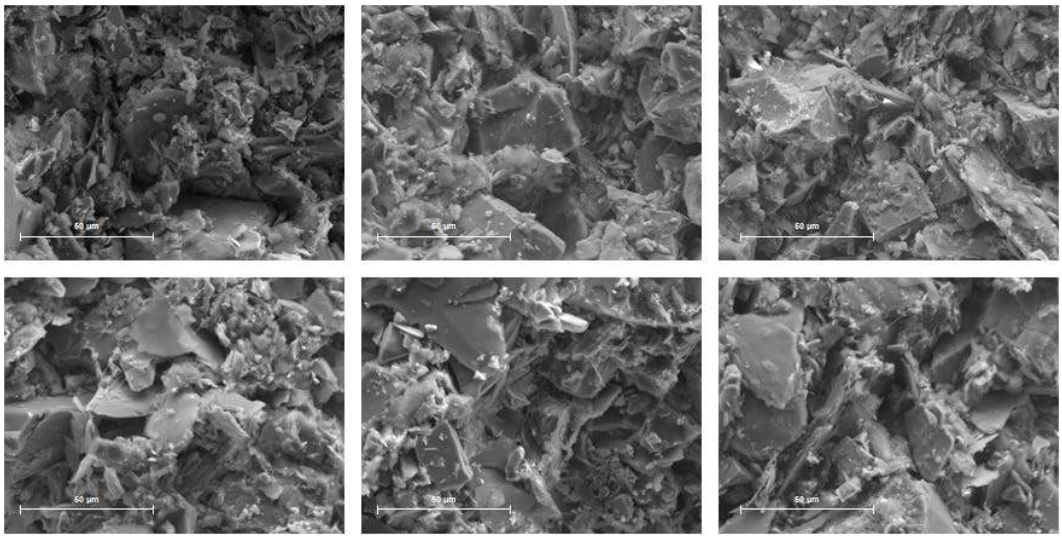

Figure 10. SEM micrographs of the freshly-fractured surface of uncemented mine tailings.

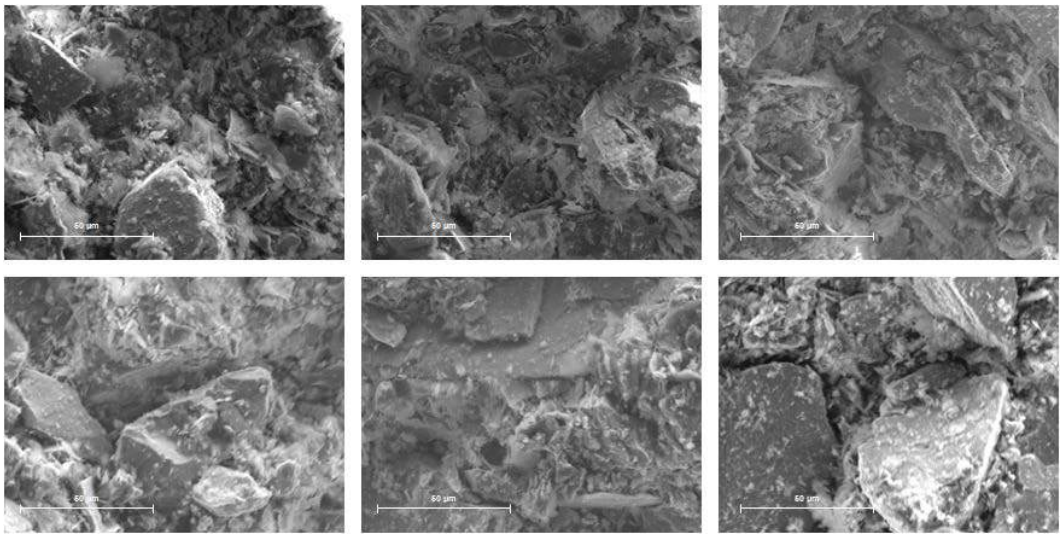

Figure 11. SEM micrographs of the freshly-fractured surface of unconsolidated CPB samples prepared with GU@100 wt% and cured under no applied pressure during curing. Samples contain a binder content of 4.5 wt% and show a curing time of 28 days.

3.3 Scanning Electron Microscopy (SEM) Investigation of 'Fractured' Samples

The fractured section analyses provide us the important information of cement hydration products such as C-S-H and general sample morphology. Due to the fact that samples are not disturbed and freshly cut (non-altered surfaces are necessary to do these analyses), the SEM-EDS analyses give us the better microstructure characterization information. After completing these works, it will be able to make clear interpretation on two extreme experimental conditions.

Figure 10 shows the SEM micrographs of the freshly-fractured surface of paste tailings without cement. The high amount of meso- and macro-pores observed in the tailings may be attributed mainly to a heterogeneous mix containing micro-cracks and irregular grain dispersion pattern. The void spaces between the coarser and angular particles are filled up mostly with ultra-fine particles. However, it is good to point out that there are still some unfilled parts in tailings which reveal gaps. The high water-to-cement ratio also affects negatively the micro-structure of tailings.

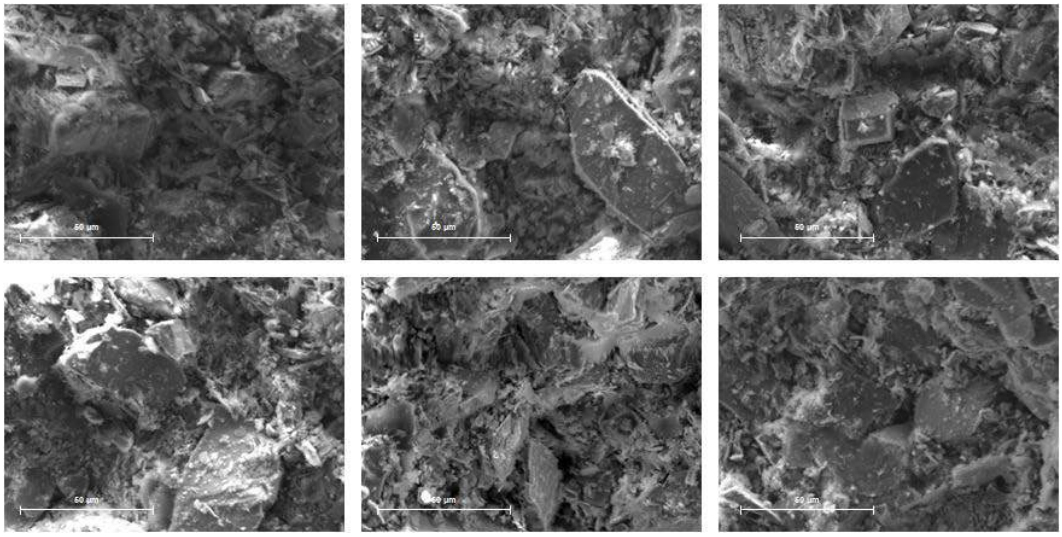

Figure 12. SEM micrographs of the freshly-fractured surface of consolidated CPB samples prepared with GU@100 wt% and cured under an applied pressure of 400 kPa during curing. Samples contain a binder content of 4.5 wt% and show a curing time of 28 days.

3.3.1 Effect of Curing Without Stress

Figure 11 shows the SEM micrographs of the fractured CPBs cured under zero pressure.
It is clear that tailings particles are not well connected to each other because there is no applied pressure during curing. Observation was made by SEM analyses that there are still some unfilled gaps within samples even though hydration products appear clearly.
It is apparent that there are no clear cement bonds around the particles as a consequence of excess free water still available in sample. Since there is no a superior testing procedure or equipments which allow samples to drain out free water from CPB during curing, the cement bonds cannot be observed within the samples studied.

One can also speak that, although empty spaces are partially filled up with the C-S-H gels, there are still some voids between the interlayer of tailings particles. This might be explained simply by the fact that there is no consolidation during curing and thus no grain rearrangement which leads to an increase in the packing density of samples (the reduction of the porosity of the material).

3.3.2 Effect of Curing Stress (400 kPa)

Figure 12 shows the SEM micrographs of the fractured CPB samples cured under 400 kPa. Results show the effect of consolidation. It is interpreted that time-dependent consolidation provides compaction during curing due to pressure application and thus the consequent porosity reduces principally due to cement hydration products. Even with a naked eye, it is seen that sample is compacted and there are no empty voids between interlayer zones, therefore porosity is fairly low compared to the samples cured no pressure. That analysis for samples cured under a pressure of 400 kPa proves why consolidated samples always produce higher strengths than unconsolidated and samples. This may be well explained by a strong bridge among the particles. Some secondary minerals like sulphate also help decreasing the porosity, precipitating during curing. Sulphate ions precipitation as well as cement hydration products, both of them, are reducing significantly the resulting porosity or void ratio of the material tested.

3.4 Energy Dispersive X-ray Spectroscopy (EDS) Analysis of 'Fractured' Samples

Figure 13 shows the results of quantitative elemental analyses through the SEM coupled with energy dispersive X-ray spectroscopy EDS analyses. To characterize the hydration performance, it is common to use the Ca/Si ratio for concretes or mortars as the most abundant hydration products are C-S-H gels. Shortly, the Ca/Si ratio allows to quantify the amount of C-S-H formed during hydration process. In this regard, the fractured backfill samples cured with 0 kPa gives the highest Ca/Si ratios (45%) when compared to others (41% for consolidated backfill samples cured with 400 kPa and 4% for tailings alone).

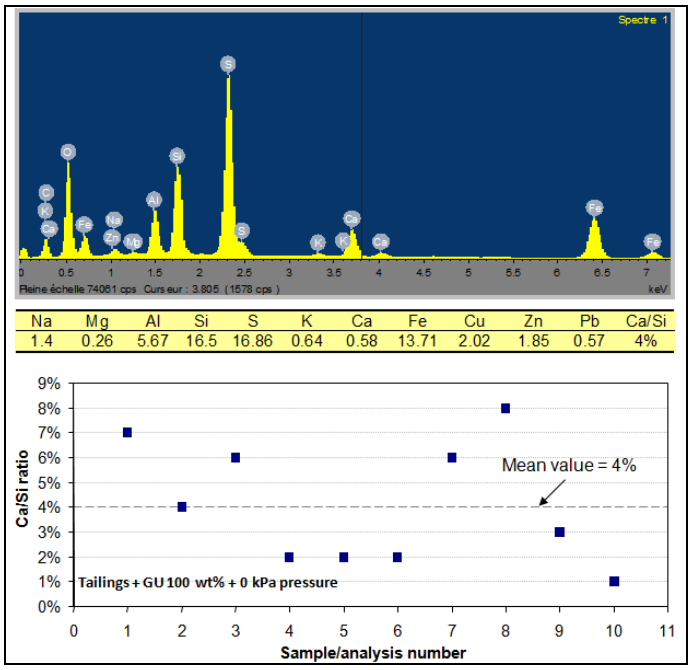

Figure 13. The EDS analysis and Ca/Si ratio curve of the freshly-fractured surface of the uncemented mine tailings.

For tailings, the lowest Ca/Si ratio (4%) is common since there is no cement hydration reaction (Fig. 13). It was also logical Ca/Si ratio for the samples cured with minimum (0 kPa) and maximum (400 kPA) pressures. Due to the fact that the higher pressure make samples more compact and denser than the sample cured with zero pressure, this sample covers lower voids to be filled completely by

hydrated produces and consequently gives lower Ca/Si ratio (41%, Figure 14).

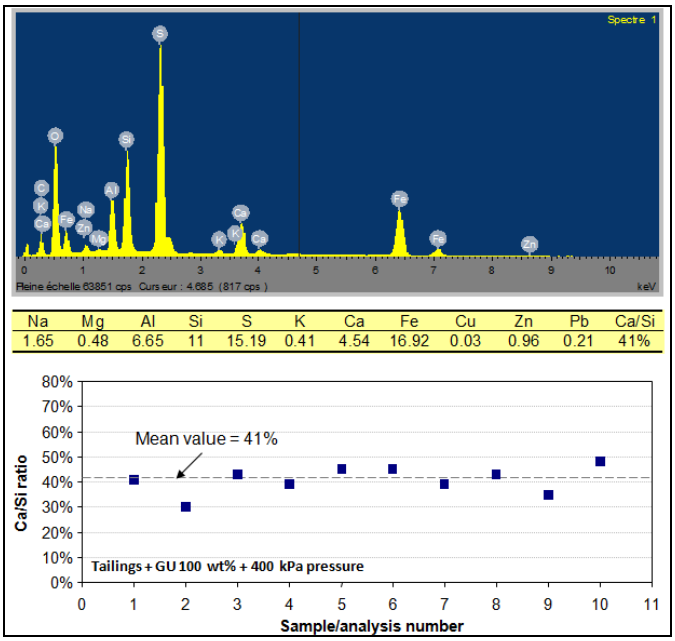

Figure 14. The EDS analysis and Ca/Si ratio curve of fractured surface of consolidated CPB prepared with GU@100wt%.

Besides, unconsolidated backfills where no pressure is applied to the samples during curing keeps larger voids to be filled fairly by cement hydration products and so gives higher Ca/Si ratio (45%, Figure 15). These analyses have shown that curing with stress does help to keep the sample denser at early stages of compaction or consolidation.

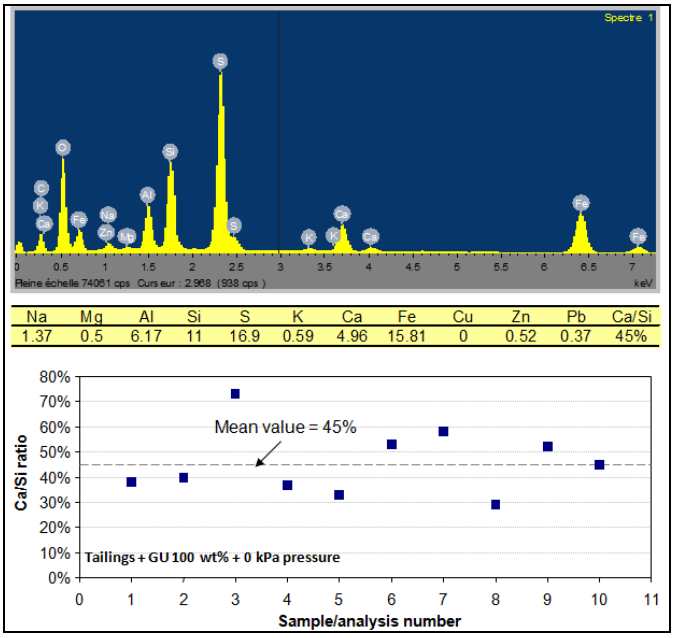

Figure 15. The EDS analysis and Ca/Si ratio curve of fractured surface of unconsolidated CPB prepared with GU@100wt%.

As a result, samples cured under pressure become denser and consequently, there does remain no space to be filled by hydration products. On the other hand, samples cured under no pressure become loose and have lots of free space which need to fill up with hydration products. Hence, the Ca/Si ratio of the latter becomes higher than the former, as we measured in the current paper.

4 CONCLUSIONS

This study presented the results of SEM-EDS analysis that were used to assess the micro-structural evolution of CPB samples. Two different curing conditions (samples cured under no pressure (0 kPa: unconsolidated) and with pressure (400 kPa: consolidated) were applied to the samples prepared using 4.5wt% cement. After 28-day curing, CPBs were first subjected to strength tests and then SEM-EDS analyses. The results have shown that curing under stress has a major effect on the CPB's microstructure. It was confirmed that consolidation greatly affects the void spaces within CPB and create sample denser and well connected between tailings particles and hydration products. SEM analyses have also confirmed that there were visible cement bonds within the consolidated samples. This work brings new light on influence of curing conditions on micro-structural evolution of CPB that can donate to better optimization of paste backfill mixes at modern mines.

ACKNOWLEDGEMENTS

The author gratefully acknowledges a number of project funds as follows: Canada Research Chair on Integrated Management of Sulphidic Mine Wastes using Mine Backfill Technology. Special thanks are Nil Gaudet, Mélinda Gervais, David Bouchard, Yvan Poirier, Mélanie Bélager, Alain Perreault and Hassan Bouzahzah of the URSTM Laboratory for their technical help in conducting a variety of physical, chemical, mechanical and microstructural tests. Finally, the author wishes to express his sincere thanks and appreciation to Professors Tikou Belem, Bruno Bussière and Mostafa

Benzaazoua for their technical and financial support during this project work.

Evaluation of Grout Curtain Efficiency of Kalu-Ganga Dam

A. Aalianvari
Department of mining engineering,Faculty of engineering, University of Kashan, Kashan, I. R. Iran

ABSTRACT The main objective of this work was to study the design rationale for the optimum grout curtain of Kaluganga dam. One of the important points in the study stages and along the performance works for the earth dams construction is seepage analysis through foundation and dam body, which is a serious problem for dam designers. So calculation of seepage amount from foundation and dam body and evaluation of control or decrease methods for this problem is essential. This study was based on a combination of geotechnical investigations, geological investigations, and numerical modeling. The dam is located in the volcani rocks such as Garnet granulitic gneiss and calcareous gneiss.This paper presents finite element model for prediction of water seepages from dam to determine optimum depth of grout curtain. Results show without grout curtain around 0.7 m3/s water seepages from dam and with the 70 m grout curtain depth, reduces to the 0.185 lit/sec.

Keywords: Grout curtain efficiency, geological and geotechnical investigation, numerical modelling

1 INTRODUCTION

Kalu Ganga Main Dam and Saddle Dam are located in about 24 km upstream of Moragahakanda Dam. The project also includes water transfer system (tunnel + canal) conveying water from Kalu Ganga Dam Reservoir to the reservoir of Moragahakanda Dam. The transfer canal and tunnel are about 7 km and 3.5 km long respectively.

The bedrock of dam consists of 3 different types of gneisses can be clearly differentiated at the main dam area garnet granulitic gneiss, calcareous gneiss and charnockitic gneiss. Figure 1 show the geological section along the dam axis.

Based on the engineering judgments and water pressure test results in exploratory boreholes the average permeability for each abutment and foundation has been estimated.

At the left abutments maximum permeability in these boreholes (DH25, DP05, DH26, DH27, and DP03) is around 20 to 30 Lu. And minimum permeability is less 1 Lu. Therefore average permeability in these boreholes has been estimated around 10 Lu.

At the right abutments maximum permeability in these boreholes (DH21, DH23, DH22, DH02, DH09, and DH17) is around 30 to 50 Lu. And minimum permeability is less 1 Lu. Therefore average permeability in these boreholes has been estimated around 4 Lu.

In the foundation of dam (riverbed area) maximum permeability in these boreholes (KT14, KT12, DH05, DH15, and DH04) is around 5 to 10 Lu. And minimum permeability is less 1 Lu. Therefore average of permeability in these holes as around 4Lu.

According to ASTM D6032-96 (table 3) at the drilled boreholes in dam site the rock quality in left bank(based on boreholes: DH25,DH10,DH26,DH27,DH28) is Medium (R.Q.D=72%), in right bank(based on boreholes: DH21, DH23, DH22, DH02, DH18, DH09, DH17) is Poor (R.Q.D=36%) and the foundation or riverbed (based on boreholes: DH20, DH19, DH05, DH15) is good (R.Q.D=84%).

In this paper, a numerical finite element model using SEEP/W software (Geo-Slope International Ltd, 2006) and analytical equations to predict water flow seepage from

dam in different conditions and according to their results the optimum grout curtain depth pit has been selected.

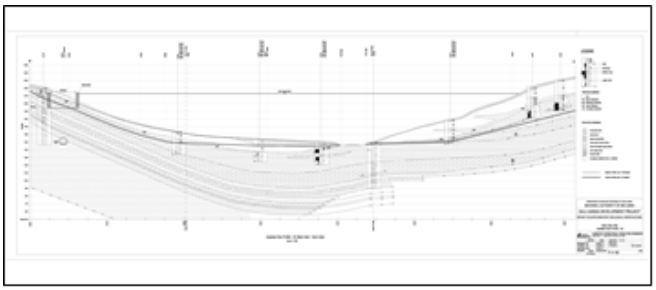

Figure 1. Geological section along the dam axis

2 SEEPAGE ANALYSIS OF KALU GANGA DAM

All earth dams are subject to seepage through the embankment, foundation, and abutments. Seepage control is necessary to prevent excessive uplift pressures, sloughing of the downstream slope, piping through the embankment and foundation, and erosion of material by loss into open joints in the foundation and abutments.

The purposes of the seepage analysis are includes:

1- Estimation of water seepage through the foundation and abutments
2- Determination of lateral extension and depth of grout curtains
3- Prediction of grout curtain efficiency

Estimation of water seepages from the Kalu Ganga dam has been done at 2-D steady state status with Geostudio package and Seep/w software.

Normal water level of reservoir, Tail water level and rock mass permeability are the major parameters regulating water seepage from dams. In this project Normal water level is 210 m.a.s.l and Tail water level is the river elevation (152 m.a.s.l) but the major parameter that affects the water flow is rock mass permeability.

Estimation of rock mass permeability is very important, so before modeling the water seepage from dam, different alternation of permeability has been studied and analyzed.

2.1 Rock Mass Permeability

The water permeabilities of most rock materials lie in the range 10-10to 10-15ms-1 (Louis, 1969), which means that from an engineering point of view an unfractured rock mass is effectively impermeable to water. All rocks, particularly those near to the ground surface, contain discontinuities which can provide major conducting pathways for migrating fluids. Natural processes such as mineralisation and aquifer recharge, together with manmade processes such as water, oil and gas recovery rely upon the contribution made to mass permeability by discontinuity networks.

Major discontinuities such as faults, bedding and geometrical properties of joints have been controlled the rock mass permeability, so to accurate estimation of seepage from dam 3 modes have been studied for rock mass permeability of dam.

- Rock mass permeability based on the average of the water pressure tests in boreholes at new axis dam.
- Rock mass permeability based on the maximum lugeons of the water pressure tests in boreholes at new axis dam.
- Sensitivity analysis for various permeability based on the geological conditions, engineering judgment and water test results

2.1.1 Permeability based on the average of lugeon tests on boreholes

Based on the engineering judgments and water pressure test results in exploratory boreholes the average permeability for each abutment and foundation has been estimated.

At the left abutments 7 exploratory boreholes have been drilled (DH21, DH26, DH27, DP03, DP04, DP05, DH10). Results show that average permeability in these boreholes is around 10 Lu.

At the right abutments 8 exploratory boreholes have been drilled (DH21, DH22 ,DH23,DH02,DH18,DH09,DH17,DP09). Results show that average permeability in these boreholes is around 20 Lu.

At the foundation of dam 8 exploratory boreholes, DH05, DH19, DH20,

DH05,KT14,KT12,DH04 DH14 and KT10 have been drilled and water pressure test has been done in these holes. The average of permeability in these holes as around 4Lu.

2.1.2 Maximum permeability in exploratory boreholes

When the number of water pressure tests in the exploratory holes is not sufficient, maximum lugeon in the holes can be considered as the basis of water seepage. Therefore at the left abutment, 30 lugeon has been considered as the equivalent permeability that this value taken from DH25 borehole.

At the right abutment due to the limestones, the 50 lugeon was the maximum value in the tests (DH21) and the foundation 11 lugeon has been considered as the highest value in the holes (DH05)

2.1.3 Sensitivity analysis for various permeability based on the geological conditions and water test results

Water pressure test results in exploratory boreholes show that in a few sections the lugeon value higher than 50 has been obtained so based on the geological conditions, engineering judgment and water pressure test results and to sensitivity analysis, numerical modeling of seepage done with 3 alternative, 100, 200 and 500 lugeons.

2.2 Seepage Analysis

There are different ways to calculate water seepage from the reservoir, such as analytical and numerical methods. In this project, water seepage from the KaluGanga dam was estimated using a finite element method.

A finite element method (FEM) is a numerical technique for finding approximate solutions to boundary value problems for differential equations. It uses variation methods (the calculus of variations) to minimize an error function and produce a stable solution FEM.

In this project, a numerical finite element model implemented in the SEEP/W software package (Geo-Slope International Ltd. 2006) is presented. It is capable of predicting the water seepage from dam.

The SEEP/W model is able to analyze different flow conditions such as saturated/unsaturated flow and a confined/unconfined aquifer in a two-dimensional situation. To calculate the amount of water seepage, different geological sections were prepared. Figure 2 show the location of geotechnical sections in the geological map.

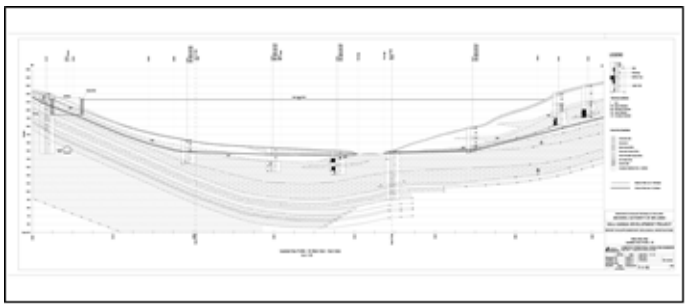

Figure 2. Location of seepage sections

The seepage model of geological sections at abutments and foundations has been generated with Seep/w software.

To determine the optimum depth of grout curtain at the abutments and foundation, seepage models have been done in 2 cases, with grout curtain at different depth and without grout curtain. Figures 2,3 and 4 show the seepage sections.

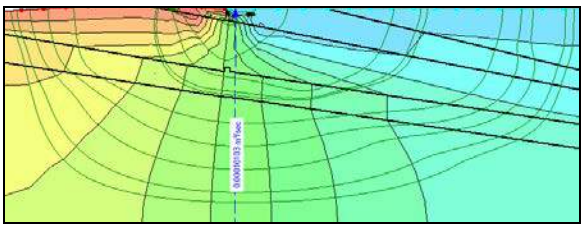

Figure 3. Seepage section along dam foundation(without grout curtain)

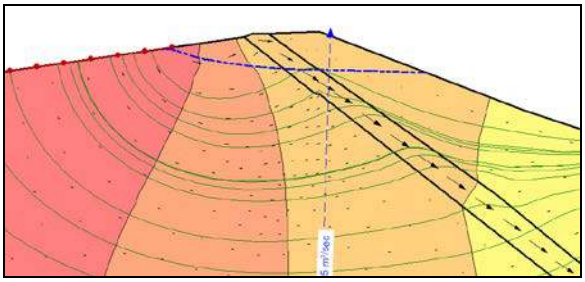

Figure 4. Seepage section at left abutment(without grout curtain)

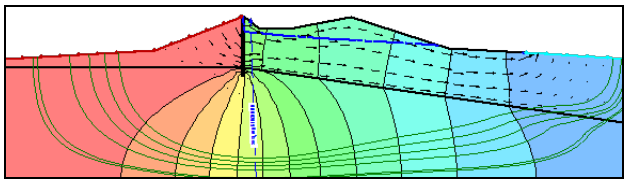

Figure 5. seepage section at right abutment(with grout curtain)

3 RESULTS AND DISCUSSION

According to results, without grout curtain about 0.7m3/Sec water seepage from dam , so this amount of water is very dangerous for construction and it is very important to design optimum drainage systems to prevent the water flow.Table 1 shows the results of numerical modeling for the seepage sections at the case of without grout curtain and various permeability.

Table 1. Seep/w results for the sections (without grout curtain and various permeability) (Lit/Sec)

Case	Right Abutment	Foundation	Left Abutment	Total
Average Permeability	9	5	4	18
Max Permeability	15	13	11	39
100 Lu	29	100	22	151
200Lu	56	194	40	290
500 Lu	138	484	96	718

To determination of optimum depth of grout curtain, seepage sections at various depth (40 m, 50 m, 60m and 70m) was modeled and results show in the table 2. The grout curtain extends to the impermeable area beneath dam foundation. The design of grout curtain mainly is depended on hydrogeological conditions and water column height on the dam foundation and condition of calcareous gneiss. Table 2 shows the results of analysis for different depth of grout curtain in whole of KaluGanga dam site.

Table 2. Seep/w results for the different depth of grout curtain (Lit/Sec)

Case	Grout curtain with 40 m depth	Grout curtain with 50 m depth	Grout curtain with 60 m depth	Grout curtain with 70 m depth
Average Permeability	17.9	17.8	17.7	17.6
Max Permeability	38	37	36	35.8
100 Lu	104	99	83.5	83
200Lu	202	190	175	122
500 Lu	447	396	188	185

Efficiency of grout curtain for right abutment, left abutment and foundation are shown on the below figures.

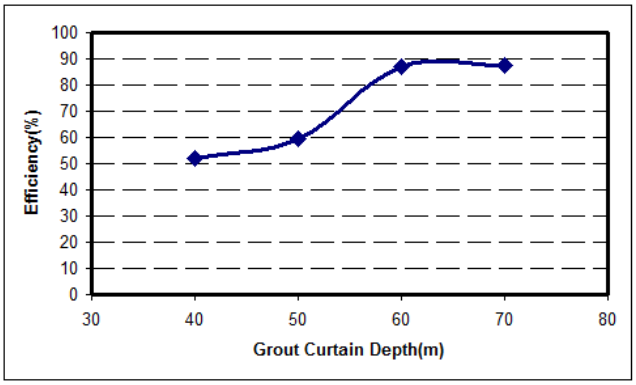

Figure 6. Grout curtain efficiency for dam foundation

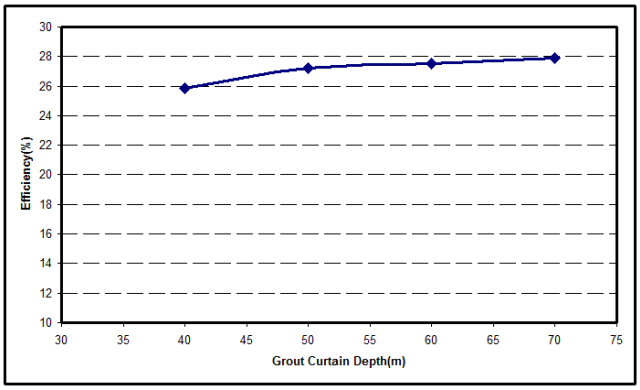

Figure 7. Grout curtain efficiency for left abutment

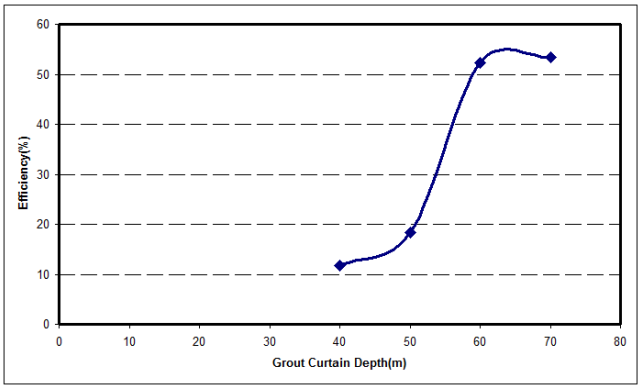

Figure 8. Grout curtain efficiency for right abutment

4 CONCOLUSION

The grout curtain extends to the impermeable area beneath dam foundation. The design of grout curtain mainly is depended on hydrogeological conditions and water column height on the dam foundation and condition of calcareous gneiss.

Based on the geological conditions for each abutment and numerical results:

- Due to the presence of calcareous gneiss with high permeability at right abutment and Seep/w results, 75 to 90 m is the optimum depth of grout curtain for the right abutment. In this case, the grout curtain efficiency is around 70%.
- The optimum depth of grout curtain for the dam foundation is around 55 m with about 60% efficiency.
- For the left abutment, due to the nearest of calcareous gneiss unit to the surface, the 25 m depth of grout curtain is an optimum depth.
- Due to the importance of accurate permeability, it is recommended to surveying the geometrical properties of discontinuities such as joint spacing, joint aperture.

A. Daya
Department of Mining Engineering, University of Sistan and Baluchestan, Zahedan, Iran

ABSTRACT One of the large province of Iran is the Sistan and Baluchestan that is a rich region based on ore deposit. From the major metal mines of Sistan and Baluchestan, it can be mentioned to the chromite mines. According to the existence of chromite deposits in the province and also various applications of chromite in different industries, it's expected that the establishment of chromite processing plant is needed in the erelong. This paper presents an application fuzzy TOPSIS which is used to select an appropriate site for chromite processing plant in Sistan and Baluchestan province. For this purpose, based on concentration of chromite deposits in different regions of the province, four feasible alternatives, including Zahedan, Khash, Iranshahr and Nikshahr cities, were selected for the chromite processing plant. Quantitative and qualitative criteria such as access to raw materials, availability of labor, education, water and weather, environmental effects, export market and domestic demand and security are used to compare the feasible alternatives. Finally, the alternatives are ranked and convenient location are recommended for the construction of chromite processing plant.

Keywords: Fuzzy, plan site, TOPSIS, chromite

1 INTRODUCTION

Localization is one of the spatial analyses that have great effect on reducing the costs of creating and construction of various activities. Today, finding a suitable place or places for the creation of an activity in a specific geographical area is an important step especially at the macro and national projects. Final possible sites must meet all provisions of these terms and constraints and lack of evaluation of such projects will lead to many undesirable results. Suitable location selection for construction of processing plant will create jobs and increase production of chromite mines. Also the demand for raw materials in Sistan and Baluchistan province and various industries such as metallurgical, chemical and pharmaceutical industries will be supplied. With proper selection of plant location, energy consumption, environmental impact and costs are significantly reduced. Site selection is a critical decision which requires considering a number of factors and evaluates several alternatives. In most cases, all the factors involved in site selection have not been taken into consideration and optimum alternative cannot be chosen. The goal of site selection is to find the best location with desired conditions that satisfy predefined criteria. Site selection for mineral processing plant needs to evaluate several alternatives with regard to a number of criteria. Therefore, this issue can be considered as a decision making process, which involves to find the best option among the feasible alternatives or to rank them. Over the past decades, many methods such as simple additive weighting (Hwang and Yoon 1981), the technique for order preference by similarity to ideal solution (Hwang and Yoon 1981), analytical hierarchy process (Saaty 1980), data envelopment analysis (Cooper et al. 2000), and so on have been developed to deal with a multiple decision making problem. in this

paper, fuzzy Analytic Hierarchy Process (Fuzzy-AHP) method is used for determining the importance weights of evaluation criteria, and fuzzy technique for order performance by similarity to ideal solution (Fuzzy TOPSIS) is used to obtain the performance ratings of the feasible alternatives in linguistic values parameterized with triangular fuzzy numbers (TFNs) (Zadeh, 1975).

2 FUZZY ANALYTIC HIERARCHY PROCESS (F-AHP)

Analytic hierarchy process (AHP) has been developed by Saaty (1990). The AHP structures the decision problem in levels which correspond to one understands of the situation: goals, criterion, sub-criterion, and alternatives. By breaking the problem into levels, the decision-maker can focus on smaller sets of decisions. In AHP technique the elements of each level compared to its related element in upper level inform by pair-wise comparison method.

It must be noted that, in pair comparison of criterion if the priority of element i compared to element j is equal to w_{ij} , then the priority of element j compared to element i is equal to $1/w_{ij}$. The priority of element compared to it is equal to one.

Inability of AHP to deal with the imprecision and subjectiveness in the pair-wise comparison process has been improved in fuzzy AHP. Instead of a crisp value, fuzzy AHP uses a range of value to incorporate the decision maker's uncertainty (Kuswandari 2004).

Fuzzy AHP method is applied in this research for criteria weighting. So, A fuzzy judgment matrix ($\tilde{J}$) is generated using fuzzy pairwise comparison index ($\tilde{j}_{ij}$). A relative importance of the pairwise comparison is assigned using a scale of 1–9 (Saaty 1977, 1988), which are fuzzified to capture vagueness in perception and meaning (Table 1). For n number of comparison items, the fuzzy judgment matrix $\tilde{J}$ is:

$$\tilde{J} = \begin{bmatrix} \tilde{j}_{11} & \tilde{j}_{12} & \cdots & \tilde{j}_{1n} \\ \tilde{j}_{21} & \ddots & & \tilde{j}_{2n} \\ \vdots & & \ddots & \vdots \\ \tilde{j}_{n1} & \tilde{j}_{n2} & \cdots & \tilde{j}_{nn} \end{bmatrix} \quad (1)$$

Table 1. Fuzzy scales for pairwise comparisons

Relative importance	Fuzzy scale
$\bar{1}$	(1, 1, 1)
$\bar{x}$	(x-1, x, x+1) for x= 2, 3, 4, 5, 6, 7, 8
$\bar{9}$	(8, 9, 9)
$1/\bar{1}$	(1/2, 1, 1)
$1/\bar{9}$	(1/9, 1/9, 1/8)

It is important to ensure that there is consistency in the pairwise comparisons (Saaty 2005). In order to measure the degree of consistency, one can calculate the Consistency Index (CI). Consistency index therefore, indicates whether a decision maker provides consistent values (comparisons) in a set of evaluation. The CI is calculated as:

$$CI = (\lambda_{max} - n)/(n-1) \quad (2)$$

The final inconsistency in the pairwise comparisons is solved using consistency ratio $CR = CI/RI$ where RI is the random index, which is obtained by averaging the CI of a randomly generated reciprocal matrix (Saaty 1980). The values of RI are tabulated in Table 2. In this paper, though the pairwise comparison indices of the judgment matrix are TFNs, however, the CI is evaluated for the most likely value.

As the next step fuzzy weights are calculated. Various techniques are used to compute the final fuzzy weights, such as, computation of the eigenvector, arithmetic mean, geometric mean, etc. In this study, for the ease of implementation the geometric mean is adopted to estimate the weights. Fuzzy arithmetic operations are utilized over matrix $\tilde{J}$ to compute the fuzzy weights. The geometric mean is computed for each row $\tilde{J}_i$. Given $\tilde{J}$ from Equation 1, the corresponding fuzzy weights are computed as:

$$\tilde{J}_i = (\tilde{j}_{i1} \otimes \cdots \otimes \tilde{j}_{in})^{\frac{1}{n}} \quad (3)$$

$$\tilde{w}_i = \tilde{J}_i \otimes (\tilde{J}_1 \oplus \cdots \oplus \tilde{J}_n)^{-1} \quad (4)$$

Where $\tilde{w}_i$ is the fuzzy weight (where i =1 to n).

Table 2. Random inconsistency indices (RI)

No. of criteria	1-2	3	4	5	6	7	8
RI	0	0.58	0.9	1.12	1.24	1.32	1.41

3 FUZZY TOPSIS

The TOPSIS method (Technique for Order Preference by Similarity to Ideal Solution) is a linear weighting technique which was first proposed in its crisp version by Chen and Hwang (1992). The ideal solution (also called the positive ideal solution) is a solution that maximizes the benefit criteria/attributes and minimizes the cost criteria/attributes, whereas the negative ideal solution (also called the anti-ideal solution) maximizes the cost criteria/attributes and minimizes the benefit criteria/attributes. The so-called benefit criteria/attributes are those for maximization, while the cost criteria/attributes are those for minimization. The best alternative is the one that is closest to the ideal solution and farthest from the negative ideal solution. The use of fuzzy theory allows us to incorporate unquantifiable information, incomplete information, non-obtainable information, and partial facts into the decision model. Therefore, in this paper, the concept of the approach used for solving the processing plant site selection problem will be based on the fuzzy technique for order preference by similarity to ideal solution (Fuzzy TOPSIS). This is because four advantages are addressed: (1) a sound logic that represents the rationale of human choice, (2) a scalar value that accounts for both the best and worst alternatives simultaneously, (3) a simple computation process that can be easily programmed, and (4) the performance measures of all alternatives on attributes can be visualized as a polyhedron, at least for any two dimensions. In the following section the fuzzy TOPSIS method is detailed in steps:

Step 1: Calculate the decision matrix (D) as equation 5:

$$\tilde{D} = \begin{array}{c} \\ A_1 \\ A_2 \\ A_3 \\ \vdots \\ A_m \end{array} \begin{array}{c} \begin{array}{ccccc} C_1 & C_2 & C_3 & \cdots & C_n \end{array} \\ \begin{bmatrix} \tilde{x}_{11} & \tilde{x}_{12} & \tilde{x}_{13} & \cdots & \tilde{x}_{1n} \\ \tilde{x}_{21} & \tilde{x}_{22} & \tilde{x}_{23} & \cdots & \tilde{x}_{2n} \\ \tilde{x}_{31} & \tilde{x}_{32} & \tilde{x}_{33} & \cdots & \tilde{x}_{3n} \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ \tilde{x}_{m1} & x_{m22} & \tilde{x}_{m3} & \cdots & \tilde{x}_{mn} \end{bmatrix} \end{array} \quad (5)$$

Where $\tilde{x}_{ij}$ (i=1, 2… m, j= 1, 2… n) are the linguistic values for alternatives with respect to criteria. The fuzzy linguistic rating the property $\tilde{x}_{ij}$ preserves that the ranges of normalized triangular fuzzy numbers belong to [0, 1]; thus, there is no need for normalization.

Step 2: Calculate the criteria weighted matrix as equation 6 (fuzzy weights for criteria in this section calculate based on Fuzzy-AHP):

$$\tilde{W} = \begin{bmatrix} \tilde{w}_1 & \cdots & 0 \\ \vdots & \cdots & \vdots \\ 0 & \cdots & \tilde{w}_n \end{bmatrix} \quad (6)$$

Where $\tilde{W}j, J = (1,2,...,n)$ are fuzzy numbers and represents the weight of the jth attribute, Cj.

Step 3: Calculate the weighted normalized decision matrix. The weighted normalized value $\tilde{v}_{ij}$ is calculated as:

$$\tilde{v}_{ij} = \tilde{w}_j \times \tilde{x}_{ij} = \tilde{W} \times \tilde{D} \quad (j = 1,2,...,n \text{ and } i = 1,2,...,m) \quad (7)$$

Step 4: Determine the positive ideal and negative ideal solutions, A^*, A^- respectively. The fuzzy positive-ideal solution (FPIS, A^*) and the fuzzy negative-ideal solution (FNIS, A^-) are shown as Equations 8 and 9:

$$A^* = (\tilde{v}_1^*, \tilde{v}_2^*, ..., \tilde{v}_n^*) = \left\{ \left(\max_j v_{ij} \middle| i \in K \right), \left(\min_j v_{ij} \middle| i \in L \right) \right\} \quad (8)$$

$$A^- = (\tilde{v}_1^-, \tilde{v}_2^-, ..., \tilde{v}_n^-) = \left\{ \begin{array}{l} \left(\min_j v_{ij} \,|\, i \in K \right), \\ \left(\max_j v_{ij} \,|\, i \in L \right) \end{array} \right\} \quad (9)$$

Where K is associated with benefit criteria, and L is associated with cost criteria.

Step 5: Calculate the separation measures, using the n-dimensional Euclidean distance. The distance of each alternative from the ideal solution (A^*) and the distance from the negative ideal solution (A^-) are given as equations 10 and 11 respectively:

$$D_i^* = \sum_{j=1}^{n} d(\tilde{v}_{ij}, \tilde{v}_j^*), i = 1,2,...,m \quad (10)$$

$$D_i^- = \sum_{j=1}^{n} d(\tilde{v}_{ij}, \tilde{v}_j^-), i = 1,2,...,m \quad (11)$$

Step 6: Calculate similarities to ideal solution. The relative closeness of the alternative Ai with respect to A^* is defined by equation 12:

$$RC_i = \frac{D_i^-}{D_i^* + D_i^-} \quad (12)$$

Step 7: Rank the alternatives according to the relative closeness to the ideal solution (RC_i)

The higher value of RC_i indicates that an alternative is closer to the positive ideal solution and farther from the negative ideal solution simultaneously. A value of 1 (or 100 per cent) for an alternative indicates that the alternative is equal to the positive ideal solution and a value of 0 (or 0 per cent) is equal to the negative ideal solution. The best alternative is the one with the greatest relative closeness to the positive ideal solution.

The proposed model for selection of chromite processing plant site, composed of fuzzy AHP and fuzzy TOPSIS methods, consists of two basic stages: (1) identify the criteria to be used in the model and Assigning criteria weights via Fuzzy-AHP (2) evaluation of alternatives with Fuzzy-TOPSIS and determination of the final rank.

In the first stage, criteria used in processing plant site selection are assigned weights using Fuzzy-AHP. In this phase, pairwise comparison matrix is formed to determine the criteria weights. The values of the elements of pairwise comparison matrices determine using the scale provided in Table 1. As the next step fuzzy weights are calculated using the geometric mean technique.

Alternatives ranks are determined by using fuzzy TOPSIS method in the second stage. Linguistic values are used for evaluation of alternatives in this stage. the linguistic variables divided to five-levels, fuzzy linguistic values ‘very bad, ‘bad’, ‘medium’, ‘good’ and ‘very good. In next step, linguistic values are converted to fuzzy numbers with transformation of fuzzy membership functions, as are shown at Table 3.

Table 3. Linguistic values for the ratings

Linguistic values	Fuzzy numbers
Very bad (VB)	(0, 1, 3)
Bad (B)	(1, 3, 5)
Medium (M)	(3, 5, 7)
Good (G)	(5, 7, 9)
Very Good (VG)	(7, 9, 10)

4 APPLICATION OF PROPOSED MODEL TO CHROMITE PROCESSING PLANT SITE SELECTION IN SISTAN AND BALUCHESTAN PROVINCE

Sistan and Baluchestan province is one of the largest and richest areas of mineral deposits in southeast of Iran. One of the important metallic mineral deposits is chromite one that can be found in various parts of the province. Distribution of chromite deposits in the province illustrated in Figure 1. The red spots in this figure represent the chromite deposits. It can be clearly seen that chromite mines are concentrated around Zahedan, Khash, Nikshahr and Iranshahr.

The first step in the process of site selection is collecting and evaluating the required information. The selection of an

appropriate site for mineral processing plant involves considering many criteria. The large number of criteria leads to a computational difficulty, a time consuming process and an unrealistic outcome.

The criteria of decision-making for chromite processing plant site selection in Sistan and Baluchestan province including access to raw materials (C1), availability of labor (C2), education (Access and promotion of labor) (C3), water and weather (temperature , humidity, precipitation, number of dusty days per year and …) (C4), environmental effects (C5), export market and domestic demand (C6) and security (C7). Also with evaluating distribution map of chromite deposits in Sistan and Baluchistan province, feasible alternatives are those locations that chromite deposits are more concentrated. Selected locations are Zahedan (A1), Khash (A2), Iranshahr (A3) and Nikshahr (A4). Each alternative is evaluated with relevant criteria based on the technical and experimental experiences and also by asking the decision makers and experts.

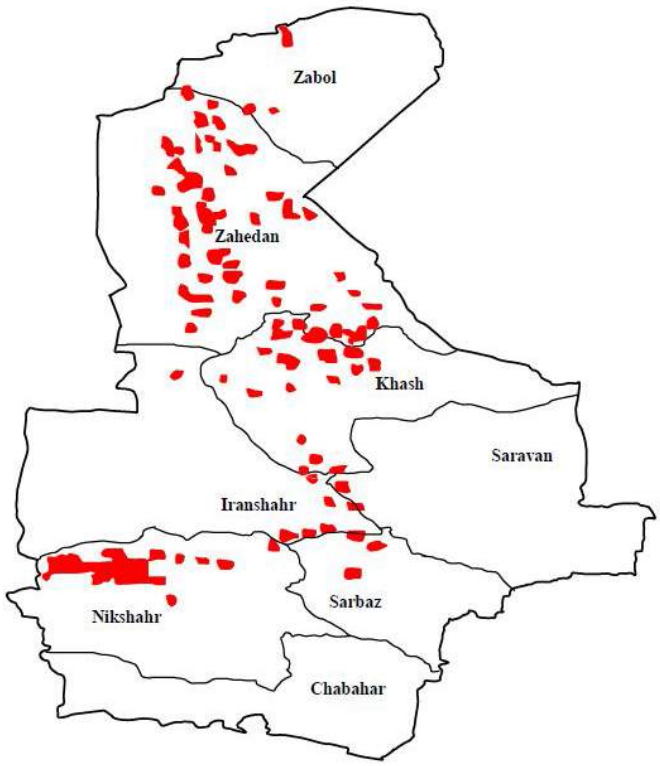

Figure 1. Distribution of chromite deposits in Sistan and Baluchestan province (the red spots represent the chromite deposits)

After determination of the criteria, the weights of the criteria to be used in evaluation process are calculated by using fuzzy AHP method. In this phase, the experts in the expert team are given the task of forming individual pairwise comparison matrix by using the scale given in Table 1. Geometric means of these values are found to obtain the pairwise comparison matrix on which there is a consensus (Table 4). The results obtained from the computations based on the pairwise comparison matrix are presented in Table 4. Consistency ratio of the pairwise comparison matrix is calculated as $0.056 < 0.1$. So the weights are shown to be consistent and they are used in the selection process.

In next step, the decision matrix establish by comparing alternatives under each of the criteria separately. Fuzzy evaluation matrix established by the evaluation of alternative rifles by linguistic variables in Table 3, is presented in Table 5. The table is composed of the triangular fuzzy numbers which are equivalent of linguistic variables. As the decision matrix should be normalized, the corresponding matrix is presented in Table 6.

After the fuzzy evaluation matrix was determined, the next step is to obtain a fuzzy weighted decision table. Using the criteria weights calculated by fuzzy AHP (Table 4), the Weighted Evaluation Matrix is established with equation 7. The resulting fuzzy weighted decision matrix is shown in Table 7.

In next step, we define the fuzzy positive-ideal solution (FPIS, A^*) and the fuzzy negative-ideal solution (FNIS, A^-). Therefore, the distance of each alternative from A^* and A^- can be currently calculated using equations 10 and 11. The final step solves the similarities to an ideal solution by equation 12. The resulting fuzzy TOPSIS analyses are summarized in Table 8. Based on RC_i values, the ranking of the alternatives in descending order are A2, A1, A3 and A4. Proposed model results indicate that A2 (Khash see Fig.1) is the best alternative with RC_i value of 0.465.

5 CONCLUSIONS

In this study, a decision model is proposed for the selection of chromite processing plant site in Sistan and Baluchestan province of Iran. The proposed model is based on the comparisons of alternatives according to identified criteria. AHP and TOPSIS in a fuzzy environment compound decision-making method have been used in the proposed model. Fuzzy AHP is used to assign weights to the criteria to be used in processing plant site selection, while fuzzy TOPSIS is employed to determine the priorities of the alternatives. Empirical results showed that the proposed model can be a suitable tool to select the processing plant site.

Effect of Different Depressants on Galena Flotation

Farklı Bastırıcıların Galen Flotasyonuna Etkisi

ABSTRACT Selective separation of sulphide minerals such as galena, chalcopyrite, sphalerite, pyrite etc., can be achieved with various collectors, depressants and modifiers. The aim of this study is to investigate different depressants for depression of galena. On this basis, the effect of Na_2S, H_2O_2 and S7260 were investigated on galena flotation. Pure galena was used as ore sample and experiments were conducted with Denver flotation cell using 3418A as a collector and MIBC as a frother. The effects of depressant amount and different pH were examined. Flotation recovery of galena approached the highest value at pH 7 and decreased at pH 11 without any depressant. As a result of experiments it is found that depressing effect of these depressants was related to their amount and pH. The depressing effect of all depressants reached highest value at pH 11. It is found that S7260 was the most effective depressant among them.

Keywords: Flotation, depressant, Na_2S, H_2O_2, S7260

ÖZET: Galen, kalkopirit, sfalerit ve pirit gibi sülfürlü minerallerin birbirlerinden seçimli olarak ayrılmasında çeşitli kollektörler, bastırıcılar ve düzenleyiciler kullanılmaktadır. Bu çalışmanın amacı farklı bastıcıların galen flotasyonuna etkisini incelemektir. Bu amaçla Na_2S, H_2O_2 ve S7260'ın bastırıcı etkileri araştırılmıştır. Saf galen numunesiyle Denver flotasyon hücresinde 3418A kollektörü ve MIBC köpürtücüsü ile flotasyon yapılmıştır. Bastırıcıların etkileri farklı miktarlarda ve çeşitli pH'larda incelenmiştir. Herhangi bir bastırıcı kullanmaksızın galenin flotasyon verimi pH 7'de en iyi değere ulaşmış, pH 11'de düşmüştür. Deneylerin sonucunda bastırıcıların etkisinin pH'ya bağlı olduğu görülmüştür ve tüm bastırıcıların etkisi pH 11'de en yüksek değere ulaşmıştır. S7260 içlerinde en etkili bastırıcı olarak bulunmuştur.

Anahtar kelimeler: Flotasyon, bastırıcı, Na_2S, H_2O_2, S7260

1 INTRODUCTION

Flotation is an important step for separation of Cu-Pb-Zn minerals from gangue minerals and pyrite. The treatment processes of selective separation Cu-Pb-Zn minerals are generally complex. Effective selective separation depends on a variety of collectors and modifiers to adjust surface properties. In practice, when treating complex sulphide ores, the use of two or more depressants are common, especially when a selectivity problem is present or separation of several valuable minerals are required (Bulatovic and Wyslouzil, 1995).

The methods used in the processing of copper-lead-zinc ore could be classified as follows (Bulatovic, 2007):

a) Sequential copper, lead, zinc flotation method

b) Bulk flotation of copper and lead followed by zinc flotation from the bulk tailings. The copper–lead separation is performed on the upgraded bulk concentrate. This is the most

commonly used method in the treatment of copper, lead-zinc ores

c) Bulk flotation of copper-lead-zinc minerals followed by a selective flotation of copper, lead and zinc from the bulk concentrate

The bulk copper–lead flotation method is the most common method. In this method, the copper–lead bulk concentrate is floated, followed by Cu–Pb separation. Usually, in the Cu–Pb separation, tailing is the final lead or copper concentrate depending on the separation method used (Bulatovic, 2007).

In general, there are two basic copper–lead separation methods commonly used during the treatment of copper–lead–zinc ores:

a) In copper depression and lead flotation generally cyanide treatment is used.

b) In lead depression and copper flotation, the methods below are preferred:

(i) Use of oxidizing reagents (i.e. bichromates, hypochlorites, etc.)

(ii) Use of sulfoxy compounds with or without oxidants, or with starch derivatives (Gül, 2007; Gül et al., 2008)

(iii) Use of SO_2 /starch with or without heating (i.e. thermal treatment)

Generally in the copper-galena selective flotation, the copper minerals are floated while galena is depressed (Houot and Duhamet, 1992).

In the literature, there are several inorganic and organic compounds used in depression of galena. These are sodium sulfide, sodium chromate, polysaccharides such as carboxy methyl cellulose, dextrin and caustic starch. Sodium sulfite and SO_2 were used for depression of galena and sphalerite between 250-2000 g/t amount. Sodium dichromate was another chemical which was used for galena depressant in Cu/Pb separation.

The aim of this study is to investigate different depressants for selective depression of galena. On this basis the effect of Na_2S, H_2O_2 and S7260 were investigated on galena flotation.

2 MATERIAL AND METHOD

The galena sample used in this study was supplied from Esan Balya Lead and Zinc plant in Turkey. The impurities were elected by handsorting. The chemical composition of galena was 85.69% Pb, 13.35% S and 0.8% SiO_2. The sample is almost 99% purity. The collector used in flotation experiments was 3418A (Cytec), and methyl isobuthyl carbinol (MIBC) from Aldrich was employed as a frother. 3418A is a sodium-diisobutyl dithiophosphinate (DTPINa) type collector. Na_2S (Merck), H_2O_2 (Merck) and S7260 (Cytec) were used in the experiments to investigate effect of these depressants on flotation recovery of galena. S7260 is a polymeric depressant and contains between 30 to 60% polymer in an aqueous solution with up to 10% isopropanol and 10% sodium metabisulphite. H_2SO_4 and lime were used as pH regulators. The pure galena sample was ground dry with agate mortar freshly for each experiment. According to sieve analysis the d_{80} and d_{50} size of the galena was found as 0.046 mm and 0.015 mm, respectively. The experiments were conducted with 50 g of sample using 1L cell with Denver machine, the impeller speed was at 1200 rpm. The results were shown as flotation recovery and calculated through the mass balance of the floated and remained products. The experimental conditions were given in Table 1.

Table 1: Experimental Conditions

Collector: 3418A	*100 g/t*
Frother: MIBC	*300 g/t*
Conditioning Time with depressant	*10 min*
Conditioning Time with collector	*3 min*
Flotation Time	*5 min*

3 RESULTS

3.1 Effect of pH

A series of experiments were conducted to investigate effect of pH at experimental conditions given in Table 1. The results were given in Figure 1 and Table 2. It was found that galena could float in every pH with high recovery however the highest recovery was obtained between pH 7-9. Above and below this pH the recoveries slightly decreased and the lowest recovery was obtained at pH 11.

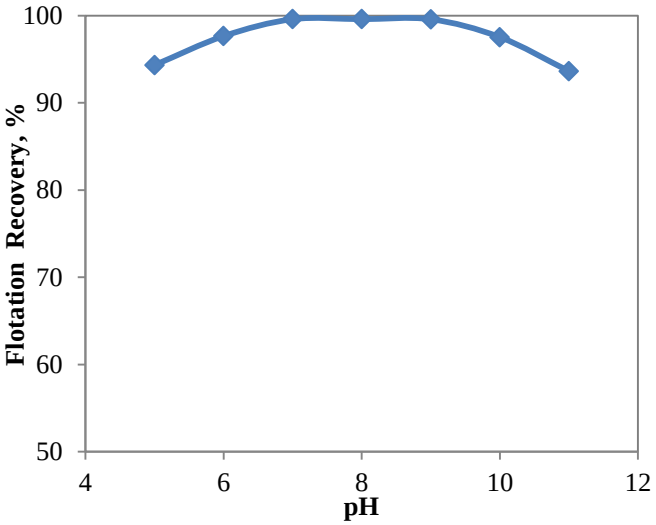

Figure 1. Effect of pH on galena flotation

Table 2: Effect of pH on galena flotation

pH	*Recovery, %*
5.0	94.34
6.0	97.66
7.0	99.60
8.0	99.60
9.0	99.59
10.0	97.54
11.0	93.64

3.2 Effect of Depressants

In order to investigate the effect of depressants on galena flotation, H_2O_2 Na_2S, and S7260 were used. The amount of H_2O_2 was changed between 500-10000 g/t at different pH values. The results were shown in Figure 2. It was found that increasing H_2O_2 amount did not affect the recovery of galena at pH 7. However a decline could be seen at other pH values. It is worth to note that very low H_2O_2 amount decreased the flotation recovery of galena at pH 11. As a result, increasing H_2O_2 amount from 500 g/t to 10000 g/t decreased the flotation recovery from 93.6% to 15.1%.

Na_2S was used as another depressant in this study. The amount of Na_2S was changed between 500-10000 g/t at different pH values. The results were shown in Figure 3. According to experiments it was found that increasing Na_2S amount decreased the flotation recovery from 99.4% to 67.4% at pH 7. Besides, increasing Na_2S amount was more effective than H_2O_2 on the flotation recovery above pH 7. The lowest recovery was obtained as 10% at pH 9 and 11 using 10000 g/t Na_2S.

The third depressant used in this study was S7260. The amount of S7260 was changed between 200-2000 g/t at different pH's and the results were depicted in Figure 4. The most efficient depressant was found to be S7260 even in very low amounts. When 2000 g/t S7260 amount was used the flotation recovery was decreased to 10% at pH 7. In other pH values, 10% recoveries were obtained even at lower amounts. The highest influence of S7260 amount occurred again at pH 11.

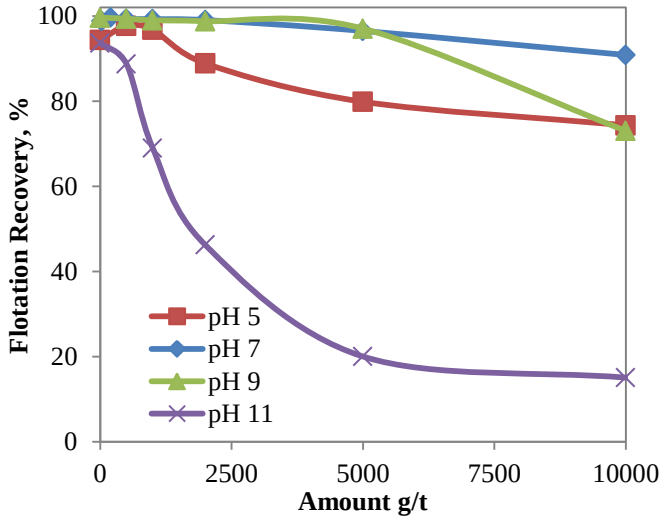

Figure 2. Effect of H_2O_2 amount on galena flotation

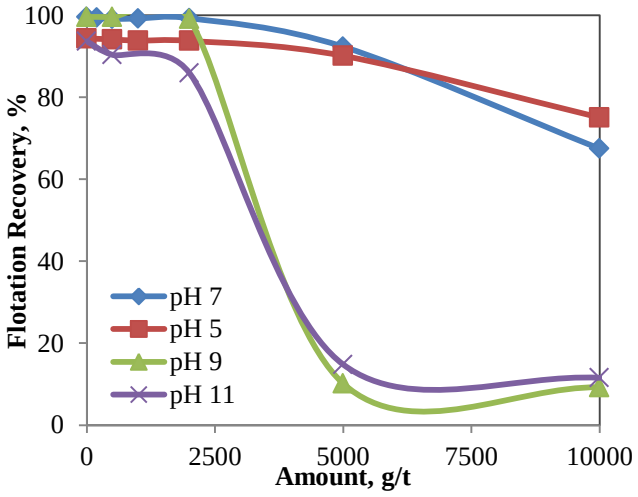

Figure 3. Effect of Na_2S amount on galena flotation

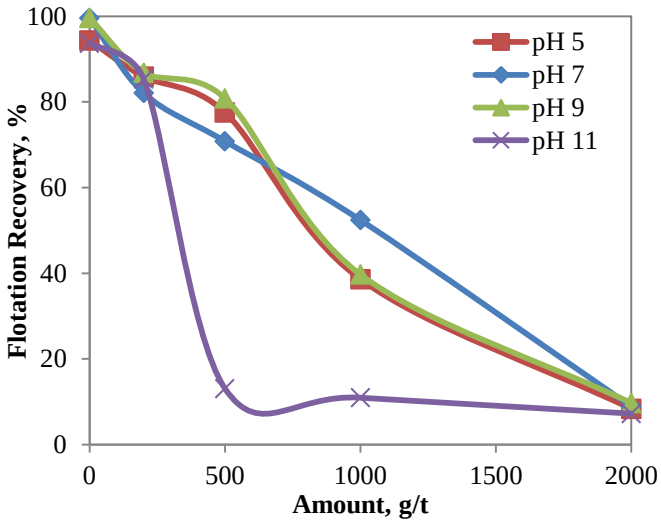

Figure 4. Effect of S7260 amount on galena flotation

4 DISCUSSION

In this study, the effects of different depressants were investigated using pure galena. The purity of galena sample was 99%. The collector used in the experiments is 3418A, which is an anionic sodium-diisobutyl dithiophosphinate collector and mainly adsorbs on galena at every pH. The collector 3418A adsorbs onto the surface of galena regardless of its negative charge, thus suggesting the contribution of a chemisorption mechanism (Pecina-Trevino et al., 2003).

First of all, the effect of pH was investigated without the use of any depressant. It was found that the flotation recovery of galena was highest between pH 7-9 and decreased above and below these pHs. The lowest recovery was found as 93.6% at pH 11. However in another study (Barsakçı, 2008) the flotation recovery was found as 66% at pH 11 using pure galena sample at same experimental conditions. The tendency of the flotation recovery was found similar while the recoveries were not due to different origin of the galena samples. In the literature it has been noted that complete flotation of galena can occur from pH 2 to 10 (Weiss, 1985). Flotation of galena in acid solutions is explained by increased hydrophobicity with oxidation due to formations of sulphur on the surface by Kocabağ et al. (1990). Passing from acidic to neutral and alkaline solutions oxidation of galena takes place forming $Pb(OH)_2$ on the surface in addition to S^0, which decreases the hydrophobicity due to the formation of $Pb(OH)_2$ or metal-sulpoxy compounds (Kocabağ et al., 1990).

In the second stage, the effect of H_2O_2 was investigated, in 500-10000 g/t amount range. It was found that, 500 and 1000 g/t H_2O_2 addition increased the flotation recovery of galena at pH 5, above this amount it was decreased and 73.4% galena recovery was obtained at 10000g/t H_2O_2 amount. The same tendency was observed at pH 9. At pH 7 flotation recovery was slightly decreased even at 10000 g/t H_2O_2 amount. H_2O_2 is a strong oxidant which causes non selective oxidation of sulphide minerals. It was also reported that galena flotation decreases and completely get depressed if the concentration of H_2O_2 exceeds 10^{-3}M (Wang, 1992). The similar findings were observed by Hu et al., (2010) who stated that the flotation recovery of galena decreased at pH 9.5 when H_2O_2 concentration was above 10^{-3}M but the chalcopyrite remained floatable and suggesting these conditions were applicable to selective separation of chalcopyrite and galena.

In the third stage, the effect of Na_2S was investigated in 500-10000 g/t amount range and different pHs. It was found that increasing the amount of Na_2S had not a significant depressing effect on galena at pH 5 and 7. However increasing amount of Na_2S depressed the galena flotation and the recovery of galena was found to be 10% at pH 9 and 11 with 10000 Na_2S. The concentration of Na_2S is very critical, low dosages of Na_2S can be used as an activator while high dosages can prevent mineral-reagent reaction so it can be used as a depressant (Bulatovic, 2007). Lead sulfide is a very insoluble compound so that additions of sodium sulfide will result in the formation of lead sulfide rather than lead-collector if two chemicals are present at the same time (Fuerstenau et al., 1985).

In the last stage, S7260 was used as a depressant between 200 and 2000 g/t amount. The results at pH 5, 7 and 9 showed

similar tendency and flotation recoveries were decreased to 9% at 2000 g/t amount. Like other depressants, the highest depressing effect was observed at pH 11, the recovery of galena decreased to 13% using 500 g/t amount of S7260. The increasing amount decreased the recovery of galena to 7%. S7260 is generally known as an iron sulphide depressant, which requires low dosages (Cytec, 2010). S7260 was previously used by Gül et al., (2013) for the selective separation of Cu and Pb . Very low amounts (25 g/t) of S7260 were used for selective depression of pyrite and Cu minerals. In addition, Baştürkcü et al., (2012) used S7260 for pyrite rejection in rougher Pb-Cu circuit. It is necessary to note that the amount of S7260 is very critical for Pb flotation; low amounts depress the other sulphide minerals and increase selectivity whereas high amounts may cause Pb depression as shown in this study.

5 CONCLUSION

According to this study, the highest recovery of pure galena found at pH 7 and lowest recovery was obtained at pH 11. Among used depressants in this study such as H_2O_2, Na_2S and S7260, S7260 was found as the most efficient in all pH ranges. H_2O_2 was found inefficient at pH 5, 7 and 9 and efficient at pH 11 at high dosages. Na_2S was found to be effective at pH 9-11 at high dosages. These depressants can be used for depression of Pb minerals.

Matematical Modeling of Elementary Act of Flotation in Vibratory Column Machine

J. Dimitrov
University of Mining and Geology, Sofia, Bulgaria

Kr. Dedelyanova
Scientific and Technical Union of Mining, Geology and Metallurgy, Sofia, Bulgaria

ABSTRACT The paper presents research on hydrodynamic processes occurring at the elementary act of flotation. Discussed existing models to determine the effectiveness of conflict of bubbles with particles in vibration column flotation machine

It is proposed an analytic description of the mathematical model representing the mechanism of attachment of the particles to the bubble.

Keywords: Flotation, vibratory column machine, mathematical model, bubble attachment

1 INTRODUCTION

The wide practical introduction of column flotation machine is a great achievement in during the last decade in the field of flotation concentration. The advantages of the column flotation machine in comparison with the mechanical and pneumo - mechanical are following: increased productivity improved hydrodynamics, of concentrate with the required quality at minimal quantity purifying and control operations, production area decrease and economy of electric power.

Work efficiency in flotation machines depends on the terms of the dispersion of air. Aerators should provide maximum gas content in optimum average particle size of the bubbles. For aerators put the following requirements: ensuring that size of the bubbles, which provide buoyancy the flotation complex and minimal macro-circulation of the pulp chamber (Finch, 1990).

At vibration flotation machine has additional factors influencing the increase of the duration of bubble's existence in the contact zone with the mineral particles was discussed. In Dedelyanova & Dimitrov (2013) the mechanism for attachment of the particles to the bubbles in the vibratory column flotation machine was studied. The effectiveness of the collision of the bubbles in the vibratory column flotation machine were defined.

This paper will focus on an improved model of the elementary act of flotation in the vibratory column flotation machine.

2 MODEL OF BUBBLE OSCILLATION

In order to make an analysis of the process of collision we assume that the bubble is spherical and around it we go over a rotational body with vertical axis passing through the center of the sphere. We denote with d_b the diameter of the bubble, d_p - diameter of the particles and a - diameter of the section of the cylindrical area including area involved in collision from particle and bubble.

Consider the model given by Bogdanov (Bogdanov, 1990). The section of the cylindrical area of the fluid before the collision at a diameter a is $S_0 = \pi a^2/4$ and at the level of collision - $S_b = \pi\left(d_b+d_p\right)^2/4$.

For the effectiveness of collision we obtain

$$E = \frac{S_0}{S_b} = \left(\frac{a}{d_b + d_p}\right)^2. \quad (1)$$

Then the parameter E is the ratio of the section of the narrow part of the area before

collision and the section through the center of the bubble.

As the bubble vibrates with acoustic frequency f, its mean diameter d_b is the same as without vibrations. While making one harmonic cycle, the volume of the bubble is preserved as it changes its form from sphere to rotational ellipsoid. A bubble with a spherical form and a diameter d_b has a volume

$$V_b^s = \frac{\pi}{6} \cdot d_b^3. \tag{2}$$

During each harmonic cycle the bubble changes from sphere to rotational ellipsoid with axis (diameter) in horizontal direction d_{xy} and axis in vertical direction $d_z \neq d_{xy}$. The volume of the ellipsoid is:

$$V_b^e = \frac{\pi}{6} \cdot d_{xy}^2 d_z. \tag{3}$$

If we disregard the change of the typical size d_b of the bubble, then we can assume that at a moment close in time the following equation is satisfied $V_b^s = V_b^e$ and hence it follows that:

$$d_{xy}^2 d_z = d_b^3. \tag{4}$$

During the experiments made in Dedelyanova (Dedelyanova, 2004), the average size of the bubbles was $d_b = 4\ mm$ and the amplitude A was from 1.5 to 3.0 mm. A significant condition for the models which we apply is the inequality $d_b > A$ executed during these experiments. In one harmonic cycle of the bubble at a given time, it has the form of a rotational ellipsoid with a larger horizontal diameter $d_{xy} = d_{xy\max}$. At another time the horizontal diameter is the smallest possible $d_{xy} = d_{xy\min}$. In these extreme conditions the respective sizes of the vertical diameter are:

$$\begin{aligned} d_{z\max} &= d_b + A \\ d_{z\min} &= d_b - A \end{aligned}. \tag{5}$$

The next equations follow from formula (4):

$$\begin{aligned} d_{xy\max} &= \sqrt{\frac{d_b^3}{d_{z\min}}} \\ d_{xy\min} &= \sqrt{\frac{d_b^3}{d_{z\max}}} \end{aligned}. \tag{6}$$

Variation changing on the size of bubble in the process of emergence is given by the formula.

$$d_b = d_0 \sqrt[3]{\frac{p_0}{p_1 + qAf^2 \sin \omega t}} \tag{7}$$

where d_b the diameter of the bubble; d_0 - the diameter of the bubble on the surface; $p_1 = p_0 + \rho_l hg$, where p_0 - atmospheric pressure; ρ_l - density of liquid; h - level from the surface of the liquid and g - acceleration of gravity.

3 EXPERIMENTAL RESEARCHES

For determination the essential parameters of the flotation process is used stereology analysis. Figure 1 represents a photograph of a part of the column machine camera.

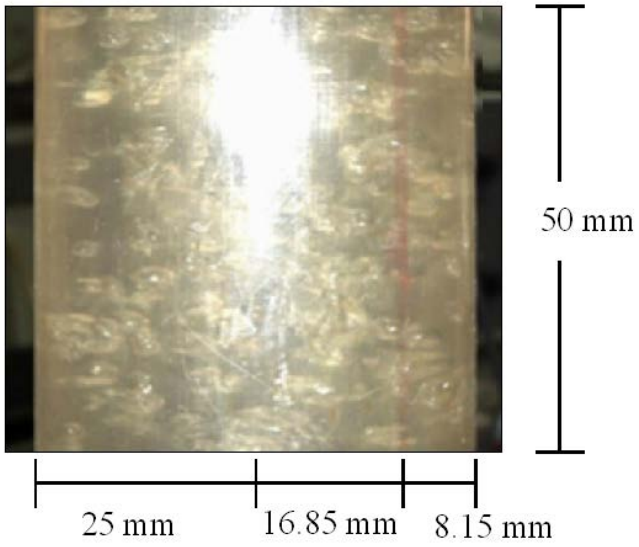

Figure 1. Photograph of a part of the camera in column machine and a scheme for stereological analysis

On the photo is applied marker with a red line. In Figure 1 are shown and dimensions with the aid of which it can calculate the geometric parameters of the cylinder representing the photographed part of the camera. The marker, represented by a red line, sets the vertically planar section of a

cylinder, which has a certain volume - sector of the cylinder. From the photographic image we can obtain the number of bubbles in the sector and the number of those of them that cross the section marked with the red line.

Section of the cylinder is a rectangle with height $50\,mm$ and width that after the corresponding calculation shall be determined on $39.94\,mm$. The surface of the section is $S = 50 \times 39.94 = 1997\ mm^2 = 19.97\ cm^2$.

The volume of sector compartments with a red line is $V_1 = 182.26 \times 50 = 9113\ mm^3 = 9.1\ cm^3$

From the photographic image in Figure 3 are counted about 30 bubbles per limited by the red line sector. Then

$$N = \frac{30}{9.1} = 3.29\ mm^{-3}. \quad (8)$$

is the number of bubbles by volume

From Figure 1 can be determined and the number of bubbles that are in contact with the section limited by the red line. This number is 26. We receive number of bubbles per unit area from section -

$$n = \frac{26}{19.97} = 1.3\ cm^{-2}. \quad (9)$$

For the determination of average diameter of the bubbles is used stereological equation (Saltykov, 1976, Weibel, 1980):

$$d_b = \frac{n}{N} = 0.395\ cm = 3.95\ mm. \quad (10)$$

In Dedelyanova (Dedelyanova, 2004) made studies on the rate of ascent of the bubble at different frequencies of vibration and without vibration. The average speed of ascent is $25\,cm/s$. Is obtained a decrease of 13-14% in the rate of ascent in vibration.

4 IMPROVEMENT OF ELEMENTARY ACT OF FLOTATION

There are two forces acting on the forming bubble during the vibration of the dispersing agent: lifting force of the fluid displaced by the bubble and the resistance force caused by the flow-around of the bubble by the flow of fluid which moves along the inclined wall of the dispersing agent. While the lifting force is always targeted upwards, the resistance force from the flow-around is dependent on the phase of fluctuations. The lifting force increases with the increase of the diameter of the forming bubble, the resistance force also increases with the increase of the diameter of the bubble but it changes also according to a sinusoidal law.

4.1 Schematic Presentation of the Harmonic Cycle of Bubble

Figure 2 shows schematically several harmonic cycles of the bubble. The harmonic cycle includes five characteristic states:

ST1 – the state in which $d_{xy} = d_{xy\max}$. In this state the bubble is with a small diameter along axis z;

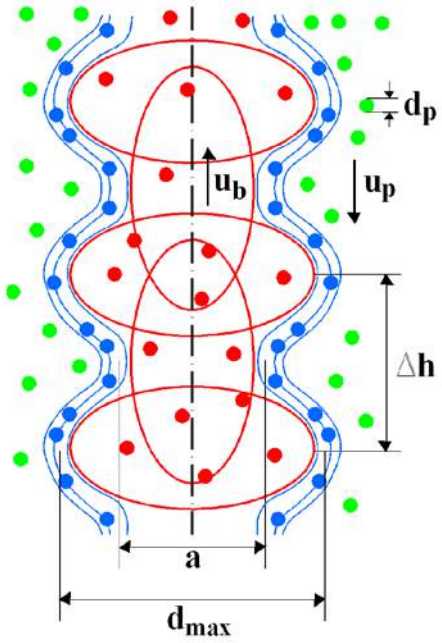

Figure 2. Scheme of several harmonic cycles of the bubble

ST2–the state following in time after ST1, in which $d_{xy} = d_z = d_b$ is the characteristic size of the bubble with the form of sphere;

ST3–state after ST2, in which $d_{xy} = d_{xy\min}$;

ST4–state after ST3, in which $d_{xy} = d_z = d_b$. We have a sphere as in state ST2;

ST5–state following ST4 and the beginning of the next harmonic cycle – it

coincides with ST1 of the next harmonic cycle.

On Fig. 3 the parameter a is the radius of the section S_0 and $d_{\max} = d_{xy\max} + d_p$ - radius of S_b. Δh designates the step in one harmonic cycle of the bubble during its movement in relation to the particles with rate $u = u_b + u_p$. It is fulfilled

$$u = \Delta h \cdot f \,. \tag{11}$$

The radius a is different for the different frequencies f of vibration. We can discern three different cases:

1. The frequency $f < f_0$ is high enough and respectively Δh - low enough, so that $a < d_{xy\min} + d_p$;

2. Case $f = f_0$, in which $a = d_{xy\min} + d_p$ and

3. Case $f > f_0$. Then $a > d_{xy\min} + d_p$.

4.2 Presentation of the Collision Efficiency

We assume that the bubble has the shape of a rotating ellipsoid with axis Oz. Denote by r_{xy} the horizontal radius of the ellipsoid and by r_z - the vertical radius (Figure 3).

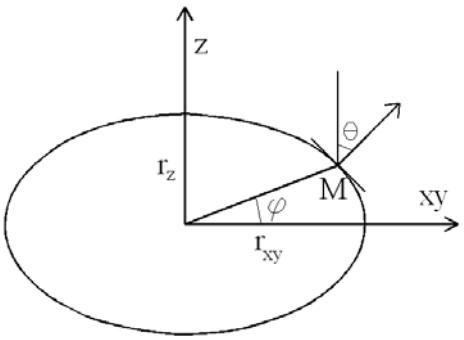

Figure 3. Schematic of contact between a particle and bubble

It is true that

$$r_{xy}^2 r_z = r_b^3 , \tag{12}$$

where r_b is the characteristic radius of the bubble when it takes the shape of a sphere.

Figure 2 schematically shows a vertical section of the ellipsoid:

θ - angle between the trajectory of the falling particle (axis Oz) and the normal to the ellipsoid at the point of contact M;

φ - polar angle of the point of contact M.

$$\theta \in [0, \theta]_{\max} \tag{13}$$

where $\theta_{\max}$ is the maximum angle at which the particles will be retained on the wall of the bubble.

Is fulfilled

$$\theta_{\max} \in \left(\frac{\pi}{4}, \frac{\pi}{2}\right), \quad \theta_{\max} = const \,. \tag{14}$$

On this position M of the point of contact corresponds abscissa a - radius of the cylindrical part of the fluid containing the particles stick to the bubble. This cylindrical portion of the fluid is in contact with the bubble and its projection on the wall of the bubble is the area of contact.

After the appropriate calculations is obtained:

$$a = \frac{r_{xy}^2 \sin\theta_{\max}}{\sqrt{r_z^2 \cos^2\theta_{\max} + r_{xy}^2 \sin^2\theta_{\max}}} \tag{15}$$

Let $\varphi_{\min}$ is the polar angle of the point of contact M, when it is in the boundary of the area of contact. Then $a = r_{xy}\cos\varphi_{\max}$ and

$$tg\varphi_{\min} = \frac{r_z}{r_{xy}} tg\left(\frac{\pi}{2} - \theta_{\max}\right) \tag{16}$$

The surface of the area of contact is

$$S(r_{xy}, r_z) = \frac{\pi r_{xy}^4 \sin^2\theta_{\max}}{r_z^2 \cos^2\theta_{\max} + r_{xy}^2 \sin^2\theta_{\max}} \,. \tag{17}$$

The shape of the ellipsoid varies periodically as the vertical radius can be represented

$$r_z = a\sin wt + r_b \,, \tag{18}$$

where $w = 2\pi f$,

f - vibration frequency.

$T = \frac{2\pi}{w} = \frac{1}{f}$ - period.

As defined, the effectiveness of a collision at the time when the bubble is in the shape of a sphere is

$$E_0 = \frac{S_0}{\pi\left(r_b + r_p\right)^2}, \quad (19)$$

where r_b - a characteristic bubble radius;

r_p - characteristic radius of the particle.

$$S_0 = \pi r_b^2 \sin^2 \theta_{\max} \quad (20)$$

is the face of the area of contact.

If we ignore the size of the particle, we can accept that

$$E_0 = \sin^2 \theta_{\max}. \quad (21)$$

Effectiveness of conflict have changed over time, together with a change in shape of the bubble. The instantaneous efficiency of conflict is represented by the formula

$$E(t) = E_0 \frac{S\left(r_{xy}, r_z\right)}{S_0}. \quad (22)$$

Effectiveness of conflict for a period of vibration T is given by the formula

$$E = \frac{1}{T}\int_0^T E(t)dt = \frac{E_0}{T}\int_0^T \frac{S\left(r_{xy}, r_z\right)}{S_0}dt \quad (23)$$

Due to the high frequency of vibration in relation to the velocity $u = u_b + u_p$ of the contact and the relatively large inertia of the particles, the radius of the cylindrical region of the fluid which is in contact with the bubble, is determined by the state of the bubble at the largest horizontal radius.

$$r_{xy} = r_{xy\max} = r_b + \frac{A}{2}$$

and $r_z = r_{z\min} = r_b - \frac{A}{2}$

In this case we have

$$\frac{S\left(r_{xy}, r_z\right)}{S_0} = \frac{r_b^2 + r_b\frac{A}{2}}{r_b^2 + r_b\left(\frac{A}{2}\right)^2 \cos 2\theta_{\max} - 2\frac{A}{2}r_b \cos^2 \theta_{\max}} \quad (24)$$

because of $\cos 2\theta_{\max} < 0$ we receive

$$\frac{S\left(r_{xy}, r_z\right)}{S_0} > 1 \quad (25)$$

which shows that the effectiveness of collision at vibration is greater than without the vibration

$$E > E_0. \quad (26)$$

5 CONCLUSIONS

In paper is presented a improved model of the elementary act of flotation.

It includes:

- model of bubble oscillation on a given level on camera of column machine;
- stereological analysis for obtaining the basic parameters of the flotation process;
- schematic presentation of the harmonic cycle of bubble and
- analytical method for the expressing of the average of the collision efficiency.

Facts which were proved through experiments are confirmed by the analytical study of the effectiveness of collision E.

The vibrations make possible the increase in the time of stay of the bubble in the contact zone with the mineral particles and the more cost-effective implementation of the elementary act of flotation by ensuring higher rates of the collision of the bubble with the solid phase.

The analytical expressions for the effectiveness of collision E can be used during the design of vibratory column flotation machines.

ABSTRACT Tailings issued from polymetallic ore flotation of Chaabat el-Hamra mine contain sulfides such as Galena (PbS), Pyrite (FeS_2) and Chalcopyrite ($CuFeS_2$). They present environmental threats such as the acid mine drainage. Chemical analysis showed that the major element of these tailings is Pyrite. The processing of the latter eliminates much of the sulfur.

The flotation is based on the difference of the minerals surface properties such as hydrophobicity, hydrophility, addition of appropriate reagents and their adhesion to bubbles.

In this work, we propose to use the method of thermodynamic analysis in view of studying and identifying the main physico-chemical parameters of flotation, such as the thermodynamic potential and pH, which play a main role in collector adsorption on the mineral surface.

The obtained results show that the optimal pH value is 7, in this condition; we can get an optimal adsorption and maximum recovery of Pyrite up to 90%.

Keywords: Pyrite, flotation, surface properties.

1 INTRODUCTION

The sulphuric minerals, having an economic value, are mainly recovered by flotation. The precious sulphides, however, are mainly found in complex ores form associated with the gangue. They can present similar surface properties. In the case of Chaabat El Hamra deposit, the Pyrite is a gangue of which surface properties are similar to Chalcopyrite, Galena and Sphalerite.

This similarity, relative to the surface properties of the above-mentioned sulphuric minerals, presents some difficulties during minerals separation by selective flotation [Hiçyilmaz, 2009].

The study of the surface properties plays a significant role in the frame of the floatability and the efficiency of minerals separation. The chemistry of sulphides surface is more complicated than that of other metals and oxides [Gonçalves, 2003]. During crushing, a galvanic contact occurs between sulphuric minerals and the liquid phase of pulp, which generates an electric field provoking the reactions of oxydo-reduction on mineral surfaces, due to the various values of the pulp potential.

The phenomena, which occur at the time of the contact of mineral surfaces with the pulp liquid phase, define the electrochemical variation of the surface properties [Chettibi, 2003]. These last directly influence on the effectiveness of the sulfurs flotation.

The relevance of the electrochemical phenomena, during the flotation of sulphuric minerals, was highlighted in the Thirties of last century. By the Sixties, this obviousness was reinforced through many applications. At the present time, it is necessary to establish a correlation between the

performance of the flotation reagents and the electrochemical properties of pulp [Junia et al., 2009].

The sulphides float for three different reasons: the presence of the element of free sulphur, the connection metal-xanthate and formation of the dexanthogen layer on mineral surface. These reactions are of electrochemical nature [Puonala et al., 1997]. So, the control of the state of mineral surfaces oxidation must be recommended during the process in order to maximize the technical and economic indices of enrichment.

The electrochemical nature of the interaction (mineral-collector) also means that the phenomena leading to the hydrophobicity of minerals can present a subject of research by using electrochemical techniques. This is important not only because it allows establishing the chemical reactions which may occur in the flotation systems, but also, such study is essential if effective potential methods of control are to be introduced in practice [Buckley et al., 1997].

Actually, it is established that, the surface state and the floatability of sulphides, are defined with high accuracy by exploiting the following parameters: the potential redox(Eh), potential of electrode and pH of pulp [Heifetz et al;, 1959].

The purpose of this work is to determine the conditions and the optimal parameters of pyrite flotation, resulting from the treatment of factory rejections, by using the thermodynamic method of analysis and chemical calculation of the mineral surface state. In terms of pH optimal values we ensure a complete pyrite flotation according to the potential minimal charge.

2 METHODOLOGY

The method of the thermodynamic analysis for a longtime is largely applied for the study of the chemical, geochemical and hydrometallurgic processes. It is also used in mineral processing and particularly in flotation [Abramov, 1993]. This method permits to define the composition of the connections representing mineral surface, to realize physicochemical models for the processes of interaction of mineral surface with the reagents, and to carry out a chemical calculation of the ionic components state of the pulp liquid phase. The latter method is based on the following equations [Chettibi, 2003]:

- Equation of the equilibrium constant:

$$K = \frac{[C]^c.[D]^d}{[A]^a.[B]^b}\ ; \qquad (1)$$

- Equation of the relation between the reaction free standard energy and the equilibrium constant:

$$\Delta F_r^0 = \sum \Delta F^0_{final.} - \sum \Delta F^0_{init.} = R.T.\ln K; \qquad (2)$$

Or, at 25 0 C:

$$\Delta F^0_r = -1{,}364.\lg K$$

- Equation of the relation between the reaction free standard energy and the potential of standard electrode:

$$\Delta F^0_r = E^0.n.f = 23{,}06.n.E^0 \qquad (3)$$

- Equation of the relation between the reactions measured potential, the standard potential and the reaction equilibrium constant:

$$E = E^0 +. \frac{R.T}{n.F} \ln \frac{[C]^c.[D]^d}{[A]^a.[B]^b} \qquad (4)$$

Or at temperature 25 ^{0} C:

$$E = E^0 + \frac{0{,}059}{n} \log \frac{[C]^c.[D]^d}{[A]^a.[B]^b} \qquad (5)$$

The possibility of estimating the surface state of mineral salts, based on thermodynamic calculation, was theoretically and experimentally confirmed in different Abramov's works [Abramov, 1993, 1978, 1977]. The point of this method is to create a system of basic reactions of dissociation and hydrolysis of minerals in solution, and to

settle the equations obtained on the basis of these reactions. Added to that, the elaborated system must be completed by the equations of balance and the electro-neutrality.

While modeling, the standard free energies (Gibbs energies) of species and compounds were used (in Kcal/mol): according to [Latimer, 1952]FeS_2 -38,29; Fe^{2+} -20,30; $Fe(OH)_2$ -115,57;$Fe(OH)^+$ -65,20; $FeCO_3$ -161,06; Fe^{3+} -2,53; $Fe(OH)^{2+}$ -55,91; $Fe(OH)_2^+$ -106,2; $Fe(OH)_3$ -166,06; Fe_2O_3 -177,1; Fe_3O_4 -242,1; FeOOH -117,2; $HFeO_2^-$ -90,6; S^{2-} +22,1, HS^- +3,01; H_2S -6,54; SO_3^{2-} -116,10; SO_4^{2-} -177,34; CO_3^{2-} -126,22; HCO_3^- -140,31; H_2CO_3 -149,0; OH^- -37,595; H_2O -56,69; H_2SO_4 -177,34; and according to [Garrels, et al., 1964] $S_2O_3^{2-}$ -127,20.

3 RESULTS AND DISCUSSION

3.1 Influence of pH on the Surface State of Pyrite

The thermodynamic analysis of the pyrite surface quality shows that oxidation of pyrite and sulphur presents many compounds derived from iron and sulphur, mainly the following: Fe_2O_3, FeO, Fe_3O_4, $Fe(OH)_2$, FeO(OH), $Fe(OH)^{2+}$, $Fe(OH)_2^+$, $Fe(OH)_3$, $HFeO_2$, FeO_2^{2-}, FeO_4^{2-}, $FeCO_3$, $FeSO_4$, SO_4^{2-}, HSO_4^-, SO_3^{2-}, $S_2O_3^{2-}$, S^0, S^{2-}, HS^-, H_2S. The most probable products of pyrite oxidation (at any oxidation variant of the minerals sulphur) are: $Fe_2O_3$and Fe_3O_4.Moreover, Garrels R. M. indicates in his works that, during the precipitation of iron salts, we could obtain also $Fe(OH)_2$and $Fe(OH)_3$, presenting a great sensitivity to the change of pH and Eh values of the medium [Garrels et al., 1964]. Thus, we can present the pyrite oxidation to $FeCO_3$, $Fe(OH)_2$ and $Fe(OH)_3$ with the release of SO_4^{2-} and HSO_4^-.

Table 1 recapitulates the various reactions of pyrite surface oxidation in the presence of water, oxygen and also according to the pH values. These reactions can occur simultaneously, in various places of the surface, depending on the reactivity induced by the crystallinity. These kinds of reactions have thermodynamic and kinetic characteristics which play a very significant role in the case of sulphides flotation presenting difficulties for their beneficiation such as pyrite [Abramov, 1978].

Results of iron ionic components activity: $[Fe^{3+}]$, $[Fe(OH)^{2+}]$, $[Fe(OH)_2^+]$, $[Fe^{2+}]$, $[Fe(OH)^+]$ and $[HFeO_2^-]$, equilibrated with FeS_2, $Fe(OH)_2$, $Fe(OH)_3$ and $FeCO_3$, show that, in all cases the principal ion resulting from the pyrite oxidation is (Fe^{2+}).

The results of thermodynamic analysis allow establishing the variations of pyrite state surface according to different pH and thermodynamic potential values of the solution (Figure. 1).

From this, it results that for:

• The highly positive values of the Redox potential of the solution, the principal product of oxidation is presented by $Fe(OH)_3$;

• In The case of less positive (or negative) values of the Redox potential of the solution, there can be a formation of $FeCO_3$ (at pH< 8,6) or a formation of $Fe(OH)_2$(at pH> 8,6). If the medium is opened, in that case, $Fe(OH)_2$ will be replaced by $FeCO_3$.

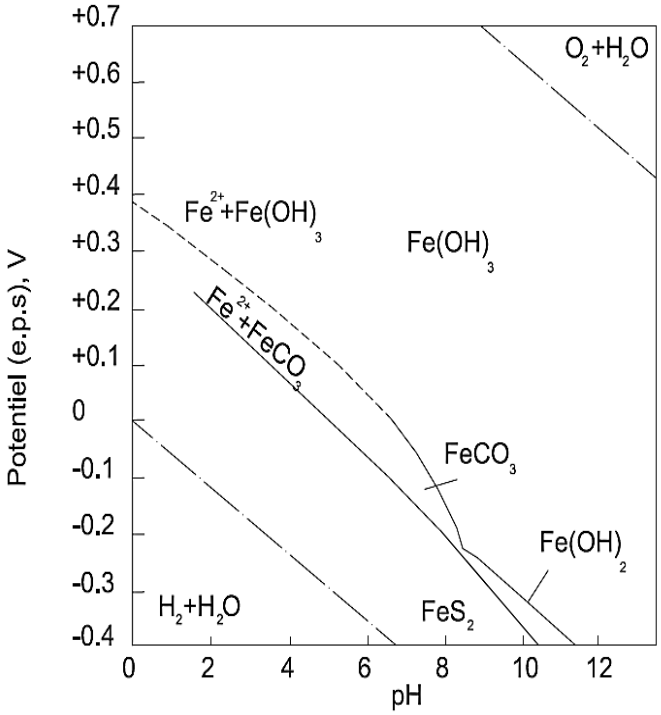

Figure 1. pH and Eh values influence on the pyrite surface state [Abramov, 1978].

3.2 Influence of the Surface State on Pyrite Hydrophobicity and Floatability, and its Equilibrium pH Determination

The surface of the pyrite in solution is not homogeneous; it presents many compounds derived from iron. According to solution conditions' (pH and Eh), we can find the sulfates:$Fe_2(SO_4)_3$, $FeSO_4Fe_2(SO_4)_3$,$9H_2O$and the oxides and hydroxides as well: $Fe(OH)_3$, FeOOH, Fe_2O_3, FeO^{2-}, FeS_2 and FeS. Each product possesses its own thermodynamic properties.

The existence of these surface species involves such heterogeneity of surface (fig. 1) due to their non-uniform distribution on pyrite surfaces. The distribution of the surface species is done according to specific zones of oxidation, created by crystallographic defects, impurities or little variations of stoichiometry of the crystal lattice [Mermillod-Cableway, 2005].

For a considered chemical species, the determination of equilibrium pH value with water is carried out by using various reactions of dissociation and hydrolysis (Table 2), which are directly or indirectly related to the considered species[Abramov, 1978].

Table 2.Thermodynamic characteristics (K, ΔF^0, E^0) reactions and equations

N°	Reactions et Equations	K	$\Delta F^0_{React.}$, Kcal./mol	E^0, V

27	$E = +0,057 + 0,059pH$			
28	$E = -0,917 + 0,059pH$			
29	$E = -0,755 - 0,059.lg.[CO_3^{2-}]$			

The calculation steps depend on one another, they consist in determining successively:

- The free energy ($\Delta F°_{reaction}$) of each considered reaction of dissociation and hydrolysis;
- The equilibrium constant (K) of each reaction;
- The concentration (C) of each ion resulting from the reactions of dissociation and hydrolysis according to K and $[H^+]$.
- Afterwards, these concentrations (C) are represented graphically according to the pH values by using the following function: log(c) = f (pH).
- The equilibrium pH value is the intersection point of the highest curves [Abramov, 1978].

3.2.1 Equilibrium pH value of [Fe(OH)₃-water] system

For the determination of equilibrium pH value of [$Fe(OH)_3$- water] system, we used the equations (11), (14), (15) and (19) see Table 2. The obtained results of chemical computing are illustrated in figure 2. They show that the value of equilibrium pH of [$Fe(OH)_3$ - water] system is equal to 7,8.

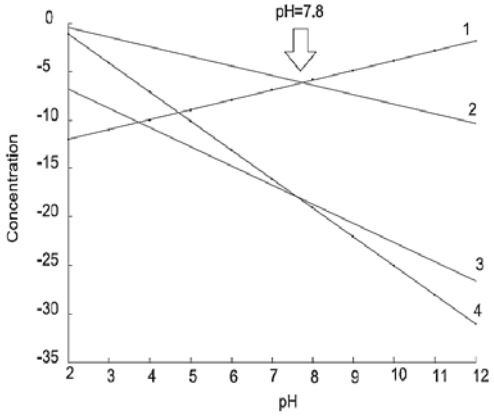

Figure 2. pH influence on the ions concentration [OH^- (1),$Fe(OH)^{2+}$(2),$Fe(OH)^{2+}$(3),Fe^{3+} (4)]

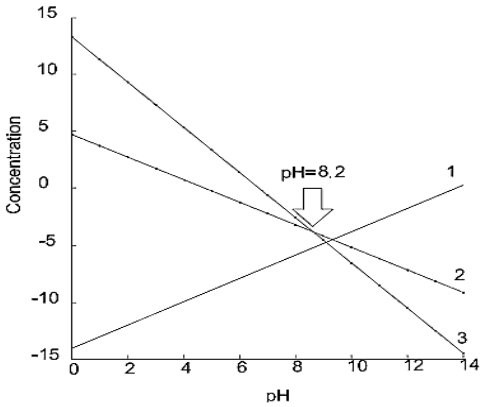

Figure 4. pH influence on the ions concentration [OH^-(1), $Fe(OH)^-$ (2), Fe^{2+} (3)]

3.2.2 Equilibrium pH value of [$FeCO_3$ - water] system

For the determination of equilibrium pH value of [$FeCO_3$-water] system, we used the following equations (13), (17), (18) and (19) of Table 2. The obtained results of chemical computing are illustrated in figure 3. They show that the value of equilibrium pH of [$FeCO_3$ - water] system is equal to10,3.

3.2.3 Equilibrium pH value of[$Fe(OH)_2$ - water]system

In order to determine the equilibrium pH value of [$Fe(OH)_2$-water] system, we used the equations (12), (16) and (19) of Table 2. The results of the carried out chemical calculation are illustrated in figure 4. It is evident that equilibrium pH value of [$Fe(OH)_2$ - water] system is equal to 8,2.

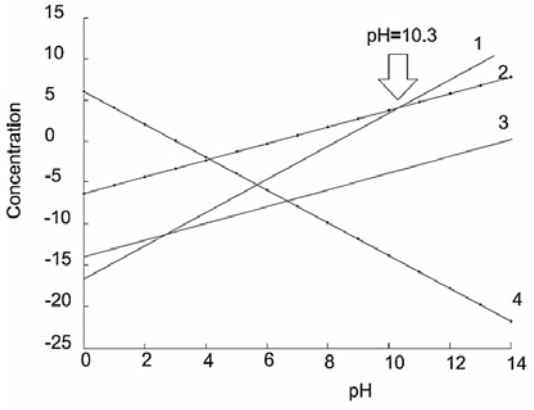

Figure 3. pH influence on the ions concentration [CO_3^{2+} (1), HCO_3^- (2), OH^- (3), Fe^{2+} (4)].

3.3 Determination of optimal pH value and thermodynamic potentials of various pyrite surface oxidation products

The studying of thermodynamic potential helps to define the major components that could be created in the equilibrium conditions [product -water] and also to know the types of chemical reactions occurring at the given moment. The standard potential values were computed by using the equations (I, II, III, IV, V).

Table 2 recapitulates the reactions which are considered for the determination of the various thermodynamic potentials, with the defined thermodynamic constants values, as well as the free energies of the various reactions.

The optimal pH value of pyrite flotation is determined from the graphic (figure 5) of the cumulated thermodynamic potentials of the considered pyrite oxidation products.

It is noticed that $Fe(OH)_3$ is located in the interval [3- 8,6], $FeCO_3$ in [8,6- 10,2] and $Fe(OH)_2$in the interval [10,2-12].

So, the line obtained represents the ΔE of each oxidation products. The optimal pH value necessary for pyrite flotation corresponding to the point of zero charge, in our case, is about 7,0, see figure 5.

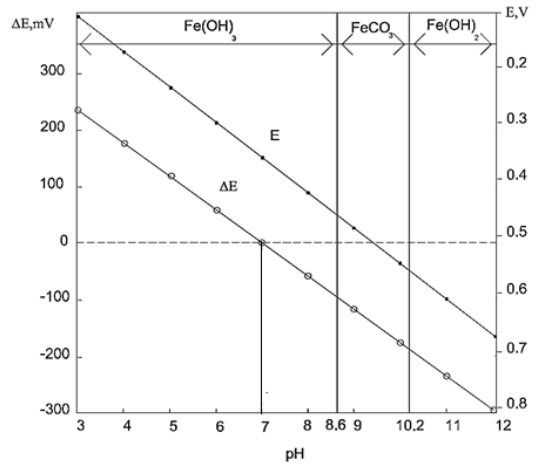

Figure 5.Variation of thermodynamic potential E and its differences ΔE of the pyrite surface oxidation products, according to the pH values.

3.4 Experimental Results and Discussion

The Results obtained by the method of thermodynamic analysis are confirmed by the experimental data in terms of initial potassium butyl xanthate concentration 10 mg/l (figures 6, 7, 8).

These last respectively present the influence of pH values on:

a/ The cumulated values of pyrite surface potential (1) and physical adsorption of dixanthogen (2);

b/ The floatability of pyrite before and after moving away the dixanthogen molecules adsorbed on pyrite surface(2, 1);

c/ The xanthate chemical adsorption before and after moving away the molecules of dixanthogen on mineral surface (2, 1).

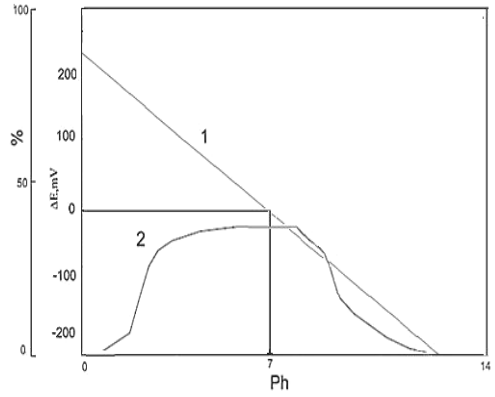

Figure 6. pH influence on dixanthogen physical adsorption on mineral surface(2) and the potential differences of pyrite oxidized surface (1).

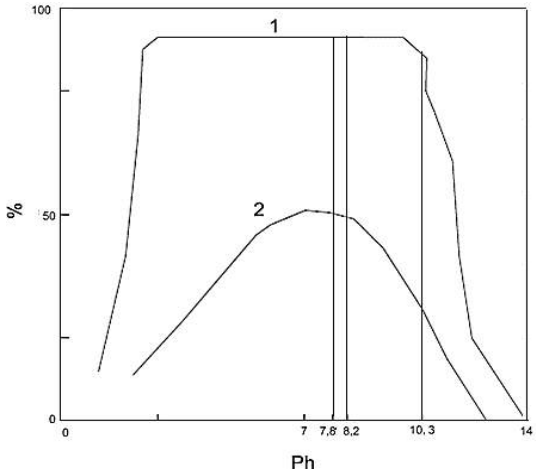

Figure 7. pH influence on the floatability of pyrite before and after moving away the dixanthogen molecules adsorbed on pyrite surface(2, 1);

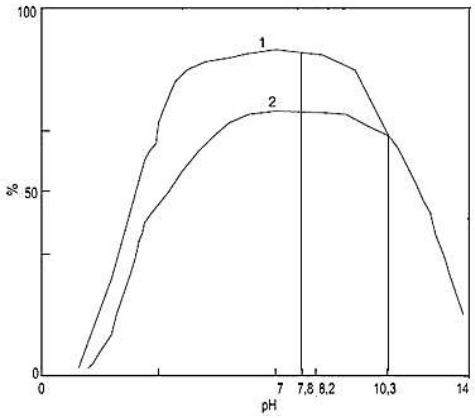

Figure 8.pH influence on the xanthate chemical adsorption before and after moving away the molecules of dixanthogen on mineral surface (2, 1).

The analysis of the results of pH influence on dixanthogen physical adsorption on pyrite surface (figure 6), shows that the maximum adsorption of dixanthogen is located in pH = 7,8 corresponding to equilibrium pH values.

The floatability variation of pyrite according to the pH values before and after dixanthogen adsorption is presented by the curves (1, 2) of figure 7. The latter presents three parts, the first one shows an increase in floatability up to an optimal value. In the second part, a regular floatability is observed. Finally we remark that pyrite extraction decreases in the third part.

In addition, the variation of xanthate chemical adoption on pyrite surface, according to the pH values before and after

the dixanthogen desorption from mineral surface, is illustrated in figure 8. For a pH value equal to 7,0, a maximum adsorption before and after taking away the collector was obtained. It is Also noticed that chemical adsorption decreases at pH equal to 10,3.

So, at pH equal 7,0, we can obtain:

•Maximum physical adsorption (40%);
•Maximum chemical adsorption (90%);
•Maximum degree of extraction (floatability) nearly 90%.

Since the equilibrium state of the system answers to the maximum value of xanthate adsorption on mineral surface and of pyrite floatability, the obtained pH values of equilibrium systems are those of zero charge potential of oxidation products surfaces and correspond to the oxidized pyrite surfaces stability.

4 CONCLUSION

From the results of thermodynamic analysis of pyrite-water system, flotation and adsorption test at various pH and initial potassium butyl xanthate concentration 10 mg/l., it has been established:

- Highlighting of thermodynamic method of analysis characterizing the chemical nature of the elements present on the oxidized pyrite surface. By using their thermodynamic potential, the optimal pH value which is the most significant parameter of the separation medium, it was computed.

- Equilibrium pH value corresponding to minimum charge potential of pyrite oxidized surface, presenting the most important condition of maximum hydrophobicity, dexanthogen adsorption and mineral floatability. The given pH value makes: in the case of $Fe(OH)_3$ 7,8; $FeCO_3$ 10,3; and $Fe(OH)_2$ 8,2.

- Optimal pH values for pyrite flotation answers the surface potential of minimal charge, and guarantees the formation of collector optimum adsorption coverings structure.

- Optimal pH value equal to 7,0 is considered valid owing to the fact that it was experimentally confirmed. It is mentioned that the critical pH flotation of pyrite starts from 6,3, beyond pH equal to 10,3 the pyrite is depressed.

ABSTRACT Molecular modeling has experienced constant and considerable development over the past ten years in India, China, Turkey, Russia and Finland. In the present study computational modeling of minerals and reagents was performed using Chem Bio 3D and ChemOffice2005 by CambridgeSoft with optimization by MM2. The semi empirical calculations were provided by MOPAC. Molecular structures of antimony clusters were created. DTF approach was used to determine energies such as HOMO, LUMO and SOMO. Absolute hardness η and chemical potential χ by Pearson and Parr have been calculated. The strategy of prognosis of collector activity evaluation (PCAE) has been proposed as a consistent approach to estimate the interaction between a collector and a mineral cluster as a difference of total energy and sum of cluster energy and collector energy. The lower PCAE the stronger the ability of the collector to interact with the mineral cluster. Although PCAE cannot play the role as an indicating physico-chemical parameter for the particle floated but allows to make some significant conclusions. To improve the separation of minerals the method of complex formation between collectors and mineral clusters was harnessed. The main physico-chemical parameters have been determined. The probable increasing collecting ability of sulfhydril collectors for stibnite follows the order as : butyl xanthic acid (BXA), dimethyldithiocarbamic acid (DMDTCA), piperidine dithiocarbamic acid (PDTCA),mixture of butyl xanthic acid and dithiocarbamic acid (BXA+DTCA), Bis(2-(dibutylamino)ethyl)dithiophosphonic acid (DBAEDTPA) and diethyl aminoethylxanthic acid (DEAEXA). Dialkylamino sulfhydril collectors may be considered to be prospective reagents for sulfide ore flotation. The results obtained were confirmed by experimental data in ore flotation.

Keywords: flotation, mineral clusters, molecular modeling, chemical programs, program MOPAC, collector activity evaluation, metal recovery

1 INTRODUCTION

Several millions organic compounds with various structure have been synthesized over the past 20 years. Several thousands of chemicals were either tested or suggested as flotation reagents. Nowadays there are only a few hundred of these reagents that are extensively used in flotation. Sulfur-containing reagents are widespread collectors for sulfide minerals recovering. The representation of sulfhydryl collectors that has been extensively studied, are xanthates, dithiophosphates and dithiocarbamates, although their derivatives are equally important (Bulatovic, 2007). Xanthates as powerful collectors are commonly used for flotation of sulfide minerals such as chalcopyrite, galena, sphalerite, stibnite and etc. Dithiophosphates are weaker but more selective then xanthates (Ackerman et al, 1987; Bulatovic,2007; Valli et al,1994; Güler et al,2006; Grano et

al,1997; Nagaraj and Ravishankar,2007).Dithiocarbamates have a high specificity for antimony minerals (Bulatovic,2007,Solozhenkin,1994).

Although all of these compounds contain sulfur, the structure of molecules is rather different. This is the connection between the spatial structure of molecules and chemical activity of the compounds. The flotation performance of these collectors have been investigated related on their functional groups. Moreover each compound has its special physico-chemical properties. Therefore the most troublesome question for researchers remains the estimation of quantitative structure-property relationship. The knowledge generated in these studies is extremely helpful in quick selection of collectors with desired properties as well as in designing of new reagents schemes. The correlation established can allow to determine the direction of synthesis of new compounds which could play the key role as collectors for sulfide flotation.

There are a fairly large number of approaches to choose the flotation reagents with definite properties (Soloviev M.E.,Soloviev M.M.,2005).The approach for reagent selection is based on the consideration of more than just the chemistry of one reagent in isolation or more than just one type of reagent for a given mineralogy. In fact, all the chemical and operational factors are considered simultaneously. The preference of using of chemical programs and computer technologies appears to be at the significant value (Khel`l`e,2013, Solozhenkin P.,2013).

Stereochemical representations of mineral and reagent molecules play the significant role in explanation of their behavior in flotation. Modern computational methods allow to find the way of visualizing a three-dimensional model of the molecule and to understand the connection between the spatial structure of the molecule and physical properties of the substance as well as its chemical activity (Soloviev M.,2005,Roshupkin S,2004) .

First principle density functional theory (DFT) method offers an effective tool in the calculation of the properties and energies of the various collectors (Porento and Hirva, 2002, 2004; Yekeler and Yekeler, 2004, 2006; Liu et al, 2008b, 2010, 2011). DFT study is used to determine the optimal molecular structure and calculate atomic charge values, the compositions and energies of HOMO and LUMO of sulfhydryl collectors. The theoretical methodology established and results obtained provide an atomic level understanding on interactions and bond formation mechanisms between collector molecules and sulfide mineral surfaces(Liu, 2012).

2 METHODS AND OBJECTIVES

2.1 Computational Methods

In the present study computational modeling of minerals and reagents was performed using Chem Bio 3D and ChemOffice2005 by Cambridge Soft with optimization by MM2. The semi empirical calculations were provided by MOPAC.

2.2 Docking Method

Complex formation have been established with the aid of computational docking technique. The docking method is a search algorithm and a scoring function that predicts the preferable orientation of one molecule to a second to form a stable complex and estimate collecting activity of reagents. The approach has proved useful in identifying relevant candidates for several flotation applications (Solozhenkin P, 2006).

2.3 Objectives

The objectives of the present study are antimony minerals and thiol collectors which are used in practice for stibnite flotation from Sb-Hg,Sb-As ores at Djijicrut deposit (Tadjikistan) and Sarilah Mineral Processing Plant (Yakutia, Russia) . These collectors have been established as standard reagents for estimation the effectiveness of organic compounds studied. The strategy of evaluation has been proposed as an approach to make a choice of organic compounds as a

prospective collectors in stibnite flotation. Possessing the high chemical activity the organic compounds studied can show the stronger complexing properties comparing to the other collectors because of the presence of the functional group of thione and thiol sulfur atoms having donor properties. The characteristics of flotation reagents and organic compounds studied are provided in Table 1.

Table 1. Samples characteristics

Table 1 contains the information about chemical formulas, molecular weights and chemical analysis data for various organic compounds where 1-Butyl xanthic acid(BXA); 2-Dimethyldithiocarbamic acid(DMDTCA); 3-Diethylaminethylxanthic acid(DEAEXA); 4-Piperidinedithiocarbamic acid(PDTCA); 5-Bis(2-(dibutylamino) ethyl) dithiophosphonicacid (DBAEDTPA); 6-Quinolinethiol (QT); 7-Tetrasol;8-O,O dibutylS-(2-mercaptoethyl) hosphorodithioate (DBMEDTPA).The stibnite cluster activated has been presented as a formula $PbSb_2S_4$ (PbS Sb_2S_3) based on the special studies. Molecular structures of mineral-collector clusters were created. DTF approach was used to determine energies such as HOMO, LUMO and SOMO. Absolute hardness η **and** chemical potential χ **by** Pearson and Parr have been calculated.

3 RESULTS AND DISCUSSION

3.1 Molecular Models of Mineral Clusters

The strategy of prognosis of collector activity evaluation (PCAE) has been proposed as a consistent approach to estimate the interaction between a collector and a mineral cluster as a difference of total energy and sum of cluster energy and collector energy.

The chemical reaction between a thiol collector and a sulfide mineral is a frontier-controlled reaction (Liu, 2008b, 2010; Klopman, 1968; Wang et al,1996), i.e. a thiol collector transfers its HOMO electrons to a metal atom on the sulfide mineral surface to form a normal covalent bond. Additionally, if a metal atom on the sulfide mineral surface has richly d-orbital electrons and a thiol

collector has the electron-accepting ability, the metal atom can transfer some of its d-orbital electrons to the LUMO of the thiol collector to form back donation covalent bonds.

The complex of the stibnite cluster with three molecules of butyl xanthate attached to antimony atom is shown in Figure 1. In case of stibnite the atom of antimony has oxidation number equal to three therefore Figure 1 indicates the collector attached using three arrows. Figure 2 represents the similar complex but for stibnite activated by Pb^{2+} cations. As arrows indicate lead cation is attached to two molecules of butyl xanthate.

Additionally, the complex of stibnite cluster activate by Pb^{2+} with dimethyldithio carbamate and its optimized geometrical structure are shown in Figure 3 a and respectively.

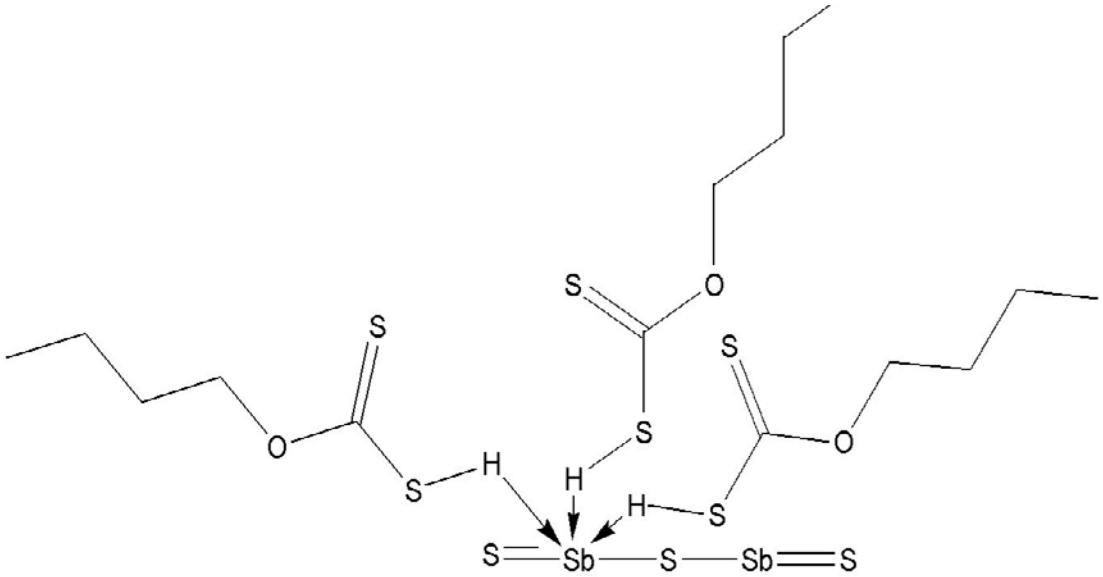

Figure 1. Complex of stibnite cluster with 3 molecules of butyl xanthate attaching to antimony atom.

.

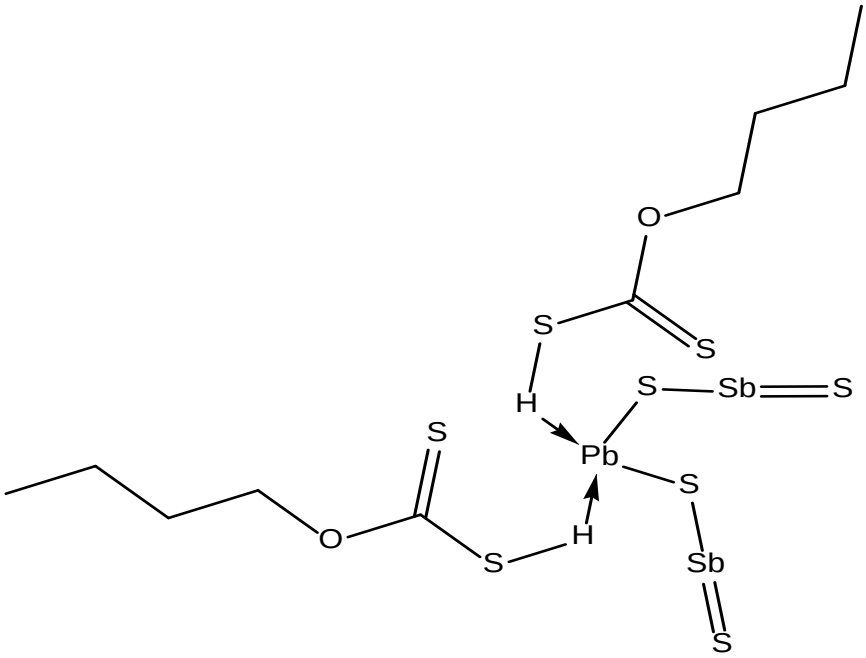

Figure 2. Complex of stibnite cluster with 2 molecules of butyl xanthate attaching to lead atom.

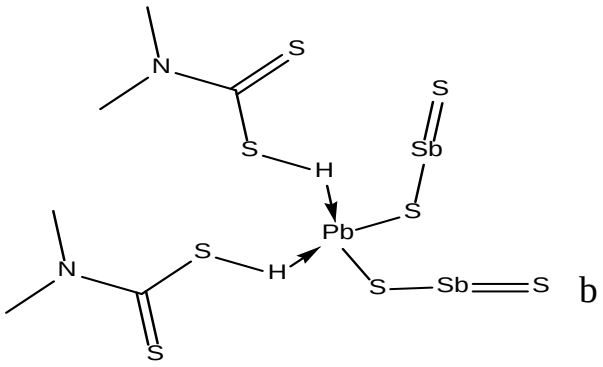
a



b

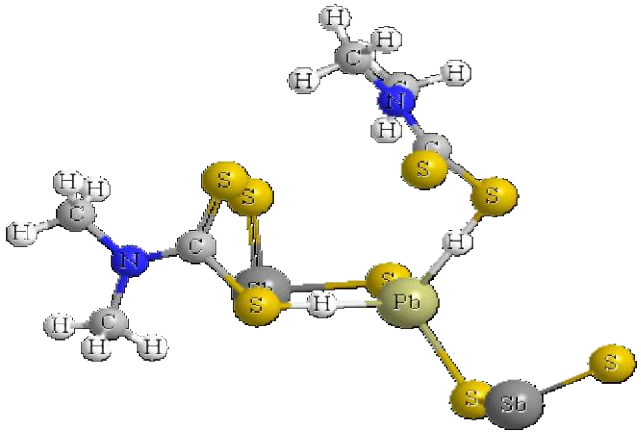


Figure 3. Complex of stibnite cluster with 2 molecules of DMDTC attaching to lead atom (a) and its optimized geometrical structure (b).

The optimized geometrical model of activated stibnite cluster with the combination of butyl xanthate and dimetyldithiocarbamate was created. This model represents the real flotation process with the mixture of collectors such as BX and DMDTC. Figure 4 shows the complex of activated stibnite attaching to three molecules of BX by antimony atom and to two molecules of DMDTC by lead atom.

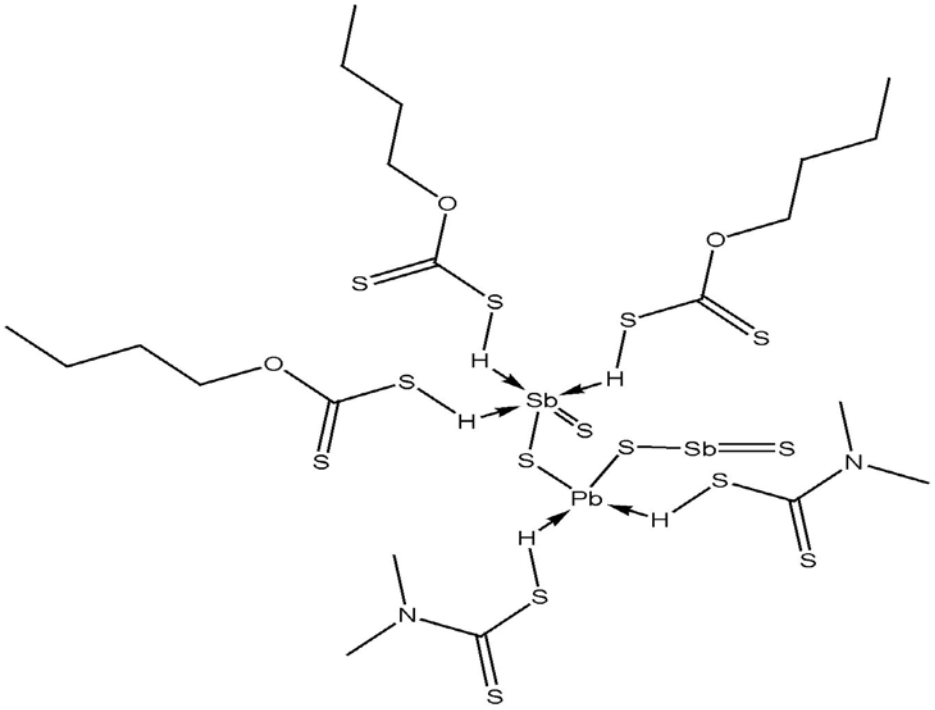

Figure 4. Complex of activated stibnite attaching to three molecules of BX by antimony atom and to two molecules of DMDTC by lead atom.

3.2 Prognosis of Collector Activity Evaluation (PCAE)

Models given in Figure 1-4 have been taken into account to calculate the physico-chemical constants for collectors.

The strategy of collector activity evaluation has been proposed as a consistent approach to estimate the interaction between a collector and a mineral cluster as a difference of total energy and sum of

cluster energy and collector energy (Solozhenkin 2012a, 2012b, 2012c).

E = E complex - (E cluster + E collector), eV(1)

The lower PCAE the stronger the ability of the collector to interact with the mineral cluster. The calculated PCAE for various mineral clusters and collectors such as BXA, DMDTCA and the mixture of them are given in Table 2.

Table 2. Calculated PCAE (eV)

Mineral cluster	PCAE ,eV BXA	DMDTCA	BXA+DMDTCA
Sb_2S_3	-0.5491	-0.6871	
$PbSb_2S_4$	-1.1517	-1.6756	-1.8463

According to Table 2 the decrease of prognosis of collector activity evaluation (PCAE) for stibnite activated is in the following order: BXA (-1,1517), DMDTCA (-1,6756), BXA+DMDTCA(-1,8463). From the relevant studies conducting on flotation it can concluded that floatability of stibnite is changing in reverse order to PCAE. Based on this order the stibnite floatability is increasing from the individual collector up to the mixture. As a matter of fact, the lower PCAE the higher floatability of stibnite. The lowest magnitude of PCAE obtained for the mixture of BXA and DMDTCA is related to the maximum recovery of stibnite.

The theoretical knowledge obtained from research on PCAE provided a basis for the industrial flotation testing of stibnite by the combination of BX and DMDTC from Sb-Hg, Sb-As sulfide ores on Sarilah Mineral Processing Plant (Yakutia, Russia). The antimony ore with the grade of 15,6-14,91% Sb and 0,33-0,21% As was processed in differential flotation circuit in which antimony is recovered to a concentrate at a grade of 62,39-59,20% Sb, 0,43-0,36% As, leading tailings containing 1,73-1,13% Sb and 0,33-0,21% As.

Furthermore on the base of computer modeling it was suggested the range of organic compounds which properties as proposal collectors were predicted. Table 3 contains a PCAE data for stibnite clusters and various reagents with amino group

Table 3. Calculated PCAE (eV)

Reagents	Mineral cluster	PCAE,eV
Tetrasol	$PbSb_2S_4$	-1.1846
DBMEDTPA	$PbSb_2S_4$	-1.0846
QT	$PbSb_2S_4$	-1.5104
PDTCA	PbSb2S4	-1.7696
DBAEDTPA	PbSb2S4	-8.0223
DEAEXA	$PbSb_2S_4$	-602.3262

The results indicate that the difference in PCAE for some derivatives and BXA does not have the significant value while the complex of stibnite with DEAEXA has PCAE of - 602,3262 eV . Comparing this with the PCAE data for stibnite activated and BXA, a significant decrease in PCAE for DEAEXA from – 1,1517 (BXA) to – 602,3262 can be seen and from the previous discussion it is evident that this reagent can be considered as the most perspective collector for stibnite flotation. The complex of DEAEXA with stibnite activated is shown in Figure 5 and its optimized geometrical structure presents in Figure 6

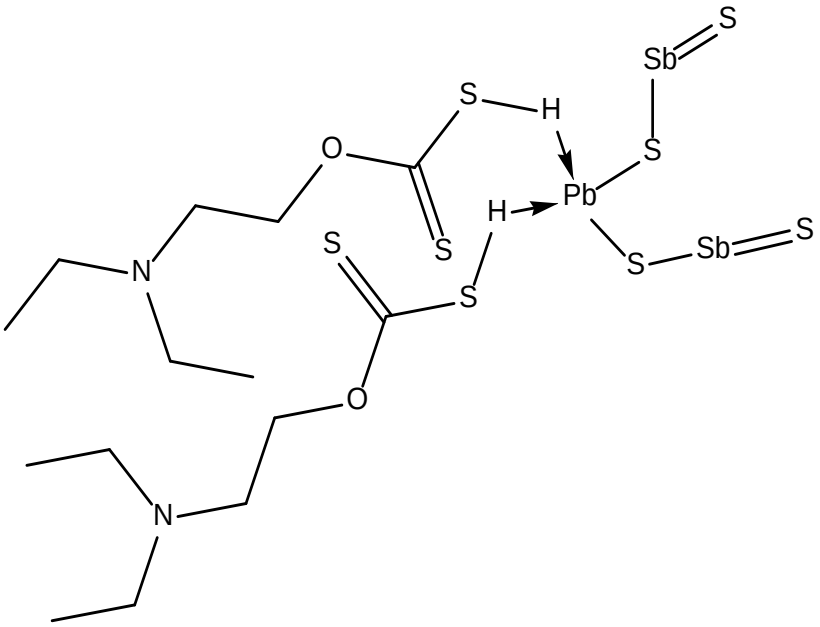

Figure 5. The complex of DEAEXA with stibnite activated Pb^{2+}

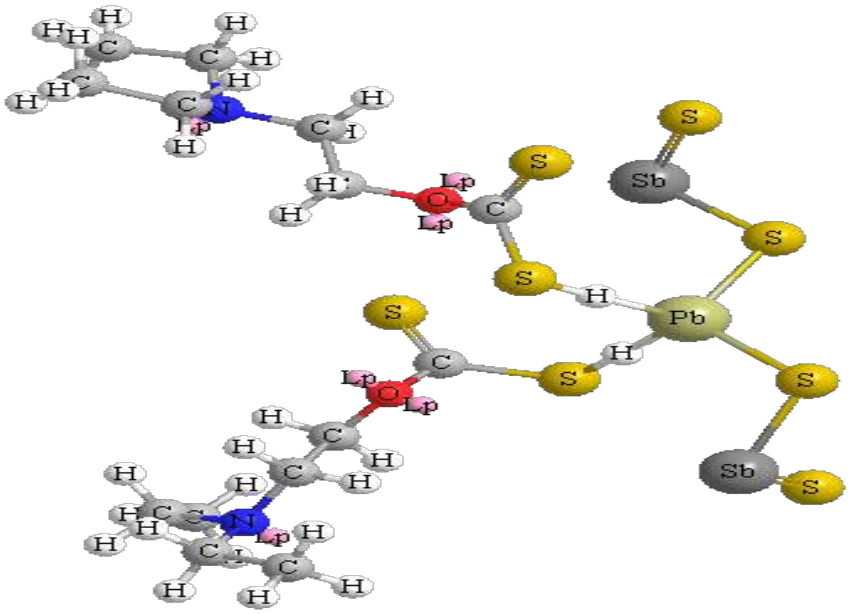

Figure 6. Optimized geometrical structure of the complex of DEAEXA with stibnite activated.

CONCLUSIONS

1. The computative method can be directly applied as a tool in investigation of surface-collector interaction.

2. The theoretical knowledge obtained from research on mineral-collector clusters provided a basis for the stibnite flotation from Sb-Hg and Sb-As ores with the combination of BX and DMDTC.

3. The values of PCAE for stibnite clusters with sulfhydril collectors have been calculated.
4. It has been established that PCAE was decreased in order of: butyl xanthic acid (BXA), dimethyldithiocarbamic acid (DMDTCA), piperidine dithiocarbamic acid (PDTCA), mixture of butyl xanthic acid and dithiocarbamic acid (BXA+DTCA), Bis(2-(dibutylamino)ethyl) dithiophosphonic acid (DBAEDTPA) and diethyl aminoethylxanthic acid (DEAEXA). The flotability of stibnite is changing in reverse order comparing to PCAE.
5. There is a strengthening effect of amino group in collectors on flotability of stibnite therefore dialkylamino sulfhydril collectors can be considered to be prospective reagents for sulfide antimony ore flotation.

Mechanical Properties of Feldspars and Their Influence on the Choice of Method of Comminution.

R.Akkal, M.Ouldhamou, S.A.Hadj-Sadok
National Polytechnic School of Algeria, Alger's, Algeria

ABSTRACT The mechanical properties of feldspathic rock have a direct impact on weight yields of different particle size fractions for purification and marketing. Therefore they affect the selection and sizing of size reduction and screening equipment.

Our analysis provides the basis for assessing the degree of homogeneity from the hardness and energy consumption standpoints. The energy consumption is evaluated by the Bond Index, which is the number of KWh consumed per ton of milled ore.

Given the demand from users of feldspars with its various particle size, the operating cost (crushing and screening) increases with the fineness of the fractions. It is very useful to determine the effect of a comminution provided with a number of recycling of refuse screenings. This provides sufficient data to optimize the production according to the demand, taking into account the level of fines and the losses caused by the selected process.

Keywords: Comminution, feldspar, purification, screening

1 INTRODUCTION

Grinding is the essential step in a processing plant for the production of a desired mesh for subsequent unit operations such as leaching, flotation. For this purpose, various types of equipment can be used according to the requirements of a processing system which directly affects the efficiency of a given process. [1]

In mineral processing, milling represents almost 80% of the energy consumed in the plant. The grinding efficiency depend not only on the high production rates, but also on conventional grinding systems used and the quality and type of ore undergoing such operations. Particularly, feldspars are a mixture of two or more minerals which differ in their chemical and physical properties, the use of a grinding pattern can lead to a significant effect on the production rate. The constituent minerals feldspar ore are of different forms and from different regions, so are heterogeneous. The grinding of such minerals requires a good understanding of the various components forming the ore. [2,3]

Crushing a large tonnage of heterogeneous run of mine ore, understanding of how the different components behave individually and in mixtures and how they interact with each other is a high priority in the proposal of a scheme final treatment. The mechanical properties of feldspathic rock have a direct impact on weight yields of different size fractions for the purification and commercialization, therefore they influence the choice and design of comminution and screening equipment, once the planned industrial capacities arrested on the basis of a study.

Any method of an ore treatment often requires fragmentation to a size that allows the release of its ingredients, minerals and gangue products thus making the separation of the latter accessible to use by following the physical, chemical or physico-chemical processes applied to the separation of minerals from a mineralized rock. These techniques are used individually or combined depending on the complexity of the mineralization and the cost of treatment.

In our present work this analysis provides the evaluation components of the degree of homogeneity of the hardness point of view and therefore the energy consumption standpoint. This is calculated according to the performance of a normative test called

Index Bond, giving the number of KWH consumed per tonne of ore milled.

Given customer demand users of feldspars in its various forms of particle size, the operating cost of crushing, grinding and screening increases with the fineness of market size slices and the economic consideration related to the losses caused by the process set up. It is very useful to determine the effects of a controlled comminution with a number of recycles screening refusal corresponding to the size determined by the choice of the operator after having extracted before each recycling, allowing to provide sufficient data to modulate the production according to demand knowing the level of fines <40 µm caused by the process.

The supported study in this work focuses on mechanical preparation of crude feldspar, to maximize comminution data and energy consumption.

1.1 Materials and Methods

A sample from the site of Ain Barbar east of Algeria was crushed to a size of 1 mm in three stages in a jaw crusher. The maximum initial size was [250mm]. This sample is undergone crushing operations in a jaw crusher, followed by grinding in an impact mill of Ain Barbar unit. The particle size obtained is in the order of [6.3mm]. All coming obtained was sieved down to [0.8 mm] in view of the application of the glass market. Fines [-0.1mm] was extracted by sieving to avoid over-grinding. These grinding / sieving are carried out as shown in Figure 1. The desired outcomes are the production of the three size fractions [-0.8 + 0.4mm], [-0.4 + 0.250mm] and [-0250 mm] taken for further processing enhancement. Sufficient amounts were treated to extrapolate the results to a scale up. Concerned size fractions were extracted in each grinding (Fig.1).

2 RESULTS AND DISCUSSION

Initially, the E1 sample is ground and sieved at [0.8mm] with recycling [+ 0.8mm] from the sieving E0 at [0.8mm] and reduced to [-0.8mm]. The results obtained are given in the following Table 1:

Table 1: Total production of different size fractions obtained from the sample E1 after crushing/screening 0.8 mm and recycling +0.8 mm size fraction.

Size fraction (mm)	W(g)	Rw(%)	Rw(%)/W0
[-0.8+0.4]	7834.75	32.65	15.21
[-0.4+0.250]	2441.60	**10.18**	4.74
[-0.250]	13717.25	57.17	26.63
Total	23993.59	100	46.58

W0: in the initial weight

The total production of different particle size from [-0.8mm] of the sample E2 obtained from the sieving of the sample E0 is given in the following Table 2:

Table 2: Total production of different size fractions obtained from - 0.8 mm from the sample E0.

Size fraction (mm)	W(g)	Rw(%)	Rw(%)/W0
[-0.8+0.4]	7814.14	28.56	15.17
[-0.4+0.250]	3358.48	**12.27**	6.52
[-0.250]	16184.75	59.16	31.43
Total	27357.37	99.99	53.11

In a second step, all size fractions [-0.250mm] obtained in all cases grinding/sieving, were screened. The results obtained are given in the following Table 3:

Table 3: Screening of all slices [-0.250 mm] obtained in all cases grinding / sieving.

Size fraction (mm)	W(g)	Rw(%)	Rw(%)/W0
[-0.250+0106]	5041.51	17.12	9.79
[-0.106+0.04]	12787.93	43.41	24.83
[-0.04]	11627.00	39.47	22.57
Total	29456.44	100	57.19

Through the results, we note that the grinding of all spared from reduced [-250 + 200 mm] to [0.8mm] gave 13.15% (Fig.1) for the portion [-0.04mm] obtained on the

basis of the screening of the sample E0 ground to [6.3mm], while the resulting crushing / screening of [+ 0.8mm] is 9.42% (22.57%- 13.15%) (see Tab3 and Fig1). An run of mine ore crushed at [0.8mm] give a class production rate of 51.43% from E0 sample. The particle size [-0.1 + 0.04 mm] represents 24.83%, while fine [-0.04 mm] represent 22.57% of the sample E0.

The fraction for the glass is provided by the process described above (Fig.1), it would give an output of 51% of run of mine ore. The production of fine [-0.04] mm is 22.57% will be used in the very ordinary ceramic (floor tiles) which his treatment after dishelming to [0.020mm] is very expensive, the rest [-0.1 + 0.04 mm] will be for ceramics of lower quality products. It is refined by the wet high field gradient for a satisfactory result.

In the following, the particle size [-0.8 + 0.4 mm] was ground to [-0.4 mm] in two stages comprising a grinding / sieving, the results obtained are given in the following table to give the total weight of each slice obtained by grinding / sieving [-0.8 + 0.4 mm] reduced to [-0.4mm] (Tab.4):

Table 4: Total production of slices obtained by crushing / screening of [-0.8+0.4] mm reduced to [0.4 mm].

Size	W(g)	Rw(%)	Rw/W0	Ex/W0
[-0.8+0.4]	376.02	2.41	0.26	0.73
[-0.4+0.250]	1014.76	6.50	0.70	1.97
[-0.250+0.106]	1529.86	9.80	1.06	2.97
[-0.106+0.04]	8154.11	52.21	5.66	15.83
[-0.04]	4543.23	29.09	3.16	8.82
Total	1567.98	100	10.85	30.32

Ex/w0: extrapolation versus the initial weight (w0)

In turn, the particle size [-0.4 + 0.250] was ground / sieved to [0.25 mm] and the results obtained are given in the following Table 5:

Table 5: Total production of grinding / sieving slice [-0.4 + 0.25 mm] to [0.25 mm]

Size fraction (mm)	W(g)	Rw(%)	Rw/W0	Ex/W0
[-0.4+0.250]	294.79	4.34	0.18	0.57
[-0.250+0.106]	2872.64	42.30	1.72	5.57
[-0.106+0.04]	1763.89	25.97	1.05	3.42
[-0.04]	1859.11	27.37	1.11	3.60
Total	6790.43	99.98	4.06	13.16

Through these results, the fine rate [-0.04mm] relative to feed down with increasing recycling. This finding can be explained by the fact that the fragile particles crumble at the first passage on the crusher or mill, the more remaining hard produce fewer fines. The particle size [-0.4 + 0.250 mm] is produced with a rate that varies little regardless of the number of recycling, this rate varies between 10 and 12% (Tab1 and Tab2). This is explained by the fact that the all-comers present a good homogeneity degree from the point of view hardness and structure.

Knowledge of results in weight crushing / screening report is used to size the unit of production equipment according to the required size fractions and demand. According to the results of the fine rate is of the order of 35.72% to reduce the size of [6.3mm] to [0.250mm] rate lower than that obtained in the treatment scheme proposed by BRGM (Bureau de recherche geologic et minière) (44.45%) including a screening of the [-4mm] to [1 mm], a classification of [-1mm] to give two fractions [-1 + 0.2 mm] and [-0.2mm], a grinding cone crusher of [-4 + 1mm] to [-0.2mm], a grinding mill cone of [-4mm] to [0.2mm]. The -0.2mm particles were subjected to attrition and classification wet to give 0.02mm and -0.2 + 0.020 mm fractions respectively. Product -1 +0.2 mm is ground in a ball mill (wet) to 0.2mm to 0.02mm and deslamming then mixed with the fraction A to be classified to [0.04mm] to give slices [-0.02 +0.04 mm] and [- 0.04 + 0.02mm] fractions respectively. The fine production of [-0.04mm] is of the order of 44.45%

Examination of the graphs relating to the mechanical tests and particle size analyzes of

the sample including the recycling of the refusal of each grinding / sieving [0.8mm] shows that the intersection of the graphs (corresponding to the 50% passing 50% refusal) moves well regularly to fine particles (Fig 2).

To better highlight the evolution of the different results, we have compiled the following table showing the cut 50% of refusal and passing cumulative in function of the grinding level. According to the results, cuts 50% refusal cumulative (CR) and 50% passing cumulative (PC) down with decreasing level grinding (Tab 6).

Table 6: Grade for 50% RC and 50% PC in function of grinding level

Experiment N°	Grinding level	Grade 50% RC et 50% PC
I	[250 mm] reduces to [6.3mm]	0.65
II	[250 mm reduces to [0.8mm]	0.27
II	[150 mm reduces to [0.8mm]	0.2
IV	[150 mm reduces to [0.63mm]	0.2
V	[0.8 mm reduces to [0.4mm]	0.065
VI	[0.4 mm] reduces to [0.25mm]	0.055

Production of [-0.40 mm] and [-0.250 mm]

The results of the production of two size fractions [-0.40 mm] [-0.250 mm] in function of the grinding level are given in the Table 7 :

Through the results, it should be noted that the production of the two size fractions increase with the grinding level. The reduction of run of mine ore from [250 mm] and [150 mm] in order to obtain [0.8 mm] and [0.4 mm] give almost the same rate of production of the grain size range, explained by that the feldspar treated with a high degree of homogeneity. Jumping production of [-0.4mm] is more important in the grinding of feldspar at [0.8mm].

Table 7: Size fractions [-0.40 mm] and [-0.250 mm] in function of grinding level

Experiment N°	Level grinding of run of mine	Production of [-0.40 mm]	Production of [-0.250 mm]
I	[250 mm] reduces to [6.3mm]	37.95	31.43
II	[250 mm] reduces to [0.8mm]	68.48	57.19
II	[150 mm] reduces to [0.8mm]	67.2	84.81
IV	[250 mm] reduces to [0.4mm]	98.07	84.81
V	[250 mm] reduces to [0.25mm]	----------	97.39

Fines production [-0.04mm]

As part of the study of the production of fine [-0.04mm], we performed several tests at different grinding levels. The results obtained are given in Tab 8:

Table 8: Size fractions of [-0.040 mm] production as a function of grinding level

Experiment N°	Grinding level	Fines production [-0.04 mm]
I	[250mm] reduces to [6.3mm]	13.15
II	[200mm] reduces to [4mm] (VS)	5.4
III	[200mm] reduces to [4mm] (VH)	14.53
IV	[250mm] reduces to [0.8mm] (BM)	22.57
V	[150mm] reduces to[0.8mm] (BNM)	27.42
VI	[250mm] reduces to [0.4 mm]	31.39
VII	[250mm] reduces to [0.250 mm]	34.47
VIII	[200mm] reduces to [0.2 mm]	45

Through the results, we note that the fine rate increases with increasing grinding level. Run of mine ore from [200 mm] size is reduced to the same size [4 mm], with two

different ways. It was found that, the wet path give a greater rate of fines (14.53%) which could be explained by the washing with the water generating further fine particles.

It should also be noted that the reduction of run of mine ore size of [150 mm] and [250 mm] respectively, with and without extraction of the desired slice [0.8mm] to each recycling mill have generate a fine rate of 22.57% and 27.42% respectively.

Overall production of the various tranches

The production of different particle size ranges [-0.8mm] [-0.4mm] and [-0.250mm] are given in the following table 9:

Table 9: Size fractions [-0.8mm], [-0.40mm], [-0.250mm] mm production as a function of grinding level

Comunition	Production of [-0.8mm]	Production of [-0.4mm]	Production of [-0.250mm]
Grinding	32.35	21.15	18.03
1st recycling	12.72	9.19	7.65
2nd recycling	1.51	1.02	0.93

Based on the results, we note that the production of different size fractions decreases with the number of recycling achieved on the grinder. Production of the size fraction of [-0.8mm] is more important as compared to the other two size fractions which are [-0.4mm] and [-0.250mm] whatever the number of recycling.

3 CONCLUSION

As part of this work, it was aimed to study the grindability of Ain Barbar fledspar ore and maximize results on the various size destined to the industries glassware and ceramics. We preferred to review by all the results obtained in the past. This allowed us to compare a number of results and draw useful conclusions to any development project. From the point of view, we enjoy the rather homogeneous nature physical property, in particular regarding the hardness and the results of comminution related to energy consumption; it is in the range of 8.5-10 kWh/t.

The rate of fines generated by a crushing / grinding system, for access to a given size fraction, is an important factor, because it is a by-product of poor quality, which is accessible at a prohibitive price. It becomes necessary to assess the fine production rates and seek to reduce it by spared grinding. We compared the results of a crushing / grinding / sieving of run of mine ore without extracting the main particle size [-0.8 + 0.1] mm by sieving or cyclone. Recycling of [+ 0.8mm] was achieved with those of the same operation but with extracting the desired slice to each recycling [+ 0.8mm]. It is shown that the second method produces less fines [-0.04mm], the over-grinding is avoided. The presented results provide a forecast of production rates of particle size which may be required by some customers and could make it more effective in the later applied purification processes.

Nomenclature:

W0: Initial weight for the sample E0 [g]
Ext: Extrapolation against run of mine ore
Rw: performance weight [%]
W: Weight [g]
E0: Initial sample

Extraction of Gold and Silver from Bolkar Gold Plant Tailings

Bolkar Altın Madeni Artıklarından Altın ve Gümüş Kazanımı

H. Bastürkcü, F. Burat, M. Özer, A. Gül, A. A. Sirkeci
Istanbul Teknik Üniversitesi Cevher Hazirlama Mühendisligi Bölümü

ABSTRACT This scientific study aims to investigate the extraction of gold and silver using agitation leaching method from tailings of Bolkar gold plant. The tailings contain 1.01 ppm Au and 41.8 ppm Ag. The effect of leaching duration, mechanical activation, pre-aeration and water quality were investigated. During the leaching tests, 40% solid ratio and 0.5 g/L NaCN concentration were kept constant, in order to provide an industrial application. After 2 hours of mechanical activation, d_{90} size of the sample was determined as 38 µm. When this sample was leached for 48h, 64.10% Au and 48.42% Ag extractions were able to be achieved. Although pre-aeration had a positive effect on extractions, in the case that was tested with the activated sample, only 1% Au increase was obtained with the same Ag extraction. On the other hand, if plants' recycle water was used in the leaching tests, the gold and silver extractions decreased 5% and 12%, respectively.

Keywords: Gold, silver, pre-treatment, cyanide leaching

ÖZET Bu çalışmada Bolkar Altın Tesisi liç artığından altın ve gümüşün kazanımı araştırılmıştır. Artık numunesi 1,01 ppm Au ve 41,8 ppm Ag içermektedir. Siyanürlü karıştırma liçi deneylerinde liç süresi, mekanik aktivasyon, ön havalandırma ve su kalitesi parametrelerinin etkileri incelenmiştir. Deneyler boyunca, endüstriyel uygulama göz önünde bulundurularak, %40 pülpte katı oranı ve 0,5 g/L NaCN konsantrasyonu sabit tutulmuştur. 2 saat mekanik aktivasyon sonunda d_{90} tane boyutu 38 µm olarak belirlenmiştir. Aktive olmuş bu ürün 48 saat liç işlemine tâbi tutulduğunda %64,10 Au ve %48,42 Ag çözündürme verimlerine ulaşılmıştır. Her ne kadar ön havalandırmanın çözündürme verimleri üzerinde olumlu etkisi görülmüşse de, mekanik olarak aktive edilmiş numune üzerinde uygulandığında altın çözünmesinde sadece %1'lik artış gözlenmiştir. Gümüş çözünme veriminde ise herhangi bir artış sağlamamıştır. Ayrıca tesiste kullanılan geri dönüşüm suyu ile liç testleri yapıldığında, altın ve gümüş çözünme verimlerinde sırasıyla %5 ve %12'lik düşüşler gözlenmiştir.

Anahtar kelimeler: Altın, gümüş, siyanür liçi

1 INTRODUCTION

The cyanidation process has been the most preferred process in the extraction of gold for the past 100 years. In 1888, MacArthur and his friends patented the process, in which gold dissolves in aerated cyanide solutions to produce the gold cyanide complex (Jeffrey and Breuer, 2000). The chemical reaction occurs is known as the Elsner (1846) equation.

Due to the environmental concerns, great effort has been made to find alternative gold lixiviants (De Andrade Lima and Hodouin, 2005; Ficeriová et al., 2005; Çelik, 2004; Broadhurst and Du Preez, 1993). Although some of the scientific studies gave promising results, today, cyanide protects its indispensable position in industrial applications.

Depending on the mineralogical structure of the gold ore, different amounts of cyanide concentrations can be used. Usually, a range of 0.15-0.50 g/L of cyanide concentration is utilized in industrial applications. However, when the gold ore contains cyanide

consuming minerals and/or high silver content (i.e.>20 g/t), then higher cyanide concentrations varying from 2 to10 g/L NaCN could be needed (Marsden and House 2006). On the other hand, in terms of solids ratios used in industrial applications of gold leaching, usually 35% to 50% ratios are used. By applying these standard criteria, above 90% gold extraction is obtained in many operating gold plants for leaching durations of 24 to 36 hours.

But in some situations, certain processes are performed before leaching, in order to expose gold particles, which increases the chance of contact with cyanide. When sulfide or carbonaceous minerals exist in the gold ore body, different pretreatment processes are practiced. With the data from Sinadinovic et al., (1999), Iglesias and Carranza, (1994) and Celep et al., (2009), these methods can be counted as roasting, pressure oxidation, biooxidation, ultrafine grinding, and modified cyanidation.

In this study, extraction of gold and silver from Bolkar Gold Plant tailings was investigated by testing the effect of mechanical activation, pre-aeration, and water quality.

2 MATERIALS AND METHOD

2.1 Material Characterization

The gold ore sample used in the present study was obtained from Bolkar Gold Plant tailings, which contained 1.01 ppm Au and 41.8 ppm. According to the mineralogical analyses performed on the polished section samples, gold particles could not be determined clearly, however, the liberated silver particles were found with a particle size up to 45 µm. Differently from liberated particles, silver was observed as associated with quartz, iron minerals, and calcite (Figure 1 and 2).

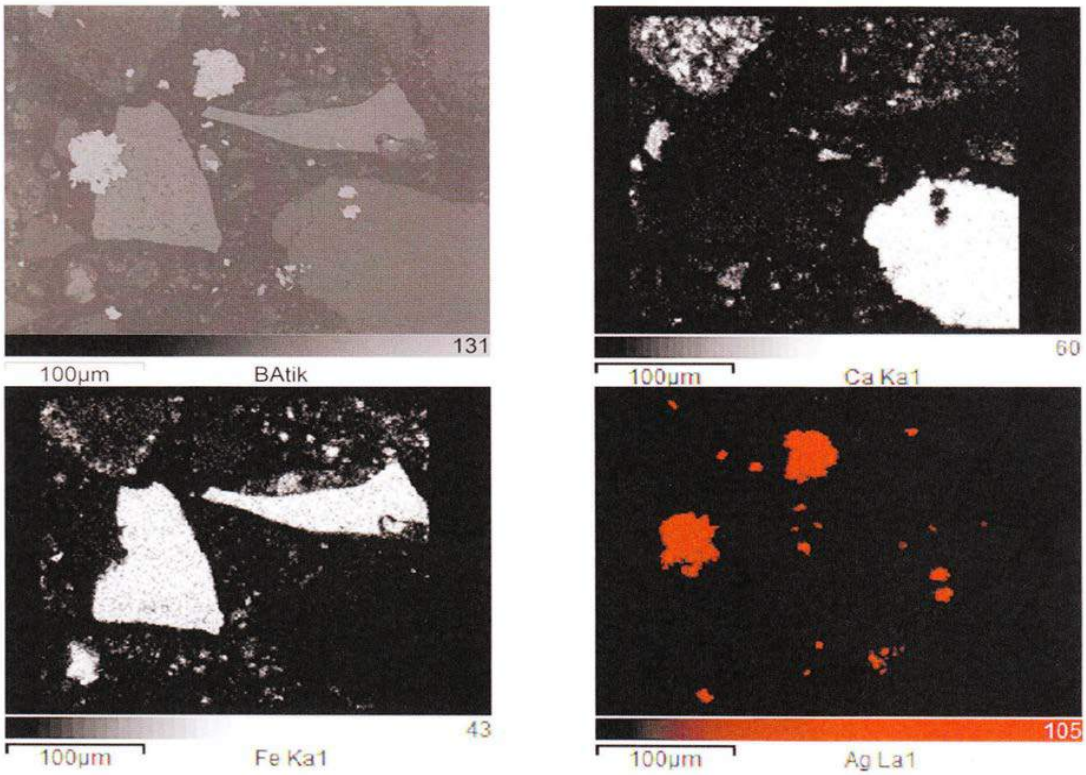

Figure 1. X-Ray Elemental Map of the Sample

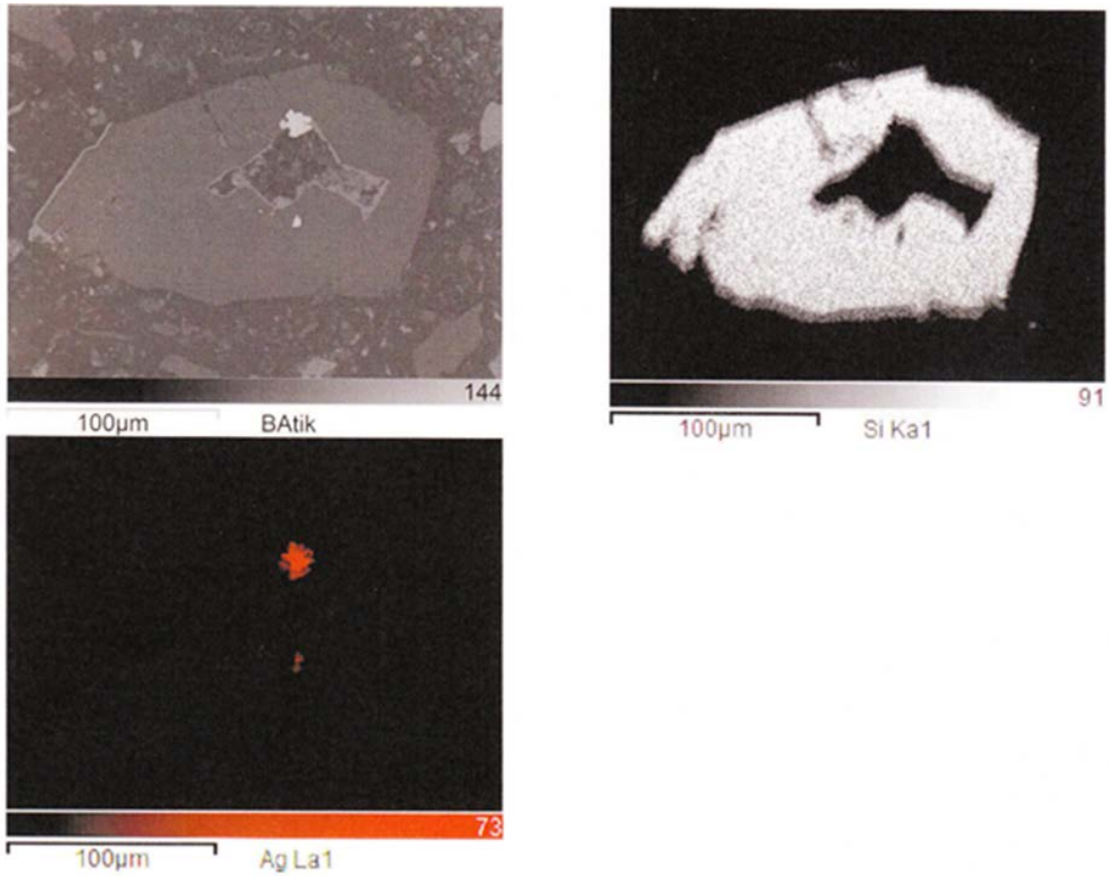

Figure 2. X-Ray Elemental Map of the Sample

The particle size of the associated silver was varying from 5 to 45 µm. Also, galena (~ 50 µm), dolomite (~ 125 µm), psilomelane (~ 75 µm), and plagioclase (~ 60 µm) were determined in the mineralogical structure of the ore sample.

2.2 Methods

The leaching tests were conducted using IKA RW 20 model mechanical stirrer, which had teflon coated impellers. During the tests, pH value was adjusted with lime and measured by WTW 3401 pH meter. After the leaching process, Buchner funnel was used in separation of solid-liquid phases. The Au and Ag contents of the dried leach cakes were analyzed by fire assay method.

In the leaching tests, the plant operating conditions of 40% solid ratio and 0.5 g/L NaCN concentration were kept constant. The effect of mechanical activation, pre-aeration, and water quality were investigated.

3 RESULTS

3.1 The Effect of Mechanical Activation

In this group of experiments, 1, 2, and 4 hours of mechanical activation durations were tested using a vibrating mill. The activated samples were then leached for 48 hours with 0.5 g/L NaCN at 40% solid ratio.

According to the results given in Table 1 and Figure 3, 2 hours of mechanical activation was seemed to be optimum, since it provided the highest gold and silver extractions of 64.2% and 48.4%, respectively. The particle sizes of the mechanically activated samples are shown in Table 2. As the particle size decreased, the extraction values increased. Particles tend to be agglomerated for longer mechanical activation durations than 2 hours.

Table 1. The Leaching Results of the Activated Samples

Mechanical Activation	Extractions, %	
	Au %	Ag
0	52.0	29.5
1	57.9	40.8
2	64.1	48.4
4	58.8	33.7

Table 2. Results of the Particle Size Measurements

Mechanical Activation	Particle Size (d_{90}), µm
0	64
1	46
2	38
4	43

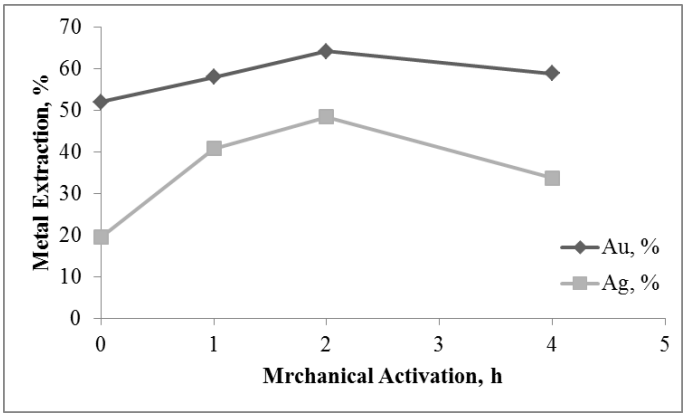

Figure 3. The Leaching Results of the Activated Samples

3.2 The Effect of Pre-Aeration with Different Leaching Durations

In this part of the study, 4 hours of pre-aeration was applied using an air pump with a 6 L/min capacity before leaching of the ore sample. Then 24 and 48 hours of leaching tests were conducted. It was expected to provide a reduction in the leaching duration required for gold extraction.

According to the results given in Table 3, better extractions were obtained with 48 hours of leaching duration.

Table 3. The Leaching Results of 4 Hours Pre-Aeration

Leaching Duration	Extractions, %	
	Au %	Ag
24	49.9	23.2
48	55.2	29.4

3.3 The Effect of Water Quality

Up to this part of the study, it was found that mechanical activation and pre-aeration showed positive effects to some extent on gold and silver extractions. Therefore, the ore sample was mechanically activated for 2 hours and pre-aerated for 4 hours. Later, 48 h of leaching was performed using two different type of water: tap water and plant recycle water.

As is seen from Table 4, application of mechanical activation and pre-aeration did not provide significant enhancements in gold and silver extractions. Only 1% of increase was obtained in Au extraction.

On the other hand, when plant recycle water is used in the leaching tests, siginificant reductions in Au and Ag recoveries were observed (5% for Au ve 12% for Ag). The reason for this result was thought to be the existence of the ionic impurities in the plant water.

Table 4. The Leaching Results of Water Quality Tests

Water Type	Extractions, %	
	Au %	Ag
Tap	65.1	48.4
Plant	60.1	36.4

CONCLUSION

- The gold ore sample used in the tests contains 1.01 ppm Au and 41.8 ppm Ag.
- It was nearly impossible to determine gold particles in the polished section samples.

- The particle size of liberated silver particles were up to 45 µm. Also, silver was associated with quartz, iron minerals and calcite.

- The positive effect of the mechanical activation was observed. However, for longer activation durations than 2 hours, the sample became agglomerated, which prevented gold and silver extractions.
- Preaeration tests showed that 3% Au increase could be obtained.
- When mechanical activation and preaeration was applied in a row before leaching, only 1% Au increase was observed. This result shows that the highest gold extraction could be reached already.
- Considering usage of the plant recycle water, the negative effect was observed depending on the ionic impurities existed in the plant water.

Determination of Leaching Cutoff Grade Using Economical Evaluation in Sarcheshmeh Copper Mine

S. N. Almasi, R. Bagherpour, A. Khademian, R. Yarahmadi
Department of Mining Engineering, Isfahan University of Technology, Isfahan, Iran

ABSTRACT There is an economical challenging question in this respect: Which portion of the deposit should be sent to leaching unit? Dispatching the trucks, which haul deposit to mineral processing plants or heap leaching unit, is subject to accurate economic computations. The issue addressed in this article is the analysis of the fundamental economic concepts in achieving optimal cutoff grade. This leaching cutoff grade sorts the ores in two sections: the high-grade, to be processed in the mineral processing plant and the low grade, to be processed in the leaching plant. The second group processing can be done in a mineral processing plant also, but it would have more profitable at the leaching plant surely. The data used in this investigation was adapted from Sarcheshmeh copper mine. According to the computation at this mine, the leaching cutoff grade equals to 0.354%, which means ores with grades between 0.15% and 0.354% should be transferred to the heap leaching unit.

Keywords: Leaching, optimal cutoff grade, Sarcheshmeh

1 INTRODUCTION

One of the most important aspects of mine design is determining the optimum cutoff grade. The extracted materials are sent to different processing units based on their cutoff grade. Optimization of cutoff grade in this industry is an accepted procedure for open pit mine planning (Osanloo and Ataei, 2003).

The cutoff grade strategy, in fact, is a decision making process about what materials have to be mined, processed and leached and which must be considered as waste, or where is the limit between mineral processing and heap leaching. The optimal cutoff grade strategy requires basic knowledge in some fields, including economics, mining production planning, mining operations, mineral processing, production restrictions and grade distribution of deposit, all of which have significant influence on annual working capital (Bascetin and Nieto, 2007). In this respect the geologic and mining restrictions in addition to the mine planning and design are the main contributing aspects focusing on an economic justification of all which is considered above (Camus, 2002). The most common approach used for obtaining the optimal cutoff grade is maximizing the net present value (NPV) which takes the unstable status of the economy into account. This approach is applicable to any type of mining operation. This concept implies that: the sum of all future cash flows discounted by an appropriate interest rate should be at least equal to the capital costs of the project (Minnitt, 2004). Of course, in this respect some researchers believe that the real NPV maximization would be actualized when the environmental costs become minimized through proper management (Osanloo et al., 2008). That is, maximizing NPV must be eliminated from the ore-based exclusivity and full control of environmental issues throughout the life of the mine should be considered in order to guarantee the optimality of the mining process (Rashidinejad et al., 2008). Now it is revealed that a special complexity has engulfed the NPV issue, so that despite the high concern on the issue, the obtained results are still uncertain (Azimi et al., 2013).

Increasing the number of variables in problems makes their solving more difficult, even impossible, especially in multi-metal

deposits. Lwambiyi et al., (2009) evaluated the effect of some by products like cobalt, manganese and quartz gangue on the heap leaching process of the Disele copper deposit in South Africa and found that they increase the complexity of problem solving significantly. This problem made the researchers to adopt some management and statistical techniques. Applying the equivalent grade factor for finding the optimal cutoff grade is one of the tactics. Here, the objective function of the multi-metal deposits is defined and the objective function is changed into variable function through the equivalent grade factors. The optimal cutoff grade of the main metal can be obtained through optimization techniques like, Lane algorithm and elimination methods. At the final stage, the optimal cutoff grade is determined by applying the grade interpolation together with tonnage distribution (Osanloo and Ataei, 2003).

Combining genetic algorithms (GA) and artificial neural networks (ANN) is the other method proposed to solve this problem. The advantage of this technique is to achieve the optimal cutoff grade instantly, so that once the general data enters, the program proposes the optimal cutoff grade. The confidence level here is influenced by the same confidence level obtained through the combined GA and ANN techniques (He et al., 2009).

This article can shed more light on the issue of determining optimal cutoff grade, which has been neglected somewhat by previous investigations. The data used in this investigation was adapted from Sarcheshmeh copper mine, which is located 160 km south-west of Kerman region (Figure.1). Sarcheshmeh is a large open cast copper mine in the Kerman Province of Iran, considered to be the second largest copper deposit worldwide. Also containing substantial amounts of molybdenum, gold and other rare metals. Geologically in a vertical section, it is divided into three zones. Named oxide, supergene, and hypogene. In recent years, copper in addition to the mineral processing has been recovered by hydrometallurgical methods (Shayestehfar et al., 2008).

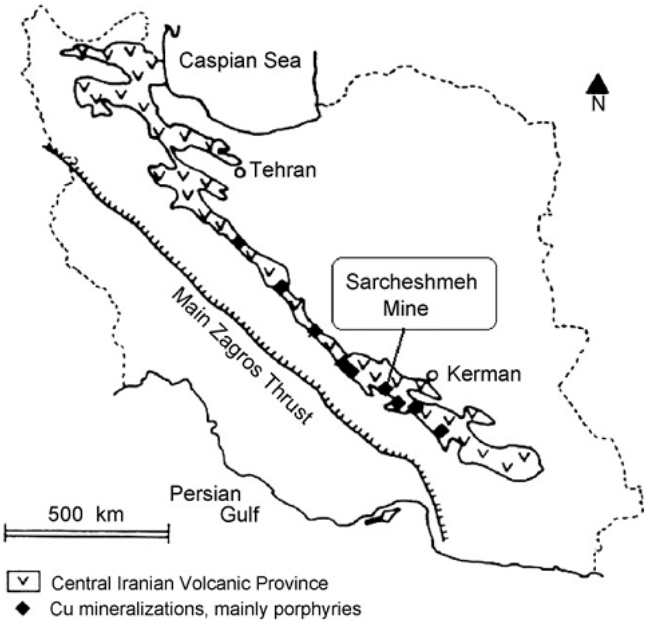

Figure 1. Location of Sarcheshmeh copper mine at the porphyry copper mineralization zone (Shayestehfar et al., 2008)

2 HEAP LEACHING

In the leaching process, the ores containing soluble metallic minerals become dissolved in aqueous solutions, containing chemical agents like sulfuric acid. The active solvent elements are some ions that due to gravity pass through the pores in the ore heap and then get separated. Complete separation may take years. The drainage layer of sand and the half-cracked polyethylene pipes are the two main features in the heap leaching drainage structure.

The metallic ion containing liquid is guided towards the half cracked polyethylene pipes through the drainage layer of sand. In this process, the Pregnant Leached Solvent (PLS) is transferred to solvent extraction electro-wining (SX-EW) plant (Majdi et al., 2009). This method in metal extraction takes the aspects of technical and the economical (providing maximum profit) production of clean and quality product into account. Of course, the factors like providing feed, mineralogical analysis and the accuracy of the analyzing apparatus should not be overlooked.

Dhawan et al. (2012) consider X-ray examination as one of the essential tools in analysis and detailed understanding of heap leaching process. Close follow up of the liquid path in the material heap and its optimization has a significant effect on heap leaching costs. Applying the available science and technologies like the X-ray and radioactive material can provide efficient data from the drainage system. Applying analytical methods which are generally based on Bernoulli Eq. as well as considering the materials particle size distribution can contribute to better explanation regarding the drainage process (Mellado et al., 2009).

At the Sarcheshmeh copper mine, copper oxide and low grade sulfide rocks are kept in the leaching dump and are exposed to a gradual flow of dilute sulfuric acid. In this process, the copper dissolves in the acid and the solution produced is collected from this section. Cathodic copper is deposited after a special electrolytic process. This method is preferred to a pyrometallurgical one on both economic and environmental grounds. The exploitation of copper oxide ores and low grade sulfide ores was not economical in the past, but heap leaching now has the advantages of low investment, better working conditions, and lower energy consumption. This process is continuously being developed to improve the removal of copper from a wide variety of ores.

3 OPTIMAL CUTOFF GRADE

In every mine where leaching process is an available choice, the grading is defined in at least two ways that has been illustrated in Figure.2. In this Figureure the horizontal bars are marked with G1 and G2 as the grades where;

G1, indicates the limit between waste and the ore and G2, indicates the limits of metal extraction method selection in a mineral processing or heap leaching method, named leaching cutoff grade.

Of course, the heap leaching technology is not specific to low grade material and it is a possible choice for some special mineralogical combinations. As in case of Sarcheshmeh copper mines, the oxidized deposits which are not capable to be processed by pyro-metallurgy methods or if so, are not economically affordable are transferred to heap leaching dump (Shayestehfar et al., 2008).

In choosing the materials destination, especially in multi-metal deposits, multiple parameters can be involved, for example, in copper mines the sulfurous or oxidized nature of the deposit or even having sulfuric materials in the primary or secondary genesis effect the processing quality and the related costs.

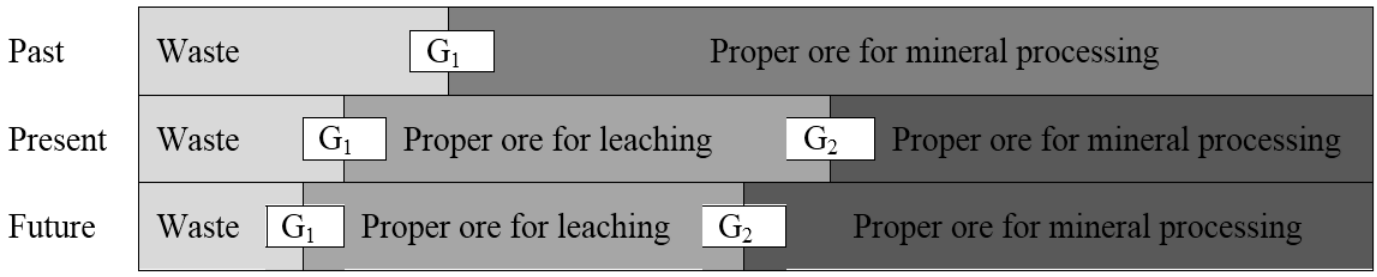

Figure 2. The changes in cutoff grade based on technology in the Past, Present and Future

This issue is more evident in oxidized minerals, so that these minerals, even with a high cutoff grade are not suitable for mineral processing and it is better to apply heap leaching technique. The availability or lack of essential elements like gold, silver and molybdenum changes the cutoff grade for both G1 and G2. In order to have an accurate and efficient assessment, it is necessary to conduct separate economic computations for each area (G1 and G2) based on the type of the mineral's main genesis and the percentage of essential elements content which would lead to determining the most

beneficial optimal cutoff grade and the best practical approach in extracting the metal.

4 THE METHODS AND PROCESS

When the metal content in a mineral is lower than a standard limit, no recovery is expected in practice. In the case of copper, the grade limit known as waste limit is 0.15%; therefore, the lowest grade limit in this study of this method is considered as 0.15%, upon which the deposit destination would be decided. The upper cutoff grade is a grade above which the minerals are sent to processing plant while minerals with lower grade are sent to the heap leaching unit.

To determine this grade, the net value should be calculated for the mineral processing and heap leaching unit in order to find the breakeven point (Hustrulid et al., 2013). To calculate the net value (NV) of one ton of mineral with a specific grade, the total costs (Ct) and the income (I) generated from metal extraction must be computed. The difference between the income and the costs is the NV (NV=I-Ct); the assessment pattern of this process is presented in a flowchart in Figure.3.

5 COMPUTATION OF NV FOR MINERAL PROCESSING METHOD

As mentioned, to calculate the net value it is required to have the incomes and costs per unit weight of mineral. In this article, the economical analysis is performed based on US dollar unit and the weight unit for ore and involved product is explained by short ton and pound.

The required costs of copper extraction at a mineral processing unit consists of:

A. Operational, 5.9 $/Ton: at this stage the copper grade increases by about 20%

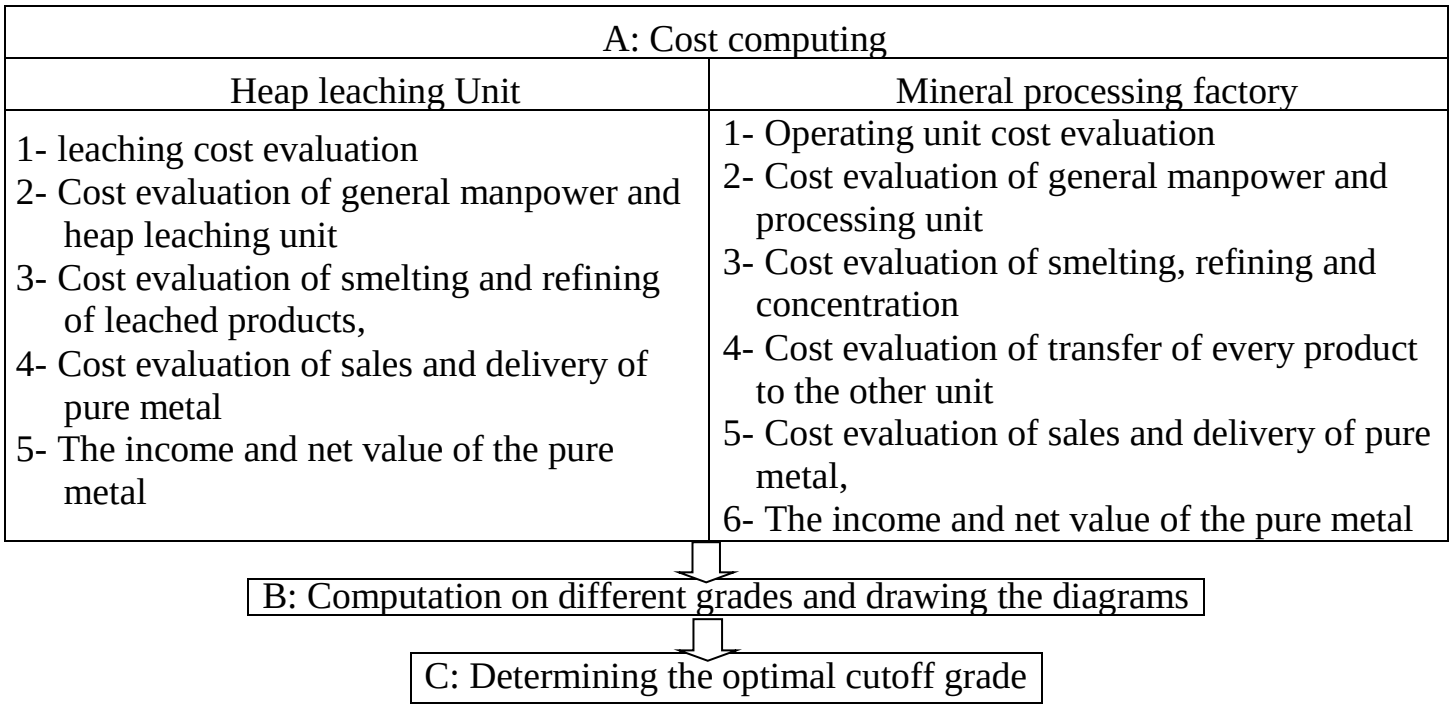

Figure 3. The leaching cutoff grade analysis and computation flow chart

B. Transferring of concentrated material to the smelting plant, 3.60 $/Ton of concentrates

C. Smelting, 100.00 $/Ton of concentrates

D. Transferring from smelting to refining plant, 210.00 $/Ton of non-refined metal

E. Refining, 260.00 $/ Ton of non-refined metal

F. The sales and delivery, and general plant at 0.16 $/Pound of pure metal

Having the detailed costs associated for each stage makes the computation of extraction costs easy. The recovery

percentage differs in each section: it is 80% at mineral processing, it increases up to %97.5 at smelting unit and the same is true as it reaches the refining unit, that is, 99.8% (Hustrulid et al., 2013).

Since the ore entering the plant releases its metal and by changing into the concentrate material exits the plant in a few days, no discount is ascribed to it. In heap leaching plant due to durability of metal extraction from the ore, such discounting is involved in the financial computations.

5.1 Describing the Method in the Copper Mineral Processing Plant

Here, it is assumed that one Ton of copper ore with metal content of 0.4% is subjected to mineral processing in the plant. The attempt is made to compute the NV after going through the full process cycle. According to Table 1, the NV/Ton for this example would be $7.81. The same computations are also made for grades ranging from 0.3% to 0.6% by 0.05 gradual steps. Details of these computations have been summarized in table 2. The diagram reflecting Table 2 is illustrated in Figure.4.

6 COMPUTATION OF NV FOR HEAP LEACHING PROCESS

At this phase, the cost and income of leaching process are computed first and the difference of these two represents the NV of product. The difference here is the time factor that was not an effective element in mineral processing, but sine the heap leaching process is time consuming, it has a direct effect on costs and naturally on the income.

Table 1. The NV of copper ore with metal content of 0.4% subject to mineral processing

Row	costs	Unit	Volume	Unit/$	Total/$	Notes
1	Operational	Ton of ore	1	5.9	5.9	--------
2	General and Administrative	Ton of ore	1	0.885	0.89	%15 of 1
3	Transporting concentrated material to smelting plant	Ton of concentrated	0.02	3.6	0.06	%80 recovery, concentrated grade %20
4	Smelting	Ton of concentrated	0.02	100	1.6	
5	Transporting from smelting to refinery plant	Ton of non-refined metal	0.0031	210	0.66	
6	Refining	Ton of non-refined metal	0.0031	260	0.41	Recovery at this stage is 97.5%
7	Miscellaneous	lb of Pure metal	6.2	0.16	0.99	--------
Total costs					10.91	--------
Metal extraction income		lb of Pure metal	6.2	1	18.72	--------
NV ($/Ton)					7.81	--------

To have a rational comparison between the two methods the NV here should be assessed in present time as described in the following sections.

Table 2. The NV calculation for different grades of copper

Grade (%)	Income ($/ton)	Cost ($/ton)	NV ($/ton)
0.30	14.4	9.88	4.16
0.35	16.38	10.39	5.99
0.40	18.72	10.91	7.81
0.45	21.06	11.42	9.64
0.50	23.4	11.94	11.46
0.55	25.74	12.45	13.29
0.60	28.08	12.97	15.11

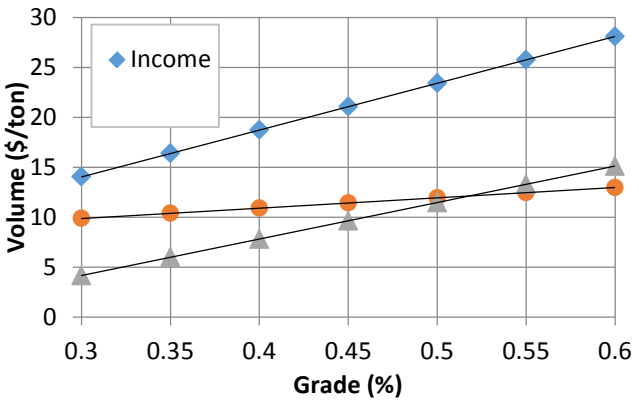

Figure 4. The NV diagram for different grades of copper in mineral processing unit

The required costs of copper extraction at a heap leaching plant consist of:

A. Leach, 0.35 $/ pound of Pure metal
B. Smelting and producing copper slabs, 90.00 $/Ton of leached material
C. Transporting from smelting to refining, 120.00 $/ Ton of non-refined metal
D. Refining, 230.00 $/ Ton of non-refined metal
E. Sales, delivery and general, 0.16 $/ pound of Pure metal

The recovery percentage at smelting and refining plants and the amount of produced metal and its sales value should be computed. Having in mind that extracted ore has to go through a period (usually few years); the generated income is subject to a discount rate. The recovery coefficient as a function of year in this process is presented in Table 3.

Table 3. The recovery coefficient as a function of year for heap leaching system

Year	Recovery Coefficient
1st	0.4
2nd	0.3
3rd	0.14
4th	0.1
5th	0.06

To compute the recovery percentage of the materials with low grade Eqn.1 is applied:

$$R\ \% = \frac{FG - FWG}{FG} \times 100 \qquad (1)$$

Where: R= Recovery, FG= Feed Grade and FWG= Fixed Waste Grade.

As for copper, the fixed wastes grade is 0.15%. Thus, for materials with a grade less than or equal to 0.4%, recovery rate is calculated using Eq.1 and for the materials with a grade above 0.4%, recovery rate over a period of five years will not surpass 50%. For example, if the heap leaching unit feed grade is 0.55%, the copper content rate will be 11 lb/Ton of ore. Since the recovery rate is 50%, it is expected to have 5.5 lb recovery in a 5 year period.

The net value is the difference between costs and incomes. Therefore, based upon aforementioned concepts, it is necessary to calculate the costs and revenues in order to determine the net present value. The calculated net value should be discounted to present time. Eq. 2 can calculate the present value of any cash flow in each year:

$$PV_n = \frac{FW_n}{(1+i)^n} \qquad (2)$$

where, PV_n is the present value of the n^{th} year of metal recovery, FW_n is the recovered metal value of the n^{th} year, i is the capital return rate and n is the designated or given year. In computing FW_n of a given year Eqn.3 must be applied:

$$FW_n = \alpha_n \times M \times P \qquad (3)$$

where, α_n is the recovery coefficient, extracted from table 3, M is the total salable metal in lb, P is metal prices in terms of $/lb.

6.1 Describing the Method by a Numerical Example in Heap Leaching Plant

Using the same procedure implemented in sections 4 and 5, economical calculations including costs, incomes and NV computations have been done for grade of 0.4 %. Table 4 expresses all of these findings.

These computations have been repeated for different grades varying from 0.3 to 0.6 and all of results are summarized in table 5 and have been illustrated in Figure.5.

The Summary of costs and incomes computations for different grades between 0.3% and 0.6% by 0.05 gradual steps are presented in Table 5.

7 DISCUSSION

Provided information in tables 1, 2, 4 and 5 leads to significant results, which all have been summarized in table 6. Also, calculated NV for both metal processing methods at grades 0.3-0.6% are illustrated as a diagram in Figure.6. As it can be observed table 6, at grade 0.354% the NV is 6.07$ per ton of deposit for both methods which indicates the breakeven point.

Above this grade, the mineral processing method reveals a higher NV and hence for lower grade ores the heap leaching method is more appropriate.

Table 5. The summation of the costs and incomes at heap leaching unit

Grade (%)	Income ($/ton)	Cost ($/ton)	NV ($/ton)
0.30	6.94	2.19	4.74
0.35	9.25	2.93	6.32
0.40	11.56	3.66	7.90
0.45	10.40	3.29	7.11
0.50	11.56	3.66	7.90
0.55	12.71	4.02	8.69
0.60	13.87	4.39	9.48

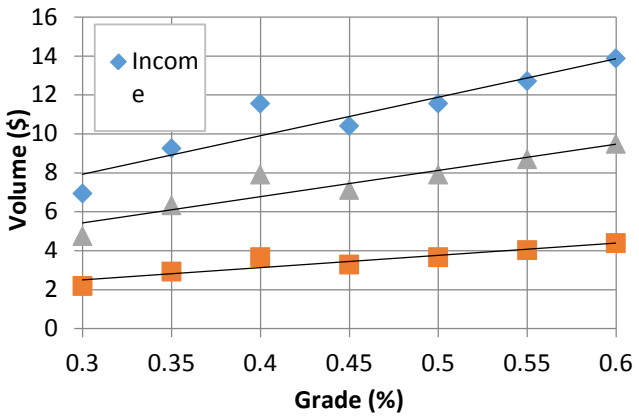

Figure 5. The NV diagram for different copper grades in heap leaching unit

Accordingly, the grade of 0.354% is considered as the breakeven point for dispatching truck to either of the plants; while, grades above this would be routed to mineral processing plant and grades below this would be routed to the heap leaching plant.

Table 4. Computing the NV of copper ore at 0.4% grade subject to heap leaching

Row	Description	Unit	Volume	Price/$	Total/$
1	leaching costs	Pound of Recovered metal	5	0.35	1.75
2	Smelting costs	Ton of leached material	0.0029	90	0.26
3	Transferring cost from smelting to refining unit	Ton of Non refined material	0.0025	120	0.295
4	Refining costs	Ton of Refined material	0.0025	230	0.565
5	Miscellaneous costs	pound of pour metal	4.09	0.164	0.78
	Total costs $/Ton of ore				3.66
	Income from metal extraction $/Ton of ore				11.56
	NV $/Ton of ore				7.90

Table 6. The NV per ton of ore for different grades and metal extraction methods

Ore grade (%)	NV ($/Ton of ore)	
	Mineral processing unit	Heap leaching unit
0.30	4.16	4.74
0.35	5.99	6.32
0.354	6.07	6.07
0.40	7.81	7.90
0.45	9.64	7.11
0.50	11.46	7.90
0.55	13.29	8.69
0.60	15.11	9.48

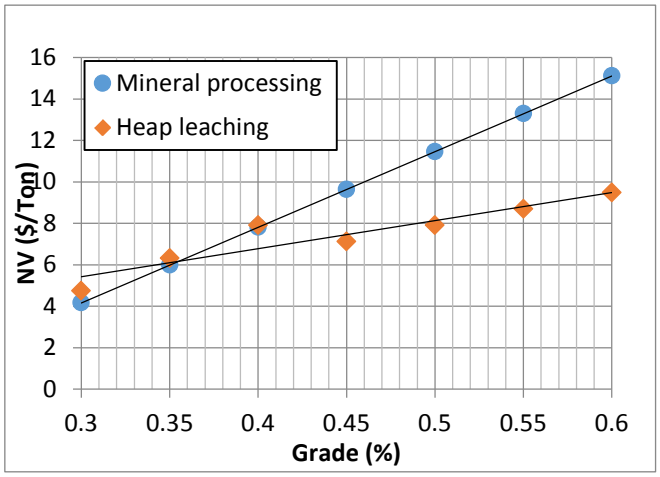

Figure 6. The breakeven point of both the methods

If in the diagram of Figure 5, X represents the grade, Y_1 represents the NV in mineral processing unit and Y_2 represents the NV in heap leaching method, the resulted trends of the parameters will be in accordance with the following:

A: For Mineral processing method

$$Y_1 = 36.5X - 6.97 \qquad R^2 = 1 \qquad (4)$$

B: For Heap leaching method

$$Y_2 = 13.5X + 1.35 \qquad R^2 = 0.87 \qquad (5)$$

8 CONCLUSIONS

The findings here are presented through the following points:

- According to the computation for sarcheshmeh copper mine, the 0.354% is the leaching cutoff grade, which means ores with grades between 0.15% and 0.354% should be transferred to the heap leaching unit.
- In the heap leaching process, due to the absence of material transfer to smelting unit and the low sedimentation cost, metal extraction from low grade minerals is justified economically. This fact is true for the oxidized copper ore as well.
- In multi metal deposits with different genesis, determining the main metal grade is a complicated task. To make this task less complicated, adopting statistical and managerial methods based on expert opinion in the field of optimal cutoff grade is of essence.
- In multi metal and multi genesis deposits the mine zoning and hauling route assignment per zone will contribute to the accurate transport of the material to the proper destination.

ACKNOWLEDGMENTS

The authors would like to thank Ali Sadjadi & Shahin Ghasemnezhad in Sarcheshmeh complex for their cooperation during the present investigation. The authors also appreciate Amin Nouri for their helpful comments.

Evaluation of Phase Transformation During Mechanochemical Leaching of Zinc from Zinc Plants Residues in Alkaline Medium

P. Ashtari, P. Pourghahramani
Mining Engineering Faculty, Sahand University of Technology, Tabriz, Iran

ABSTRACT In Iranian zinc plants, hot filtercake (HFC) is an important waste which contains valuable metal like zinc, manganese, calcium and cobalt. Commonly, HFC is processed by selective mechanochemical alkaline leaching to zinc extraction. In this paper, the phase transformation during mechanochemical alkaline leaching of HFC was studied using an attritor. XRD patterns of leaching residues in milling time of 3, 15, 26, 37 and 48 revealed that a progressive phase transformation occurred. Sulfate form of calcium ($CaSO_4.2H_2O$) and oxidic form of manganese (Mn_2O_3) transform to a mixed hydroxide form of calcium and manganese. This finding is very important to disclose the zinc leaching mechanism.

Keywords: Leaching, Zinc, phase transformation, alkaline medium

1 INTRODUCTION

In Iranian zinc plants, to eliminate cobalt from zinc sulfate solution manganese permanganate is used. Hot filtercake (HFC) or cobalt filtercake is generated during this step which contains 0.5-3% cobalt, 6-16% manganese and 8-20% zinc. Thus, HFC appears to be a promising source for further processing. Hydrometallurgical processes are usually preferred for processing of valuable metals from various residues because of their advantages (Gupta and Mukherjee, 1990). According to Arzu Özverdİ and Mehmet Erdem studies, concentration of the contaminant released from zinc plants residues (ZPRs) is higher than the threshold values which cause HFC to be classified as a hazardous waste (Özverdİ and Erdem, 2010). Therefore, HFC should be inevitably retreated for Zn, Mn and Co recycling.

Acidic leaching commonly dissolve Co, Mn and Zn collectively with low selectivity. However, alkaline leaching could be utilized to leach zinc selectively. Then, zinc powder can be obtained by electrowinning (Dutra et al., 2006; Gürmen and Emre, 2003; Lee and Piron, 1995; Li et al., 2012; LIU et al., 2005; Orhan, 2005; Zhang et al., 2014; Zhao et al., 2009). Zinc extraction from HFC facilitates the following processes of cobalt and manganese extraction. Therefore, alkaline leaching can promote cobalt and manganese extraction steps. As seen in literature, zinc is not usually dissolved in alkaline medium completely.

Mechanochemical treatment enhances the reactivity of material through a wide structural changes occurring during the extensive milling. Structural changes like lattice strain, bonds breakages, X-ray amorphization degree, decreasing in crystallinity, phase transformation, increasing in dislocation density and surface area and so on are responsible for the reactivity improvement (Balaz, 2008; Boldyrev, 2006; Zdujić et al., 1992; Zhang et al., 1997).

During mechanochemical leaching, namely combination of the leaching and mechanical activation process into a single step, the performance of leaching could be promoted, remarkably (Baláž and Achimovičová, 2006; Chenglong and Youcai, 2009). Consequently, it would be expected that high amount of zinc from HFC could be recovered by mechanochemical alkaline leaching (MCAL).

The objective of this study is to investigate

the phase transformation of crystalline phases present in HFC which was treated by mechanochemical alkaline leaching method to zinc selective dissolution. The main aim was to evaluate the effect of various milling conditions on phase transformation which occurred during zinc dissolution. In addition, the performance of zinc dissolution was related to the crystalline phase.

2 MATERIALS AND METHOD

A representative hot filtercake (HFC) sample was collected from ALVAN zinc plant, Zanjan, Iran. In order to remove the soluble salts, the as-received wet HFC was first washed with distilled water several times. The pre-treated HFC (PHFC) was dried in an oven at 95 °C for 24 h. The mechanochemical alkaline leaching (MCAL) experiments were performed in a vertical stirred ball mill (attritor) with a stainless steel chamber using a 9 M NaOH solution. Milling time (leaching time) of 3, 15, 26, 37 and 48 min as well as milling speed of 0, 420 and 670 rpm was parameters and their levels that considered to zinc leaching from PHFC with MCAL method. Milling conditions were as given in Table 1. Pure NaOH from Merck was used in leaching experiments.

Table 1. Milling conditions.

Balls to powder weight ratio	50
Mill speed (rpm)	420-670
Mill Volume (cm^3)	470
Void volume of media (cm^3)	187
Filling ratio of ball volume (%)	80
Number of balls	750
Ball weight (g)	1500
Ball diameter (mm)	7.8
Media type	Tempered steel
Media corrosion	negligible
Media density (g/cm^3)	7.8

3 RESULTS AND DISCUSSION

3.1 PHFC characterization

Chemical composition of PHFC is presented in Table 2. The average particle size of the initial PHFC sample was 6.5 µm which is very fine.

Table 2. Chemical composition of PHFC.

Element	Zn	Mn	Co	Ca	Ni	Cd	Cu	other
wt. %	10.46	15.43	2.2	7.5	0.08	0.30	0.075	trace

The XRD pattern of HFC is shown in Fig. 1. As shown, different kinds of hydrous calcium sulfate like gypsum ($CaSO_4 \cdot 2H2O$) and plaster of pairs ($2CaSO_4 \cdot ½H_2O$) were the major crystalline phases in PHFC. Other phases included manganese oxide (MnO_2), zincite (ZnO), quartz (SiO_2) and cobalt oxide (Co_3O_4). But, intricate composition of PHFC, likewise very fine particles and low degree of crystallinity made phase assessment more difficult.

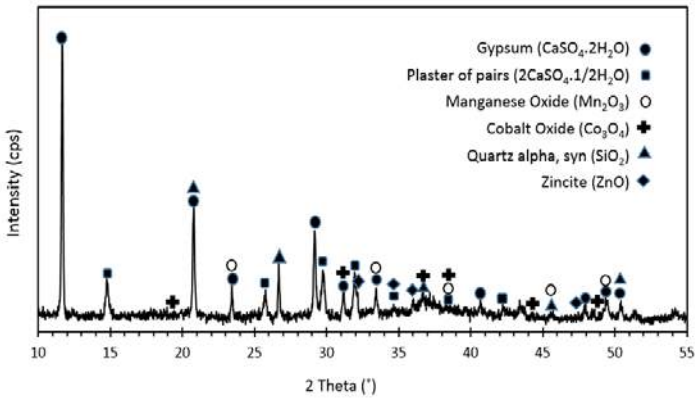

Figure 1. XRD pattern of the PHFC sample.

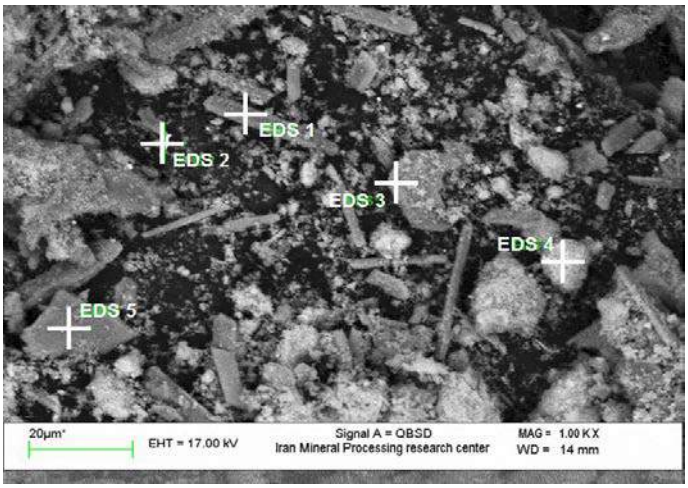
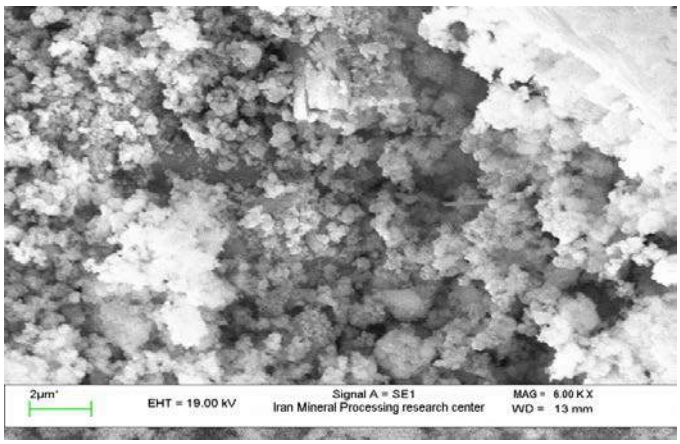
SEM-EDS analysis was used to find more information. As shown in Figure 2a, the only crystalline particles which have relatively large grains (compared to other particles) viz. EDS1, EDS3 and EDS5 points contain Ca and S, confirming the presence of calcium sulfate phases. Zn, Mn and Co could be observed instantly on the some fine particles with varying ratios of zinc, manganese, cobalt, calcium and oxygen. High-resolution image of fine surface morphology is also shown in Figure 2b.



(a) Backscattered electron mode



(b) Secondary electron mode

Figure 2. SEM micrograph of HFC.

It was concluded that most of the particles are in sub-micron sizes and fine particles aggregate on surface of larger crystalline particles.

3.2 Zinc dissolution with MCAL method

Based on XRD analysis of PHFC sample, the main zinc bearing phase is zincite (ZnO). Among the all phases presents in PHFC, ZnO was the only phase could be dissolved in alkaline medium. Our preliminary experiments showed that lead and cadmium have not leached, remarkably. So, the leaching process could be completely selective for zinc. It is thought that Zincite dissolves in alkaline medium according to the reaction below:

$$ZnO_{(s,\ in\ PHFC)} + 2NaOH_{(aq)} + H_2O \rightarrow Na_2Zn(OH)_{4(aq)}$$

The results of all experiments as well as their operational condition are summarized in Table 3 and graphically shows in Fig. 3. It can be seen that when leaching time progressed, there were three different behaviors for zinc alkaline leaching: 1.Through CAL method (conventional alkaline leaching or MCAL with R=0 rpm), the recovery of zinc remains approximately at a constant value; 2. In MCAL method, a slight increase in the recovery of zinc can be observed by applying low milling speed (R=420 rpm); 3. By spending more energy in milling (R=670 rpm), a noticeable increase in zinc recovery can be obtained during MCAL. Based on the results, in CAL method, the maximum recovery was 82.4%. However, in MCAL zinc recovery of 99.9% can be achieved with 9 M NaOH concentration, 670 milling revolution and 15 min of milling. During MCAL, zinc leaching readily increases while the milling speed and leaching time increase. At a given leaching time, with increasing of milling speed from 420 to 670, leaching recovery will be promoted. It means that more energy applied in milling leads to more zinc dissolution.

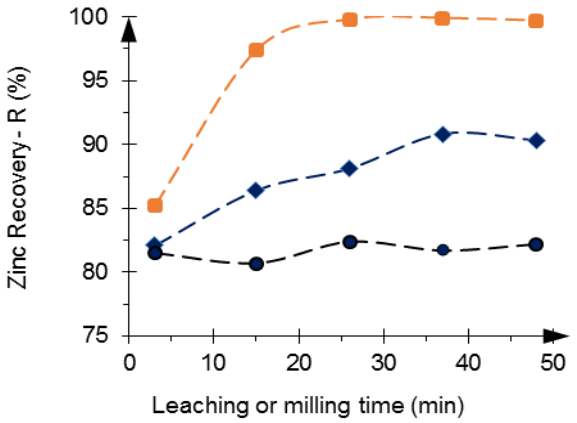


Figure 3. Effect of milling speed on zinc alkaline leaching recovery from PHFC at C_{NaOH}= 9 M, liquid to solid ratio= 6/1 (V/W), mass ratio of ball to HFC= 50/1 (W/W) and temperature= 25±2 ˚C [(●), (◆) and (■) stand for mixing in CAL, R=420 and R=670 in MCAL, respectively].

Table 3. Operating parameters of zinc alkaline leaching and results.

Leaching method	Milling speed (rpm)	Zinc alkaline leaching recovery (%)				
		Leaching time (min)				
		3	15	26	37	48
Conventional alkaline leaching (CAL)	0 (mixing)	81.5	80.7	82.4	81.7	82.2
Mechanochemical alkaline leaching (MCAL)	420	82.1	86.4	88.1	90.8	90.3
	670	85.2	97.4	99.8	99.9	99.7

* Mixing was used to denote mechanical mixing of solution in CAL method.

** the values of the other parameters including temperature, liquid to solid ratio (L/S) and mass ratio of ball to PHFC (B/P) were kept constant at 25±2 ˚C, 6/1 (V/W) and 50/1 (W/W), respectively.

As seen, in alkaline leaching of zinc from PHFC using CAL method, an unusual rapid increasing in zinc recovery was observed during the first seconds of leaching. But, the first stage followed by the second step with constant recovery. With high probability, during the leaching process an insoluble layer was progressively formed on the surface of the dissolving particles to prevent leaching of unreacted core. This insoluble layer is very stable in alkaline medium and it was expected to be in hydroxide form.

3.3 Phase transformation of crystalline phases presents in PHFC during MCAL process

In this section phase transformation of main crystalline phase of PHFC during MCAL process was studied. As given in Fig. 5, Pattern (a) shows the main crystalline phases presented at PHFC. To simplify the figure, minor phases hasn't been shown.

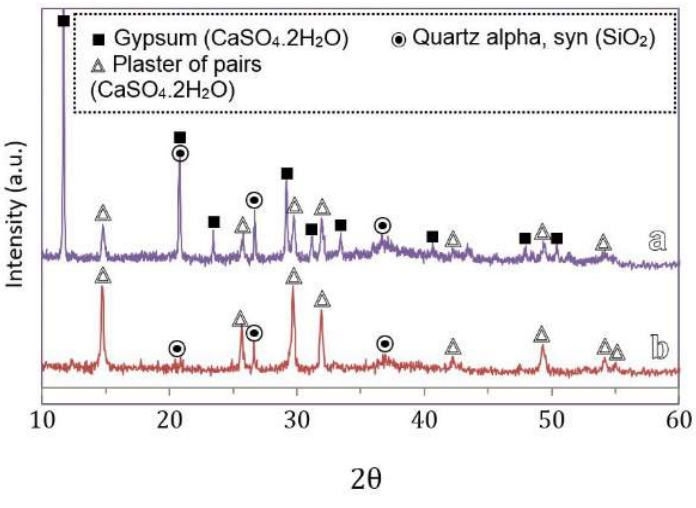

Figure 4. Effect of MCAL on phase transformation of crystalline phases presents in PHFC during wet milling (C_{NaOH}= 0 M, liquid to solid ratio= 6/1 (V/W), mass ratio of ball to HFC= 50/1 (W/W), temperature= 25±2 ˚C and milling speed= 670 rpm).

Pattern (b) at Fig. 5 shows wet mechanical activation of PHFC after 48 min with milling speed of 670 rpm [The values of the other parameters are mentioned at the caption]. As a result, gypsum peaks disappeared, while compare to pattern (a) plaster of pairs peaks became more intense. For this reason, it could be concluded that in wet mechanical activation of PHFC gypsum phase converts to plaster of pair.

Fig. 5 shows the effect of time on the XRD patterns of the residues of PHFC leaching during MCAL method. Pattern (a) shows PHFC and patterns (b), (c), (d), (e) and (f) related to leaching residue for 3, 15, 26, 37 and 48, respectively. As it is obvious, even after a few minute, all peaks of gypsum and plaster of pairs was disappeared and just quartz peaks remained unchanged. On the other hand, after a while, some other new peaks grew up. All new peaks belong to a certain phase named calcium manganese hydroxide. After beginning of reaction and progressing of time, amount of calcium manganese hydroxide increases since almost at t=26 min becomes detectable with X-ray diffractometer. This trend continued till 37 and 48 min that we can see sharp peaks with high intensity. As expected, quartz peaks are same at the all patterns.

Therefore, additional to abrasion, the most part of transferred energy during attrition process in MCAL method, expends to crystal growth of new phase. Based on low broadening of this new phase peaks, no amorphization occurred. Another important point is that the mentioned insoluble layer probably is composed of identified calcium manganese hydroxide.

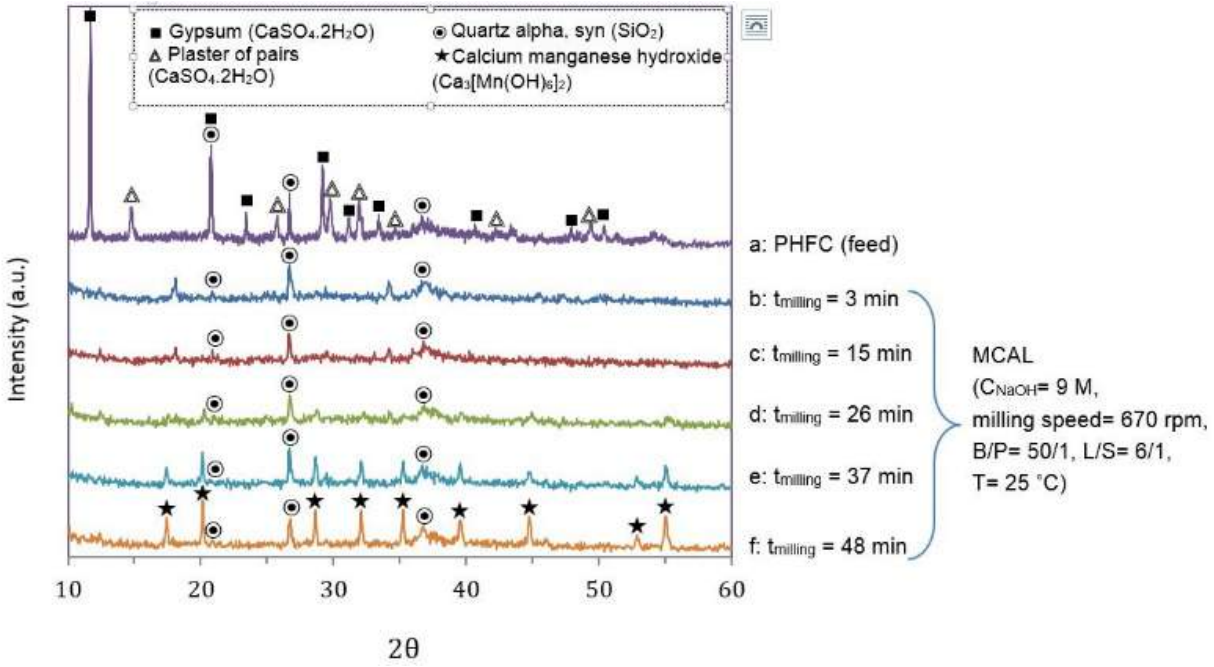

Figure 5. Effect of milling time on phase transformation and XRD patterns of zinc alkaline leaching from PHFC using MCAL method at C_{NaOH}= 9 M, liquid to solid ratio= 6/1 (V/W), mass ratio of ball to HFC= 50/1 (W/W), temperature= 25±2 ˚C and milling speed of 670 rpm.

4 CONCLUSION

In this work, phase transformation of crystalline phase presented in PHFC was considered to study during MCAL. It was found that during wet mechanical activation of HPFC for 48 min and at milling speed of 670 with ball to powder ratio of 50/1 (W/W), gypsum transformed to plaster of pairs. But, at the same condition and in the alkaline medium, all gypsum and plaster of pairs in addition to manganese bearing phase during MCAL of PHFC transformed to a new calcium manganese hydroxide phase. Therefore, it could be concluded that some of transferred energy during MCAL process expends to crystal growth of new phase.

Galvanic Leaching of Chalcopyrite Using Manganese Oxides in Spent Carbon-Zinc Batteries

H. Nakazawa and W. Hareyama
Faculty of Engineering, Iwate University, Morioka 020-8551, Japan

ABSTRACT It is well known that galvanic interaction between sulfide minerals and manganese oxides in manganese nodules accelerates the leaching of sulfide minerals. Carbon ï zinc batteries contain a moist paste (hereafter, black paste) of manganese oxides and graphite powder as cathode mix. In Japan spent carbon-zinc batteries are collected and treated by incineration and landfill. We have investigated the feasibility of galvanic leaching of chalcopyrite concentrate using chemical reagent MnO_2 and black paste. Addition of MnO_2 enhanced the leaching of chalcopyrite concentrate in sulfuric acid solution with pH1.0 and Mn concentration also increased remarkably. Extraction yields of Cu and Mn were 42% and 20% respectively at a MnO_2 to chalcopyrite mass ratio of 4 in 14 days. In the presence of black paste the kinetics of chalcopyrite leaching was accelerated dramatically and 83% of Cu in the concentrate was extracted in 40 hours. The graphite powder contained in black paste could play an important role in the galvanic leaching of chalcopyrite in the presence of MnO_2.

Keywords: Galvanic leaching, chalcopyrite, manganese oxides, spent carbon-zinc batteries.

1 INTRODUCTION

Galvanic interactions among different minerals are well-known phenomena. Paramguru and Nayak (1994) investigated galvanic interaction between sphalerite and manganese dioxide in sulfuric acid solution and found a substantial increase in leaching of both the minerals. Galvanic leaching of manganese nodule and cobalt-rich crust has been investigated using sulfide minerals. Nakazawa et al (2010) showed that the dissolution of manganese in cobalt-rich crust was accelerated in the presence of pyrite. Since manganese dioxide was nobler than pyrite, manganese dioxide acts as a cathode to be reduced resulting into release of manganese from the crust in the contact with pyrite. On the other hand, pyrite acts as an anode to be oxidized.

Gantayat et al (2000) investigated galvanic interaction between chalcopyrite and manganese dioxide in sulfuric acid medium using compact disc electrodes of both minerals. They reported that chalcopyrite and MnO_2 form a galvanic corrosion couple where the former acts as anode and the latter as cathode leading to strong interaction between the minerals. Devi etal (2001) studied the dissolution in the presence of manganese dioxide in hydrochloric acid medium. They found that chalcopyrite didnœt dissolved independently but underwent oxidative dissolution with manganese dioxide by (i)galvanic interaction (ii) cyclic action of F^{3+} /Fe^{2+} redox couple and (iii) chlorine gas by MnO_2 dissolution. The last one was observed to be most effective. But so far, no study is reproted on galvanic leaching of chalcopyrite using manganese dioxide in sulfuric acid solution.

Spent carbon-zinc batteries and alkaline batteries are mostly collected as incombustible waste by municipal authorities and are buried in landfill sites without recycling them in Japan. These batteries contain variable materials such as manganese, zinc and iron. Carbon-zinc batteries consist of a carbon rod cathode with a moist paste (hereafter, black paste) of MnO_2 and NH_4Cl mixed with graphite powder to improve conductivity and retain moisture in the acid electrolyte (McComsey,2001). During discharging of carbon-zinc batteries, chemical reactions between the anode and cathode could occur

to give ZnO, and Mn_2O_3 (McComsey, 2001)

.

$$Zn + 2MnO_2 \rightarrow Mn_2O_3 + ZnO \quad (1)$$

Mn_2O_3 dissolves to form MnO_2 in sulfuric acid solutions according to equations (2)

$$Mn_2O_3 + H_2SO_4 \rightarrow MnO_2 + MnSO_4 + H_2O \quad (2)$$

In this study, we have examined the feasibility of the galvanic leaching of chalcopyrite using black paste obtained from spent carbon-zinc batteries and chemical analysis reagent MnO_2 in sulfuric acid solution.

2 SAMPLES AND EXPERIMENTAL PROCEDURE

Chalcopyrite concentrate (-100μm) used in this study was provided by Atakama mining in Chile. XRD analysis of the sample shows only the peaks of chalcopyrite. The chemical compositions are as follow; Cu: 28.9%, Fe:28.9%.

Chemical analytical grade MnO_2 was provided by Kanto chemical Co.Ltd. Black paste was collected from the dismantled spent carbon-zinc batteries and dried at 80 ^oC for 24 h followed by grinding with a porcelain mortar and a pestle. In order to remove the zinc from the black paste, the original black paste was washed with 1N sulfuric acid solution at 1/10 solid/liquid ratio by mixing at 200rpm for 1h with a magnetic stirrer. The washed black paste was dried and ground in the way as described above. Table 1 shows the chemical compositions of MnO_2 and black paste. XRD patterns of MnO_2 and black paste are shown in Figure 1. The counts are low and broad peaks are observed for black paste. XRD analysis of the black paste indicates the presence of graphite that is used as conductive material in carbon-zinc batteries.

Table 1. chemical composition of black paste samples

Sample	Mn	Zn
MnO_2	54.6%	ND
Black paste	40.8%	0.4%

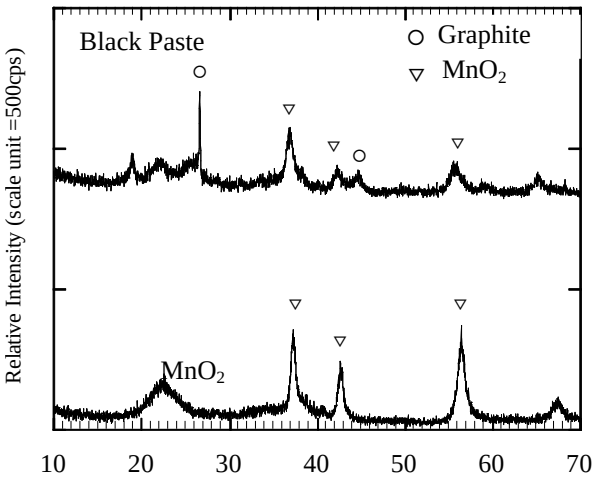

Figure 1. XRD patterns of MnO_2 and Black paste

Leaching experiments were carried out in 300mL elementary flask with 200mL sulfuric acid solution. Samples were added into the flask and stirred on magnetic stirrer at 200rpm. At desired interval the pH and the redox potential of the leaching solution were measured. The redox potentials were measured using Pt electrode with Ag-AgCl (3.3N KCl) reference electrode and it was converted to a value against NHE. Then an aliquot was withdrawn and centrifuged (10000rpm, 10min). The supernatant was analyzed for Mn, Cu, total Fe and ferrous irons (Fe(II)). Cu, Mn and total Fe(Fe(II)+Fe(III)) concentration were measured with an atomic absorption spectrophotometer (Hitachi Z-5000).

At the end of the leaching experiment the leachate was filtered and the residue was recovered with filtration and dried at 60 ^oC and RDX analysis was conducted. The surface studies of the residues were also investigated by scanning electron microscopy (SEM) equipped with an energy dispersive X-ray spectrometry (EDS).

Rest potential was measured using MnO_2 and chalcopyrite electrodes prepared by mounting granular MnO_2 (chemical grade,Kanto chemical Co.Ltd.) and chalcopyrite obtained from a mine in Indiana state, USA in 6.25mm ID Lucite tubing as described by Adam et al (1984). Electrical contact was made using a few drops of mercury to contact to a platinum wire. Before each measurement, the electrode

surfaces were cleaned by polishing with 400 and 600 grit abrasive papers and then on a metallurgical polishing wheel with 0.5μm diamond powder as the abrasive.

3 RESULTS

3.1 Rest Potential of MnO_2 and Chalcopyrite

The steady-state rest potentials of MnO_2 in chemical grade and chalcopyrite after one hour in pH0.8 sulfuric acid solution were 965mV and 321 mV (NHE), respectively. These materials are expected to form galvanic couple in contact with each other. MnO_2 can act as a cathode while chalcopyrite serves as an anode, suggesting that chalcopyrite could be oxidized to dissolve.

3.2 Effect of MnO_2 on the Kinetic of Chalcopyrite Leaching

Fig.2 (A)-(D) show the effect of the MnO_2 on the chalcopyrite leaching. The leaching rate of chalcopyrite increased in the presence of MnO_2. The extraction yield of copper was 52% in 24 days while that was17% in the absence of MnO_2. MnO_2 dissolution was accelerated in the presence of chalcopyrite and the extraction yield was 22%. Chalcopyrite and MnO_2 could be leached through galvanic interaction between them according to equation (3) and (4).

$$CuFeS_2 \rightarrow Cu^{2+} + Fe^{2+} + 2S^o + 4e^- \quad (3)$$

$$MnO_2 + 4H^+ + 2e^- \rightarrow Mn^{2+} + 2H_2O \quad (4)$$

Iron ions occurred as ferrous ions in the absence of MnO_2 whereas ferric ions existed in the presence of MnO_2. Ferrous ions dissolved from chalcopyrite were oxidized to ferric ions by MnO_2 according to the reaction (5):

$$2Fe^{2+} + MnO_2 + 4H^+ \rightarrow 2Fe^{3+} + Mn^{2+} + 2H_2O \quad (5)$$

Overall reaction between chalcopyrite and MnO_2 is described as follow:

$$2CuFeS_2 + 5MnO_2 + 20H^+ \rightarrow 2Cu^{2+} + 2Fe^{3+} + 5Mn^{2+} + 4S^o + 10H_2O \quad (6)$$

The molar ratio of dissolved Mn ions to Cu ions was 3.9 at the experiment.

The redox potential in the presence of MnO_2 remained over 900mV during the experiments whereas it was about 600mV without MnO_2.

MnO_2 accelerates the kinetics of chalcopyrite leaching, but leaching rate of chalcopyrite was not so adequate that it would require a lot of time to complete the leaching.

3.3 Effect of Black Paste on the Leaching of Chalcopyrite

The leaching experiments were carried out using black paste. The results are shown in Figure 3. The kinetics of chalcopyrite leaching was enhanced dramatically in the presence of black paste. The extraction yields of copper in the presence of 2g black paste was 60% in 16h while that was 4.6% in the absence of black paste. 83% of copper in the concentrate dissolved in 40h, but extraction yield of copper leveled off after then. Extraction yield of Mn increased remarkably and were 53%.

The pH increased with time in the presence of the black paste while pH didn't change in the absence of the black paste. Eh also increased up to over 900mV in the presence of the black paste while it decreased without the addition of black paste because of increase in ferrous concentration. Iron ions occurred as ferrous ions in the absence of black paste whereas ferric ions existed in the presence of black paste. Ferrous ions were oxidized by MnO2 in the black paste according to the reaction (1). Figure 4 shows SEM microphotograph of the residue. Unleached chalcopyrite and graphite powder are observed.

Following experiments were carried out using the black paste

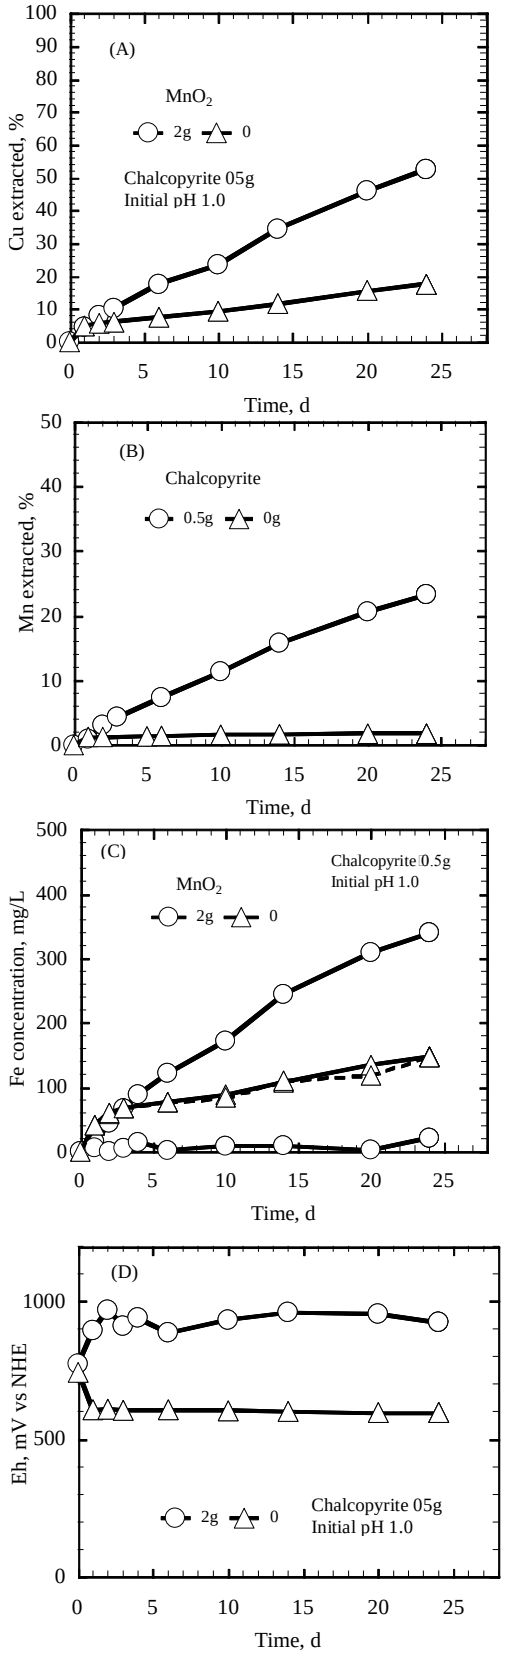

Figure 2. Effect of MnO_2 on the chalcopyrite leaching

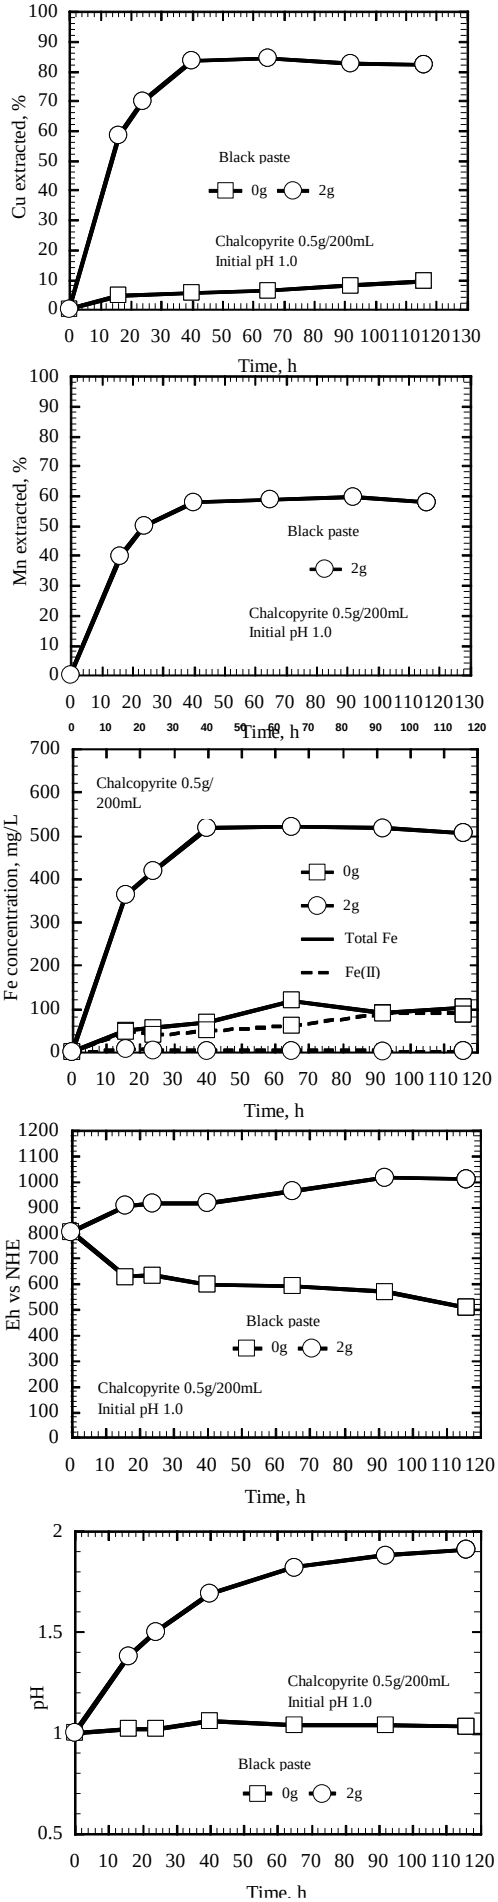

Figure 3. Effect of black paste on the chalcopyrite leaching

3.4 Effect pf Initial pH on the Kinetics of Chalcopyrite in the Presence of Black Paste

In order to investigate the effect of initial pH, leaching experiments were carried out at initial pH 0.8 and 1.2. The results are shown at Figure 5. There are no so much differences in the copper extraction rate between them. For initial pH 1.2, pH raised to 2.4 in 116h.

3.5 Effect of Temperature on the Kinetics of Chalcopyrite in the Presence of Black Paste

In order to study the effect of temperature on the leaching of chalcopyrite, leaching experiments were conducted at 50°C and ambient temperature. The results are shown at Figure 6. Elevating temperature increased extraction rate at the middle stage of the experiment, but the extraction yield of copper was the same as that at the ambient temperature in 50h. Total iron concentration deceased after 20h at higher temperature. Ferric ions could precipitate as jarosite because jarosite tend to form with increase in temperature.

3.6 Effect of the Graphite Powder in the Black Paste on the Chalcopyrite Leaching in the Presence of MnO_2

Black paste contains graphite powder to increase the electric conductivity. Effect of graphite powder was examined on the leaching in the presence of MnO_2. The graphite powder in black paste was collected in the way described below:

0.2g black paste was digested with aqua regia

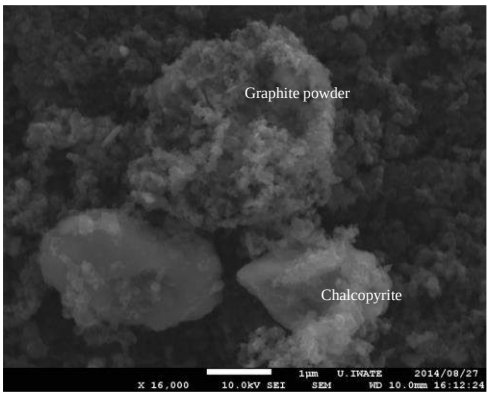

Figure 4. SEM microphotograph of the residue

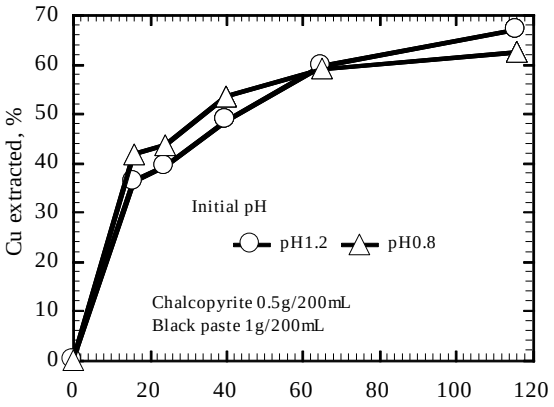

Figure 5. Effect of initial pH on the chalcopyrite leaching in the presence of black paste

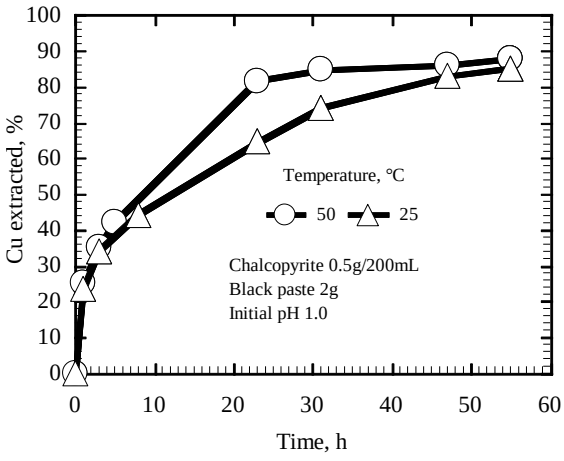

Figure 6. Effect of temperature on the chalcopyrite leaching in the presence of black paste

mL of HNO_3:HCl=1:3) by gentle boiling on a hot plate for 6h. The sample was filtered and the residue on the filter paper was rinsed with distilled water until the electrical conductivity of the filtrate remained constant and dried at the 40°C for 24h. Leaching experiment was conducted by adding 0.03g graphite powder to the leaching solution with 0.5g chalcopyrite and 2g MnO_2. The results are shown in Figure 7. The kinetics of chalcopyrite leaching rate was accelerated extremely in the presence of graphite powder and extraction yield of copper was 78% in 5days in. The leaching rate of MnO_2 was also increased significantly and 37% of MnO_2 was dissolved in 5days.

4 DISCUSSION

Since MnO_2 is noble than chalcopyrite, chalcopyrite and MnO_2 form a galvanic corrosion couple in sulfuric acid solution where the former acts as anode and the latter as cathode leading to simultaneous dissolution of both materials.

In the presence of MnO_2 the kinetics of chalcopyrite leaching was enhanced, but the leaching rate was not so adequate that it would require a lot of time to complete the leaching. Adding the black paste increased the rate and extent of chalcopyrite leaching significantly. Carbon-zinc batteries contain manganese dioxide and graphite powder. The graphite powder obtained from black paste enhanced the kinetics of chalcopyrite leaching in the presence of MnO_2, indicating that graphite powder play important role in the galvanic interaction between chalcopyrite and MnO_2.

It is widely accepted that on the chalcopyrite leaching in the ferric sulfate solution sulfur layers of extremely low electrical conductivity form on the surface of chalcopyrite by the oxidation of ferric ions. Graphite powder is used to increase the electrical conductivity of the black paste in the carbon-zinc batteries. The graphite powder could improve electron transfer from chalcopyrite to MnO_2, which accelerates the galvanic interaction between them resulting into increasing the kinetics of chalcopyrite leaching.

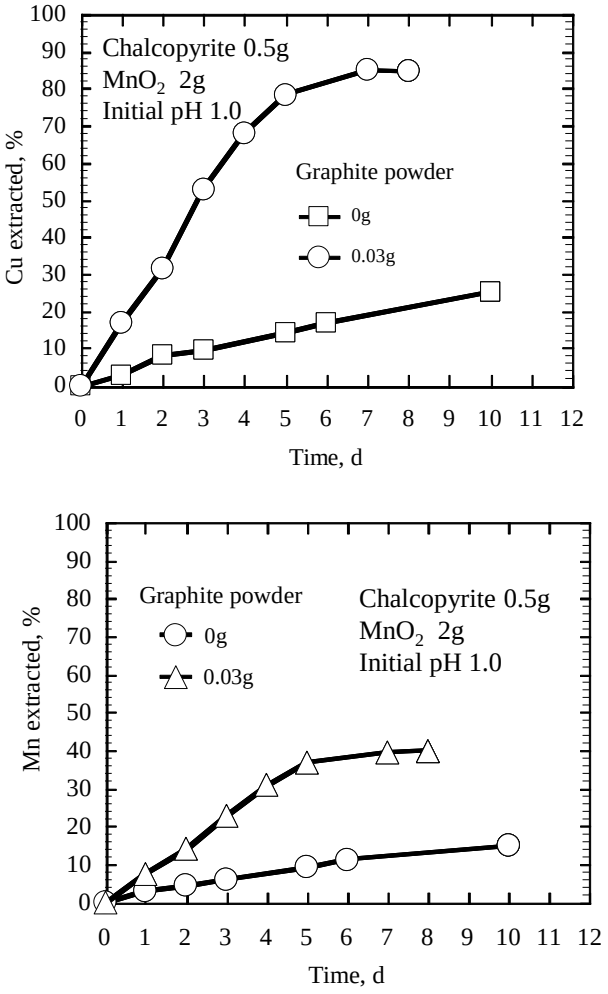

Figure 7. Effect of graphite powder e on the chalcopyrite leaching in the presence

5 CONCLUSIONS

The feasibility of galvanic leaching of chalcopyrite was examined using MnO_2 and black paste collected from spent carbon-zinc batteries. Black paste accelerated the kinetics of chalcopyrite leaching dramatically. The graphite powder contained in the black paste could smoothen electron transfer between the chalcopyrite and MnO_2 resulting into acceleration of the galvanic leaching of chalcopyrite.

Improvements the Performance of the Sungon Secondary Flotation Circuit

P. Pourghahramani
Mining Engineering Department, Sahand University of Technology, Tabriz, Iran

A.Bagherian
Sungon Copper Mine Complex, Tabriz, Iran

ABSTRACT In this paper the performance of the secondary flotation circuit at Sungon plant was evaluated using several systematic sampling surveys from the plant. The evaluation of cleaner performance indicated that the recovery of molybdenite never exceed of 24.29%. The copper recovery varies from 23.27 to 90.9%. Troubleshooting investigations revealed that the formation of dry and strong froth in cleaner cells is responsible for decreasing dramatically the copper and molybdenum recoveries. By changing operational conditions, the copper and molybdenum recoveries increased by 86.04% and 60.8% which show considerable improvements. Changes in re-cleaner operating conditions increased the recovery of molybdenum from zero to more than 99.4% and molybdenum contents increased from 0.21% to 1.031%. The operation in scavenger was found to be normal and satisfactory at the current state.

Keywords: Secondary flotation, Sungon plant, copper

1 INTRODUCTION

The secondary flotation circuit in the Sungon plant consists of cleaner, re-cleaner and scavenger units for up grading of the rougher concentrate. Recently, a decision was made for molybdenum upgrading because of operating molybdenum plant. Initially, it was planned to produce a copper concentrate with 30% Cu in the secondary flotation circuit [1]. However, due to wide changes in ore properties and operation conditions, the final concentrate grade was declined and in addition the recovery of molybdenum was not satisfied and upgrading molybdenum in newly operated plant faces with difficulties. The objective of this paper is to investigate the performance of the secondary flotation units to achieve to the nominal copper and molybdenum recovery and grade at secondary flotation circuit. For the investigation, several sampling surveys were planned for systematic investigation. In addition, improvements were made to improve the circuit performance.

2 THE SUNGON REGRINDING AND SECONDARY FLOTATION CIRCUIT

The Sungon copper complex is located at the East Aazarbaijan province, in the north-west of Iran. The Sungon mine is an open pit mine of the porphyry copper deposit which is the second largest copper mine in Iran. At this plant, a 3.962x5.791 m regrinding tumbling ball mill with an overflow discharge is used to grind and subsequently liberate locked valuable minerals from an entering feed ground to-300µm using primary and secondary milling processes in a circuit closed with cyclones. The discharge of the regrinding mill is mixed with the rougher and scavenger concentrates and then sent to the secondary cyclones. The discharge of the regrinding mill is named as the regrinding product through the manuscript. The underflow of the secondary cyclones is the regrinding mill feed (Fig. 1). The secondary flotation circuit includes cleaners with two column cells, re-cleaner with one column cell and scavenger with 4 RCS50 cells. The load circulation is shown in Fig.1, wherein cyclones overflow forms

the secondary flotation feed. Cleaners concentrate is upgraded once more by re-cleaner unit and re-cleaner-tail is circulated as cleaner feed for further upgrading. The cleaner tail is also upgraded by scavenger unit and its tail passes into final tail dam and scavenger concentrate is classified, regrinds by regrinding mill and classification units and then is sent to the secondary flotation circuit.

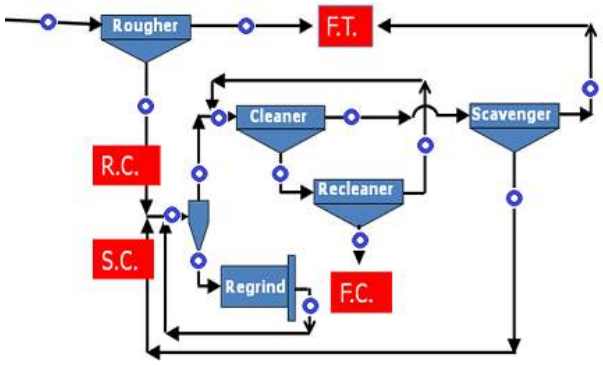

Figure 1. Re-grinding and secondary flotation circuit, Open circles are sampling stations [2].

3 EXPERIMENTAL

The ability to access the complete evaluation of the flotation circuit performance mainly depends on the quality and nature of the collected information from the flotation circuit. To collect a valid and reliable data, flotation circuit was initially investigated to find appropriate stations for sampling.

To get insight into the performance, it was planned to take samples from the streams of cyclone, regrinding mill, rougher, cleaner, re-cleaner as shown in Fig.1 with circles. At the next step, proper sampling cutters were designed and constructed by considering the available geometry in the flotation circuit cutters as shown in Fig. 2.

The sampling duration from the circuit was around 3h in each survey. The gross samples obtained by mixing of increments collected in an equal time intervals. During each sampling survey, 8-10 increments from each sampling station were collected. Dry mass of the samples were determined for each survey and then the percent solid was evaluated. The five sampling surveys were made at various date depending on pending feed into circuit. At each survey, available operation parameters of fresh feed rate (t/h), air flow rate (m^3/h) in flotation cells, pH value in cells,… were collected. Once the representative samples were collected, a number of the samples were dried and weighed for size analysis. The size distribution of the sample was determined using the sieve analysis to-37µm. The size analysis was repeated to insure the measurement reliability.

Figure 2. Sampling cutters for collecting samples from the secondary flotation circuit

4 RESULTS AND DISCUSSION

In the following sections, the performance of three upgrading units in the secondary flotation circuit are explained and discussed.

4.1 The Performance of the Cleaners Units

To evaluate the performance of cleaner unit, five sampling surveys from cleaner streams including its feed, concentrate and tail were taken. Three surveys were made without any changes in circuit operating conditions and the two other surveys were made by changing some operational variables in order to improve its performance. The cleaner feed size distribution is shown in Fig. 3. It is seen that the cleaner feed was finest and coarsest during surveys 5 and 1, respectively. In addition, the fraction -37µm

increases steadily from surveys 1 to 5. In other words, surveys 5 have more slime and fines amount.

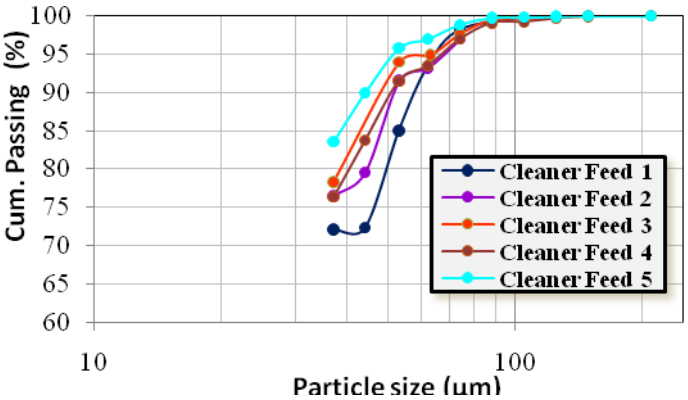

Figure 3. Particle size distribution of cleaner feeds during surveying periods

The operating conditions of cleaners unit are given in Table1. It is obvious that feed solid in survey 1 math the initial design value but during surveys 2 and 3, which is higher than the initial design value. The observation during surveys revealed the formation of dry and strong froth during surveys 2 and 3 as shown in Fig. 4. In these cases, the recovery of froth to concentrate is hindered and the newly floated particles cannot be reached on froth surface. As a result, molybdenite and copper particles losses considerably and passes into tail stream. The situation in surveys 3 was stronger than survey 2.

Table 1. Operating conditions of cleaner during surveys

Operating factor	Initial	S. 1	S. 2	S. 3	S. 4	S. 5
feed rate (t/h)	900	851	929	932	792	855
Feed solid (%)	22.2	22.87	27.41	27.13	23.08	13.7
Tail solid (%)	16.2	15.2	20.76	25.43	20.8	-
Air flow (m^3/h)	180	2*175	2*180	2*181	2*200	2*225
K_{80} of Feed (µm)	40	49.4	44.3	38.4	40.4	34
K_{80} of Tail(µm)	--	55.7	41.8	40.2	--	--

The evaluation of cleaner performance during three initial surveys indicated that the recovery of molybdenite never exceed of 24.29% which approaches zero in survey3 (Table 2). The copper recovery varies from 23.27 to 90.9% wherein the minimum values are attained in surveys 3. Higher performance in surveys 1 could be related to larger size of feed avoiding entrainment, proper percent solid and higher feed grade as a results of re-circulated higher tailing grade. However, by the formation of dry and strong froth during surveys 2 and 3, the copper and molybdenum recoveries decreased dramatically. As expected, the concentrate 1 has higher grade. Higher copper and molybdenum in the tail of surveys 2 and 3 implies the tailing of valuable minerals because of strong and dry froth (Fig. 4). This is while using low flow rate and the formation of higher froth depth in columns.

Figure 4. The formation of dry and strong froth during surveys 2 and 3

To improve the cleaner performance, the air flow increased from 180 to 200 m^3/h and solid in feed declined to the designed value approximately. In addition, fuel oil with 0.25L/min rate was added to cleaner feed tank. As results, the copper and molybdenum recoveries increased to 76.74% and 51.64%, respectively. In addition, the molybdenum content was increased 2.5-4.1 folds compared with previous surveys. Slight increase in copper recovery should be related to the competition between copper and molybdenum mineral particles during attachment step to air bubbles. In addition, being finer feed could be another reason for decreasing concentrate grade. After the initial changes in circuit, the obtained results are satisfying in comparison with the initial design, wherein the production of a copper concentrate with 18.33% Cu content and recovery of 76.91% from a feed with 6.36% Cu is target.

To improve further the circuit performance in survey 5, the air flow rate

was increased to 225 m^3/h and feed solid decreased to 13.7%. In addition, the amount of fuel oil was kept constant similar to survey 4 and A70 frother with 0.05 L/min rate was added in cleaner feed tank. Once the operation stabilized, the sampling was made and the obtained results are summarized in Table 2. The copper concentrate grade increased to 22.02% Cu in spite of finer feed. The copper and molybdenum recoveries calculated by 86.04% and 60.8% implying considerable improvements in comparison with survey 4. Generally, the results proved that the recovery of molybdenum increases as feed solid decreases. This could be probably related to the decrease in pulp viscosity and subsequently increasing local distribution which affect the hydrodynamic behavior of flaky molybdenum particles.

Table 2.The evaluation of cleaner performance through 5 sampling surveys

NO	St	Cu %	Mo%	C/F%	R_{Cu}%	R_{Mo} %
1	F	13.4	0.261	53.5	90.9	18.1
	T	2.6	0.243			
	C	22.7	0.392			
2	F	9.0	0.389	32.5	73.28	24.39
	T	3.6	0.38			
	C	20.4	0.42			
3	F	10.2	0.269	12.8	23.3	--
	T	8.9	0.485			
	C	18.5	0.259			
4	F	5.7	0.396	22.5	76.7	51.6
	T	1.7	0.237			
	C	19.5	1.065			
5	F	8.3	0.446	32.5	86.0	60.9
	T	1.7	0.237			
	C	22.0	1.029			

In general, the imperfection in cleaner units can be ascribed to much more fine feed, the formation of strong and dry froth which hinders the recovery from froth zone to concentrate stream and subsequently the newly floated valuable minerals cannot reach to froth zone surface. In addition, the formation of dry and strong froth on cleaner cell avoids entrainment process and caused to the concentrate grade declines as a result of entering gangue particles into froth zone.

4.2 The Performance of the Re-Cleaner Units

According to the initial plant design, the re-cleaner unit operation with a grade of 18.66% Cu must result in a concentrate having 30% Cu with a recovery of 81.26% and a tail having 7.07% Cu.

The particle size distributions of re-cleaner feed for five sampling surveys are shown in Fig. 5. It is clear that about 76 – 86% of feed is finer than 37 µm depending on surveying time and date. d_{80} of feeds are almost the same, accounting for 37-40 µm and the differences enhanced in fine fractions. Also, the results verify that 96-95% of feeds are finer than 74µm. it is expected that with the mentioned feeds including much more fine fractions, upgrading could not be satisfied because of much more fines particles entrainment.

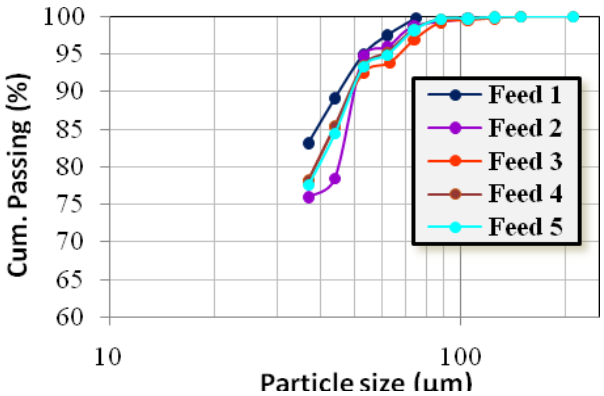

Figure 5. The particle size distributions of re-cleaner feeds

For investigation of re-cleaner performance, the sampling was made simultaneously with cleaner surveys. During three initial surveys, no changes were made in operating conditions. In surveys 4 and 5, only the air flow rate was changed to 180 and 225 m^3/h, respectively. The operating conditions for re-cleaner unit are given in Table 3.

Table 3. Operating conditions of re-cleaner during surveys

Operating factor	Initial	S.1	S. 2	S. 3	S.4	S. 5
Feed rate (t/h)	900	851	929	932	792	855
Air flow rate (m^3/h)	180	167	165	158	180	225
Feed solid (%)	28.6	12.14	17.29	22.8	17.2	19.5
Tail solid (%)	15	7.89	8.58	12.5	9.79	7.42
K_{80} of Feed (µm)	40	37	40.9	38.8	38.7	39.4
K_{80} of Tail(µm)	--	K90=37	K93=37	--	--	--

The obtained results are summarized in Table 4. It is seen that the weight recovery increased significantly by 50.55% which could not be due to the increase of feed grade. No dramatic changes can be observed in concentrates grade as a result of tailing of valuable minerals in tail and entrainment as the tail grade is always higher than the initial design value. The comparison of feed size distribution with tails grade reveals that with increasing feed fineness, the grade in tail stream would be increased. On the other hand, molybdenum recoveries in the three initial surveys approaches to zero but copper recovery is satisfied. It can be concluded that the fine particles spilt into tails and concentrate and flotation is not selective and lowering concentrate grade.

The changes through surveys 3 and 4 improved dramatically the re-cleaner performance especially for molybdenum. Although, the copper grade in concentrate was not increased considerably, the recovery of molybdenum has increased dramatically. As molybdenum recovery increases from zero to more than 99.4% and molybdenum contents increased to 1.23 and 1.031% during surveys 4 and 5, respectively. Increasing molybdenum in final concentrate will certainly improve the processing scheme in subsequent molybdenum beneficiation plant.

Table 4. The evaluation of re-cleaner performance through 5 sampling surveys

4.3 The Performance of the Scavenger Units

Scavenger circuit consists of 4 cells designed for processing of the cleaner tail as feed. The scavenger concentrate sent to regrinding circuits for further grinding and classification and the scavenger tail passes into final tail dam. Based on the initial plant design, for a feed with 1.99% Cu, a concentrate with 7% Cu and a recovery of 87.15% in scavenger should be obtained. Then, the copper lose in tail will be maximum 0.34% Cu content.

For evaluation of scavenger performance, four sampling surveys were made.33.3% of total fuel oil is added in scavenger unit. Fig. 6 represents scavenger feed size distribution during 4 samplings. As seen, Feed 1 is coarser than the other feeds and the finest feed was processed in survey 3. The most difference in size distribution is in fine fractions of feeds. In Survey 3, about 85% of feed is smaller than 37µm which shows an increase of 15% compared to the feed in suvey1.

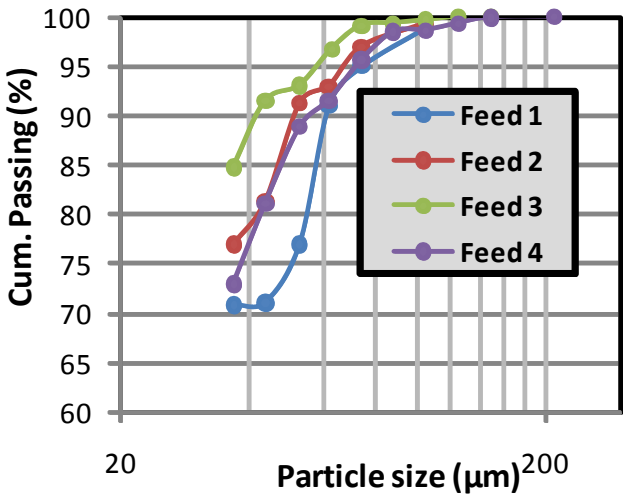

Figure 6. The particle size distributions of Scavenger feeds

The operating conditions during 4 surveys are summerized in Table 5 where the solid in feeds 2 and 4 are more than the others. d80 of feed varies between 35 and 55 µm depending on surveying dates.

Table 5. The operational conditions in scavenger unit in 4 survey

Operating factor	Initial	S.1	S. 2	S. 3	S. 4
Circuit feed rate (t/h)	900	851	929	932	792
Feed solid (%)	16.2	15.2	20.76	25.43	20.8
Tail solid (%)	15.2	14.8	18.25	15.54	19.7
K_{80} of Feed (µm)	40	54.9	41.8	35.4	43
K_{80} of Tail(µm)	--	59.9	45.9	44.5	--
fuel oil (g/t)	--	6.96	7.5	3.46	7.8

The obtained results for scavenger unit are summarized in Table 6. With a first glance, it can be seen that the performance of scavenger unit is satisfied comparing with cleaner and re-cleaner units as the copper recovery varies from 93.13% to 97.05%. The concentrate grade is even higher than the value of initial plant design. A close look on the results indicates that copper grade in scavenger tail 3 is higher than the others. The reason may be related to feed size distribution, higher feed grade and fuel oil consumption wherein more than 85% of feed is finer than 37 µm and the minimum amount of fuel oil is used during this survey. Unexpected increase in weight recovery may be related to much more fine size of feed. On the other hand, the recovery of molybdenum varies between 91% and 92.8% through surveys of 1-3 and the results are much more appreciated. Decreasing molybdenum recovery in survey 4 could be due to low grade feed because of much more recovery of molybdenum in cleaner and re-cleaner units. As a whole, it could be concluded that the scavenger performance is satisfactory and higher losses of valuable minerals in scavenger should be related to much more fines presence in feed. In the situation molybdenum recovery increases, while the copper recovery declines. It is recommended that an increase in air flow rate or using some oily frother in scavenger unit would result higher recovery.

Table 6. The evaluation of scavenger performance through 4 sampling surveys

NO	St	Cu%	Mo%	C/F%	R_{Cu}%	R_{Mo}%
1	F	2.62	0.143	38.61	93.67	91.05
	T	0.27	0.019			
	C	6.35	0.399			
2	F	3.59	0.38	29.55	97.05	91.85
	T	0.15	0.037			
	C	11.79	2.14			
3	F	8.98	0.485	62.10	96.96	92.86
	T	0.72	0.078			
	C	14.02	0.81			
4	F	1.72	0.237	19.23	95.3	77.46
	T	0.1	0.064			
	C	8.52	1.11			

5 IMPROVEMENT IN THE PERFORMANCE OF THE SECONDARY FLOTATION CIRCUIT

The secondary flotation circuit could be summarized as given in Fig. 7. The recovery each unit is given into parentheses with appropriate synonyms.

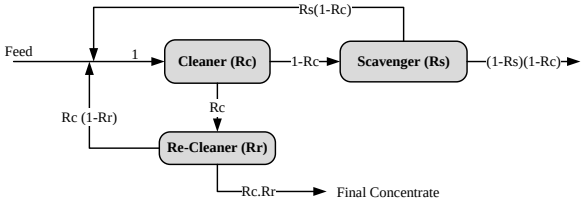

Figure 7.Summarized scheme of the secondary flotation circuit

The total recovery of secondary flotation circuit can be calculated from the equation:

$$R_2 = \frac{Rc \times Rr}{1-[Rc(1-Rr)+Rs(1-Rc)]} \quad (1)$$

Using the above mentioned equation, the total recovery of the secondary flotation circuit was calculated as given in Tables 7 and 8.

Table 7. Overall recovery of copper in the secondary flotation circuit (%)

NO	Rc	Rr	Rs	R2
initial	77	81	87	95
1	91	84	93	99
2	73	80	97	98
3	23	67	96	87
4	77.4	91	95	98
5	86	99	95	99

Table 8. Overall recovery of molybdenum in the secondary flotation circuit (%)

No	Rc	Rr	Rs	R2
1	18	0	91	0
2	24	0	92	0
3	0	0	92	0
4	51	72	77	77
5	61	99	77	87

The results show that the copper recovery is always higher than the initial design value but the final concentrate grade is always lower than the initial design value. The improvement in the secondary flotation circuit performance will be certainly enhanced the overall flotation circuit performance.

6 CONCLUSIONS

It was found that the performance of scavenger unit is satisfied comparing with cleaner and re-cleaner units as the copper recovery varied from 93.13% to 97.05%. The concentrate grade was even higher than the value of initial plant design. The evaluation of cleaner performance indicated that the recovery of molybdenite never exceed of 24.29%. The copper recovery changed from 23.27 to 90.9%. It was found that the formation of dry and strong froth in cleaner cells was responsible for decreasing dramatically the copper and molybdenum recoveries. By changing operational conditions, the copper and molybdenum recoveries calculated by 86.04% and 60.8% which show even considerable improvements. Changes in re-cleaner operating conditions increased the recovery of molybdenum from zero to more than 99.4% and molybdenum contents increased to 1.031%. The operation in scavenger was found to be normal and satisfactory. Generally, by improvement the copper and molybdenum recoveries at the secondary flotation circuit increased to more than 99.4% and 87.29% respectively.

ACKNOWLEDGEMENTS

The authors would like to thank National Iranian Copper Industries Company (N.I.C.I.Co.) and Azarbayjan copper Co. for supporting this research and permission to publish this article. Special Thanks is also extended to the metallurgy and R&D personnel for their continued assistance.

Microstructural Characterization of Pyrite during Mechanical Activation by Using Rietveld and XRD Line Profile Analysis

B.N. Akhgar, P. Pourghahramani
Mining Engineering Faculty, Sahand University of Technology, Tabriz, Iran

ABSTRACT The X-ray diffraction analysis was used for the characterization of structural changes in mechanically activated pyrite. Applying the Rietveld and XRD line profile analysis, comprehensive investigations were carried out to separate the crystallite size and microstrain contributions in peak broadening. The results indicated that no phase transformation occurred in pyrite during mechanical activation. In addition, crystallite size and microstrain decreased and increased, respectively. Also, the lattice parameter of mechanically activated pyrite increased as a function of milling time, implying that pyrite lattice volumes were expanded probably due to vacancy formation. Regarding to shape parameter study, the crystallite size broadening portion is more than the strain broadening portion on the broadened peaks. This may ascribed to the pyrite structure which refined mainly by decreasing crystallite size rather than lattice strain increases. The X-ray amorphization degree increases to about 67% after 100 min intensive milling, reflecting the refractory nature of pyrite.

Keywords: Microstructural characterization, Pyrite, Rietveld and XRD line profile analysis

1 INTRODUCTION

Mechanical activation is a branch of mechanochemistry science with a wide range of potential applications. It has been proved that mechanical activation of minerals can accelerate reactivity of activated minerals in subsequent process such as leaching and adsorption (Akhgar, et al., 2012, Pourghahramani and Akhgar, 2014). These advantages are related to changes in mineral structures such as formation of amorphous phase, grain refinement and lattice strain (Pourghahramani et al., 2008). The mentioned changes are responsible for the reactivity improvement of mechanically activated pyrite.

The mechanical activation pretreatment was employed to improve hydrometallurgical processing of minerals. The obtained results demonstrate that the mechanical activation pretreatment brings about the enhanced dissolution of the minerals due to crystalline disorders and new surface formation (Balaz, 2003; Akhgar et al., 2012). The measurement of crystallite size, lattice strain, amorphization degree and lattice parameter can provide detailed information for behavior prediction of mechanically activated minerals in different process related to its reactivity variations.

Pyrite (FeS_2) as a most common gangue sulfide mineral is associated with valuable minerals in ore deposits. Pyrite hydrometallurgical processing has been studied because of its importance in cyanidation of gold ores (Hu et al., 2002). Regarding to refractory nature of pyrite (Lehmann et al., 2000), improvement of the sulfide mineral reactivity during the hydrometallurgical processing can be a matter of interest. Therefore, mechanical activation would be a promising treatment for the improvement of pyrite reactivity due to extreme structural changes (Hu et al., 2003, 2004, 2007). Also, the used techniques for reactivity promotion of pyrite can give some insight into hydrometallurgical treatments of other sulfide minerals.

The X-ray diffraction (XRD) analysis as an indirect and non-destructive method can provide valuable information about structural changes in mechanically activated

minerals. The microstructural analysis is based on XRD peak broadening reflecting imperfections in the crystal structure. The peak broadening subdivided into crystallite size and microstrain portions after the removal of instrumental effects. In present paper, we made an attempt to investigate the structural changes of mechanically activated pyrite using the XRD analysis. Different approaches such as the Rietveld, Williamson-Hall and Warren-Averbach methods were employed for the assessment of the structural characters of mechanically activated pyrite.

2 EXPERIMENTAL

A high purity concentrate was prepared through conventional beneficiation methods. The XRD analysis of the concentrate showed only pyrite reflections corresponding with JCPDS No. 1-1295 (Figure 1).

The XRD analysis was applied for the examination of pyrite, milled samples and the standard sample, LaB6 SRM660a, used for the elimination of instrumental effects (Figures 1 & 2). The X-ray diffraction test was performed by Bruker Axs D8 advanced instrument by applying Cu Kα radiation (λ = 1.5406 Å) at 50 kV and 250 mA in the two theta range of 25–70°. All records were performed using a step size of 0.02 and a counting time of 3 s per step.

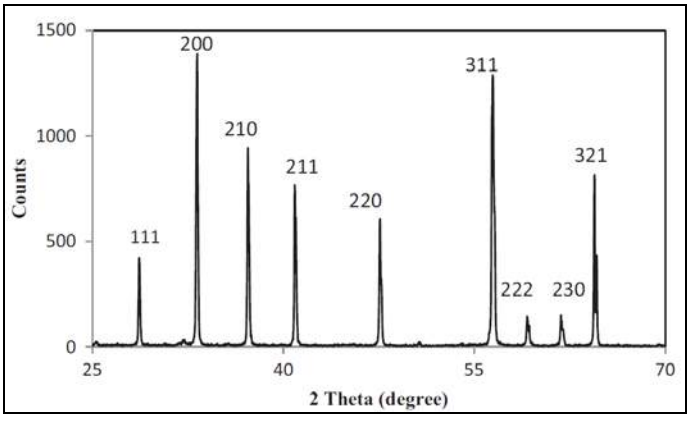

Figure 1. XRD pattern of initial pyrite.

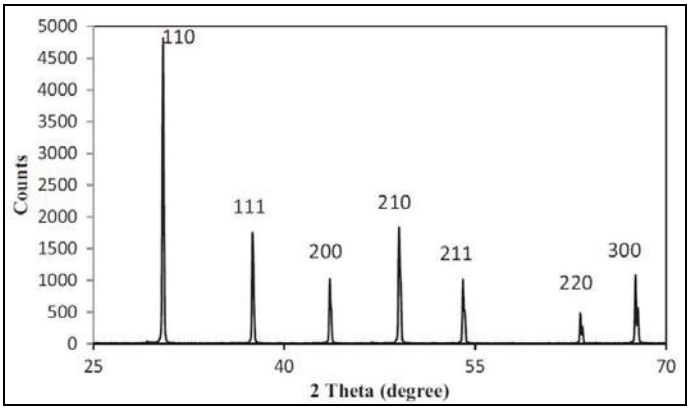

Figure 2. XRD pattern of standard LaB_6 (SRM660a).

The mechanical activation of pyrite was conducted in a planetary ball mill (Pulverisette 6, FRITSCH, Germany) with a 250 ml cup volume and rotation speed of 400 rpm under argon atmosphere to prevent possible chemical reaction. 15 stainless steel balls with a diameter of 20 mm were used for milling by a ball to powder weight ratio of 20:1. The samples were mechanically activated for 20, 50 and 100 min. The obtained powders were kept in sealed condition in a freezer. According to the XRD patterns, no major oxidation phase occurred during sample preparation and mechanical activation (Figure 3).

The Rietveld and Warren-Averbach methods was performed by the X'pert high score plus and Winfit software, respectively.

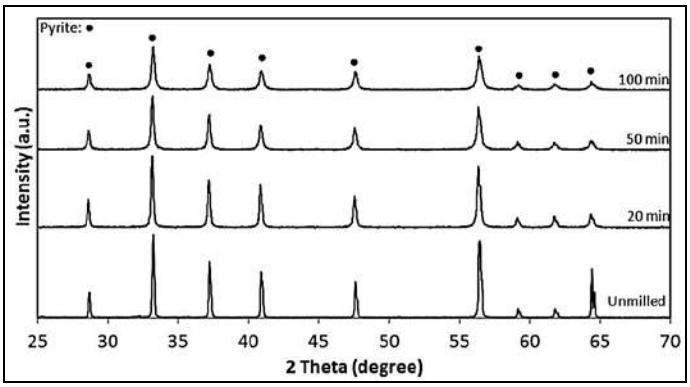

Figure 3. XRD patterns of the initial pyrite and mechanically activated pyrites.

3 RESULT

3.1 X-Ray Diffraction Analysis

The XRD patterns of the initial pyrite and mechanically activated pyrites were matched with the standard XRD pattern of FeS_2 (JCPDS No. 1 -1295) in simple crystallographic arrangement (face-centered cubic, FCC). Additionally, diffraction peak positions shifted toward lower peak positions indicating that the unit cell measures in mechanically activated pyrites were increased.

The lattice parameters of mechanically activated pyrites were calculated by using UnitCell software. The lattice parameter and consequently unit cell volume of pyrite expanded during mechanical activation with increasing milling time (Figure 4). The expansion can be ascribed to the elemental sulfur release during mechanical activation (Hu et al., 2004) forming point defects (vacancies) in pyrite structure. In general, the unit cell volume of pyrite would be larger with more release of elemental sulfur.

Regarding to the XRD patterns of pyrite and milled powders, the broadening increased and the intensity of reflection peaks decreased with milling time (Figure 3). The production of amorphous phase during the mechanical activation can result in the weakening of the intensity of peaks. The X-ray amorphization degree (A) of milled samples was calculated using the four most intensive reflection peaks as defined before (Ohlberg and Strickler, 1962).

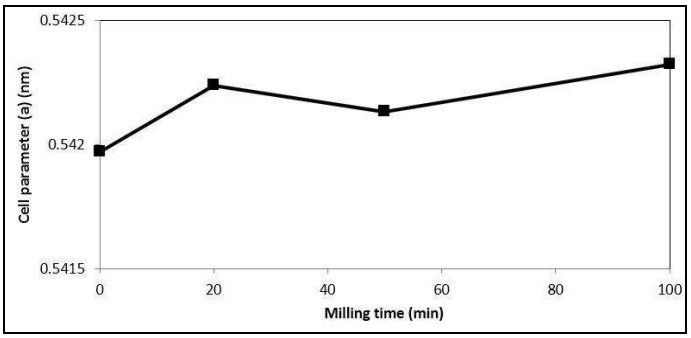

Figure 4. Changes in the lattice parameter of milled pyrite powders.

The X-ray amorphization degree increased more rapidly in the initial stage of mechanical activation and peaked about 67% after 100 min milling (Figure 5). The endurance of crystalline structure of pyrite (more than 30%), even in intensive milling conditions, proved that pyrite has the resistant and refractory structure.

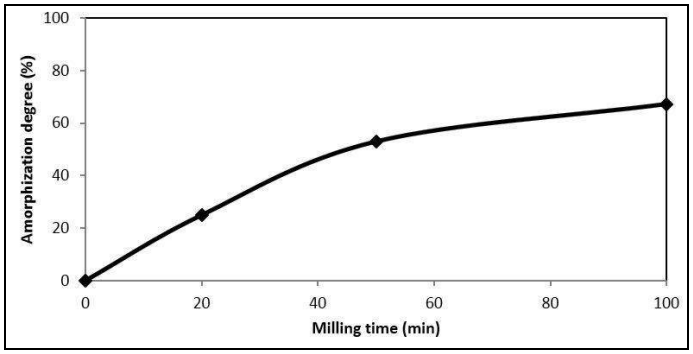

Figure 5. X-ray amorphization degree variations during the mechanical activation of pyrite.

3.2 Microstructure Characterization

The methods of Rietveld, Williamson-Hall and Warren-Averbach were applied to investigate microstructural changes of pyrite during mechanical activation. The Williamson-Hall plot was used to deconvolute the broadening component of crystallite size from microstrain. The results of Williamson-Hall method are summarized in Table 1. The volume weighted crystallite size decreased and microstrain increased with milling time. The obtained results are in line with previous reports (Hu et al., 2004; Li et al., 2008).

The Williamson-Hall curves were obtained by the regression method and all diffraction peaks were involved. The volume weighted crystallite size and microstrain were attained from intercept and slope of Williamson-Hall plots.

Table. 1 The volume weighted crystallite size and microstrain values obtained by using Williamson-Hall method

	Milling time (min)	D_v (nm)	(%)
P1	0	316	0.05
P2	20	182	0.1
P3	50	100	0.141
P4	100	57.73	0.224

The Warren-Averbach method was conducted by the Winfit software and the surface weighted crystallite size and the root mean square strain (RMSS) were computed after profile fitting and removal of instrumental effect (Table 2). The changes observed in surface weighted crystallite size and RMSS using the Warren-Averbach method were the same as the Williamson-Hall method. The surface weighted crystallite size decreased and RMSS increased with the milling time.

Also, regarding to the results, it can be claimed that the surface weighted crystallite size would be smaller than volume weighted crystallite size.

Table 2. The surface weighted crystallite size and RMSS values obtained by using Warren-Averbach method

	Milling time (min)	Ds (nm)	RMSS (%)
P1	0	103.6	0.04
P2	20	53.8	0.085
P3	50	27	0.105
P4	100	25.1	0.117

The obtained crystallite size and microstrain by using Rietveld method are presented in Table 3. It is clear that the parameters variation are similar to the previous results obtained by Williamson- hall and warren-Averbach methods, when crystallite size decreases and microstrain increased in mechanically activated pyrites. The crystallite size gradually decreases to 74 nm in mechanically activated pyrite for P4(100min).

Table 3. The volume weighted crystallite size and microstrain values obtained by using Rietveld method

	Milling time (min)	Dv (nm)	ε (%)
P1	0	763	0.06
P2	20	132	0.08
P3	50	77	0.09
P4	100	74	0.183

Comparison of the crystallite size and strain values obtained from Williamson-Hall and Warren-Averbach methods (Tables 1&2) indicated that the smallest crystallite size and strain were obtained by the Warren-Averbach method. The results clarified that with increasing milling time and the peak broadening, the separation of crystallite size and strain by Williamson-Hall and Warren-Averbach methods would be more different. The comparison also verified that Williamson-Hall method devotes more broadening portion to strain rather than crystallite size in comparison with the Warren-Averbach method.

Shape parameter value were used to determine the broadening portions of crystallite size and microstrain by using a Voigt function with predominant Lorentzian and Gaussian character, respectively (Clearield et al., 2008). An increasing influence of crystallite size portion on the microstructural changes and consequently on the peak broadening results in the shape variations of the fitting profiles from the Gaussian character (shape parameter = 0) to the Lorentzian character (shape parameter = 1). The two most intensive diffraction peaks of (200) and (311) were selected and the mean value of their shape factors was presented (Figure 6). This result clarified that the shape parameter was about zero in the initial pyrite when the crystallite size was not small enough to have a significant influence on peak broadening. The shape parameter increased to about 0.74 in 20 min milled pyrite powders and then peaked at 0.94 after 50 min milling indicating the crystallite size had a more important role than microstrain in the peak broadening of milled pyrite. The shape parameter decreased to 0.77 in 100 min milled pyrite demonstrating that the strain broadening portion increased in comparison to the 50 min milled pyrite. The shape parameter measurements indicated that the strain broadening had less influence on peak broadening and crystallite size portion remained the predominant broadening component during mechanical activation of pyrite.

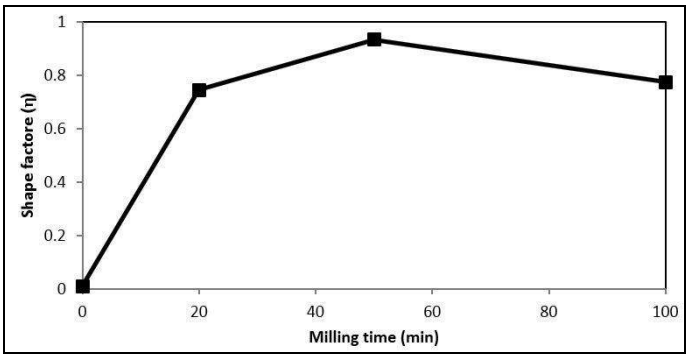

Figure 6. Variations of shape parameter during mechanical activation of pyrite.

As mentioned before, the Williamson-Hall devoted more broadening to strain than crystallite size in comparison with Warren-Averbach. Regarding to obtained shape factors and mentioned fact, the results obtained by Rietveld method which share properly peak broadening to the crystallite size and microstrain can be more reliable than other methods.

4 CONCLUSION

The XRD line profile analysis of the Williamson-Hall and Warren-Averbach methods and Rietveld method were applied to extract microstructural characteristics of mechanically activated pyrite. The conclusions can be as follows;

1. The primary XRD studies confirm that pyrite concentrate has the FCC crystallographic arrangement. The investigation of obtained XRD patterns proved that due to the intensive milling of pyrite, the intensity of diffraction peaks was reduced and the amorphization phenomena occurred. The refractory nature of pyrite was reconfirmed when the XRD amorphization degree of mechanically activated pyrite was 68% after 100 min intensive milling.

2. As expected and all methods proved, the crystallite size decreased and microstrain increased with milling time. The comparison of the obtained result by the methods also proved that Williamson-Hall and Rietveld methods devote more broadening portion to strain rather than crystallite size in comparison with the Warren-Averbach method.

3. Rietveld method which share moderately peak broadening to the crystallite size and microstrain can be more reliable than other methods.

Preparation of Nano Zero-Valent Iron (NZVI) From Mechanochemically Treated Pyrite

B.N. Akhgar, P. Pourghahramani
Mining Engineering Faculty, Sahand University of Technology, Tabriz, Iran

ABSTRACT A new procedure has been proposed to prepare nano zero-valent iron (NZVI) form the sulfide mineral of pyrite by using mechanochemical pretreatment. The XRD analysis indicated that pyrite and iron phases remained after 50 min co-milling of pyrite and iron during mechanochemical treatment and new phase of troilite was formed. The microstructural changes of mechanochemically treated pyrite were investigated by Rietveld method. The mechanochemical treatment reduced crystallite sizes and microstrain measures. Total iron extraction increased from 1% in initial pyrite to 87% in 50 min mechanochemically treated pyrite after leaching by 1M sulfuric acid at ambient temperature. Finally, the NZVI particles were synthesized from the obtained leach liquor through precipitation method by titration of sodium borohydride. The FE-SEM and XRD results indicated that the NZVI was prepared with particles less than 100 nm which are protected by an iron oxide shield.

Keywords: Nano zero-valent iron (NZVI), Mechanochemical pretreatment, Pyrite

1 INTRODUCTION

Nano zero-valent Iron (NZVI) preparation is classified in nanoscale environmental technology due to appreciable capability of NZVI for removing of various contaminants such as chlorinated organic solvent, organochlorine pesticides, organic dyes, various inorganic compounds and metal ions such as Pb (II), As(III), Cu(II) (Yuang-Pang et al., 2006).

Various methods have been used for preparation of nano zero valent iron. In general, most of the methods are based on reduction of ferric or ferrous iron from related aqueous solutions. Among the methods, preparation of NZVI by using sodium borohydride has been described as simplest method wherein titration of sodium borohydride into iron aqueous solutions brought about the reduction of ferric or ferrous ions to zero-valent iron (Zhang, 2003; Karlsson et al., 2005).

There are lots of minerals containing noticeable amount of iron and during hydrometallurgical processing of them, ferrous sulfate solution was produced raising serious environmental concerns (Habashi, 1999). Preparation of NZVI form the iron ferrous sulfate solutions can be interesting matter which has the advantages such as preparation of advanced nano powders of NZVI and provision a solution for disposal problems of the iron sulfate solutions.

The hydrometallurgical treatment of pyrite has been studied for various reasons. The iron sulfate solutions can be obtained during pyrite concentrate leaching and the solutions produced from the gangue mineral of pyrite will be cost-effective. In addition, the leaching of pyrite as refractory mineral can provide more information to improve leaching of other sulfide minerals such as chalcopyrite.

The hydrometallurgical treatment of pyrite is technologically difficult operation for extreme reaction conditions required. The new method of mechanochemical pretreatment is proposed to overcome the problems. The aim of this paper is to prepare zero-valent iron nanoparticles from the leach liquors obtained during pyrite leaching. Also, an attempt was made to increase iron extraction from pyrite during its leaching with sulfuric acid at ambient temperature and pressure by using high-energy ball milling pretreatment.

2 EXPERIMENTAL

2.1 Materials

A high purity concentrate was provided using conventional beneficiation methods. An ore bearing high amount of pyrite mineral as raw sample was crushed and milled manually to a particle size of -100 μm. For the preparation of pyrite concentrate from the mentioned raw sample in laboratory scale, the flotation tests were performed in three steps of rougher, cleaner and recleaner. Then, pyrite concentrate was passed through a wet magnetic separator for further upgrading. Finally, the probable contaminations trapped between pyrite particles were removed by washing. The XRD analysis of pyrite concentrate proved that pyrite reflections corresponded with JCPDS No. 1-1295 (Figure 1).

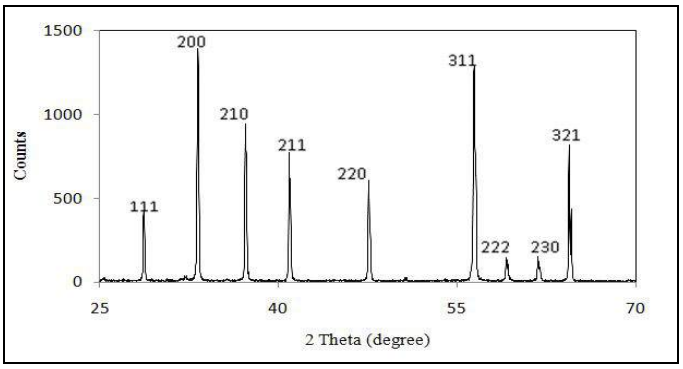

Figure 1.XRD pattern of the initial pyrite.

2.2 Mechanochemical treatment

To reduce disadvantageous impact of high-energy ball milling processes on energy consumption and industrial capacity, the mechanochemical treatment was performed in a short period, less than one hour. Mechanochemical treatment was conducted by a planetary ball mill (Pulverisette 6, FRITSCH, Germany) for 50 min with a rotation speed of 400 rpm under argon atmosphere to prevent probable chemical reactions. 15 stainless steel balls with a diameter of 20 mm were used for milling by a ball to powder weight ratio of 20:1. As initial feed for the planetary ball mill, a mixture of pyrite and iron powder (Merck 3800.1000) was prepared by the stoichiometry ratio presented in following reaction.

$$FeS_2 + Fe \rightarrow 2FeS \quad (1)$$

2.3 Leaching tests

The leaching experiments were carried out in a 500 ml baker reactor by 1M H_2SO_4 solution. According to experimental details (Table 2), the initial feeds of leaching experiments were the natural pyrite and mechanochemically treated pyrite (MCTP) for 50 min. The experiments started with addition of the initial feed and an agitator with 475 rpm stirring speed was used for mechanical agitation. The leaching experiments were performed for 5 h and then the leach liquors were separated from the leach residues.

The final concentrations of extracted iron in the obtained leach liquors were measured by UV spectophotometr (specord 200 plus, analytikjena, Germany).

Obtained leach liquors from 50 min mechanochemically treated pyrite was used for preparation of nano zero-valent iron (NZVI). NZVI can be prepared through reduction of ferric or ferrous iron from their aqueous solutions by using sodium borohydride (Dickinson and Scott, 2010). The preparation of iron nanoparticles was performed by titration of sodium borohydride (Merck, 8.06373.0100) in a flask reactor equipped with a mechanical agitator (500 rpm), as described in previous investigations (Dickinson and Scott, 2010). Then, the precipitated powder was dehydrated using freeze drier for XRD analysis. Figure 2 shows a schematic route of the used techniques for preparation of NZVI from natural pyrite.

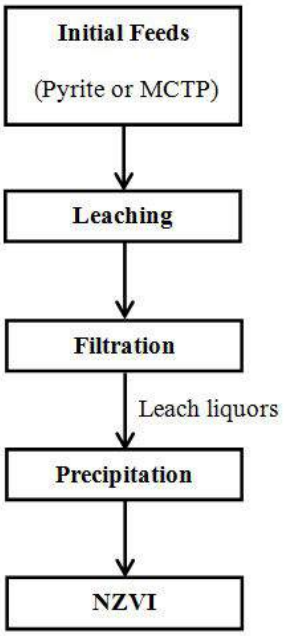

Figure 2. A schematic flow sheet of techniques used.

2.4 Characterization

The X-ray diffraction patterns were collected with Bruker Axs D8 advanced instrument (Germany), applying Cu Kα radiation (λ= 1.5406 Å) at 50 KV and 250 mA in the two theta ranges of 25-70º. The patterns were recorded using a step size of 0.02 and a counting time of 3s per step. Also, investigation of field emission scanning electron microscopy (FE-SEM) was carried out by using a Hitachi S4160 (Japan) instrument.

3 RESULT AND DISCUSSION

3.1 Microstructural changes during mechanochemical treatment

The XRD patterns of mechanochemically treated pyrite are illustrated in in Figures 3 & 4. As seen in Figure 3, the intensity of iron peaks (JCPDS No. 6-0696) decrease by increasing the milling time. The pyrite and Fe peaks remain after 50 min milling and do not disappear. The result reveals that the induced mechanical energy to the mixture of pyrite and iron during mechanochemical treatment cannot provide the sufficient energy for complete reaction between them- even after 50 min intensive milling.

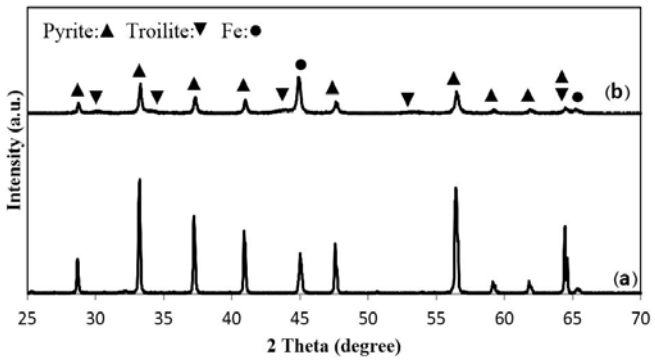

Figure 3. XRD patterns of a) the initial pyrite and b) mechanochemically treated pyrite for 50

According to the Bragg equation (Eq. 2) and lattice parameter equation of cubic systems (Eq. 3), (Suryanarayana and Norton, 1998), the unit cell parameter of the added Fe increases during mechanochemical treatment.

$$n\lambda = 2d\sin\theta \tag{2}$$

$$\frac{1}{a^2} = \frac{h^2 + k^2 + l^2}{d^2} \tag{3}$$

where d is the interplanar spacing, n is known as the order of reflection (n=1, 2, 3 and…) and (h,k,l) are Miller indices of diffracting plan. λ and θ are wavelength and Bragg angle of a defined reflection, respectively and (a) is referred to the unit cell parameter in cubic form. The anchor scan data of XRD patterns reveals that the anchor of iron most intensive peak changes from 45.02 in initial feed (iron and pyrite mixture) to 44.92 in 50 min mechanochemically treated pyrite. The shift of the main peak position toward lower angles during mechanochemical treatment verified that Fe unit cell parameter increased. Point defects created by Fe atoms lost during mechanochemical treatment are responsible for the increase. For more explain, the Point defects can be formed during incomplete mechanochemical reaction between iron and pyrite where the iron atoms leave their position in Fe structure empty to form troilite (FeS- JCPDS No.1-1247) during a mechanochemical treatment with pyrite (Figure 4).

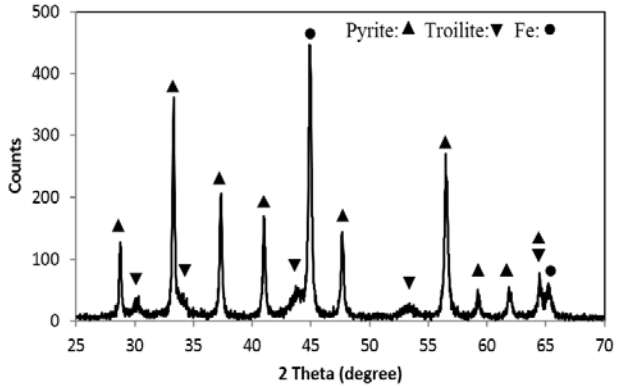

Figure 4.XRD pattern of mechanochemically treated pyrite for 50 min

To begin the structural changes study of mechanochemically treated pyrite, amorphization degree (A) calculated for obtained XRD pattern after 50 min milling as described before (Ohlberg and Strickler, 1962). According to the results (Table 1), the amorphization degree of mechanochemically treated pyrite rises to 83% after 50 min milling. Regarding to the fact that amorphization phenomena is the main reason for the enhancement of pyrite reactivity, mechanochemical treatment can tremendously affect the leachability of pyrite.

Table 1. Microstructural parameters of pyrite and mechanochemically treated pyrite (MCTP).

	pyrite	MCTP
A (%)	0	83
Unit cell volume (Å3)	159.2315	159.5515
Microstrain (%)	0.06	0.052
Crystallite size (nm)	763	57

The unit cell volume of the face-centred cubic pyrite increased by milling time during mechanochemical treatment (Table 1). The results reveal that the unit cell of pyrite expanded during intensive milling. Similar to added iron powder, vacancies were forming in pyrite structure when elemental sulfur was releasing during mechanochemical treatment. The release of elemental sulfur during high-energy milling of pyrite was reported in previous investigations (Hu et al., 2004). Due to the phenomena and the mentioned mechanochemical reaction, the point defects (vacancies) were formed in pyrite structure increasing pyrite unit cell volume.

The mechanochemical treatment effects on crystallite size and microstrain are presented in Table 1. It is clear that crystallite size and microstrain decrease in mechanochemically treated pyrite. The crystallite size decreases from 763 nm in initial pyrite to 57 nm in mechanochemically treated pyrite for 50 min. The results indicated that the structural changes has completely different influences on the pyrite reactivity. The microstrain reduction has a hindering effect on the pyrite reactivity promotion, but the variations of crystallite size and amorphization degree have positive influences on pyrite reactivity improvement.

3.2 Leaching tests

There is no doubt that the most advantageous aspect of high-energy milling of minerals can be reduction of reaction temperature and rise of metal extraction. As mentioned before, the mechanochemical treatment induced structural changes in pyrite with discrepant effects on the reactivity of pyrite by microstrain reduction.

The leaching tests was conducted on pyrite at ambient temperature by 1M sulfuric acid, according to the technique illustrated in Figure 2. Also, the result of leaching tests provide information to evaluate influence of the microstructural reduction during mechanochemical treatment on leachability of pyrite. The results are summarized in Table 2. As expected, the maximum iron extraction was attained by the leaching of mechanochemically treated pyrite for 50 min when 87% of total iron was extracted. It is notable that by consideration of complete digestion of iron powder, the iron extraction from pyrite is about 74% which is much more than 1% in initial pyrite leaching.

The leaching tests confirm that the amorphization degree rise and crystallite size reduction promote iron extraction by reactivity enhancement of mechanochemically treated pyrite and the

microstrain reduction cannot hinder the pyrite reactivity improvement.

Table 2. Iron extraction percentage in leaching of pyrite and mechanochemically treated (MCTP) pyrite

Feeds in leaching tests	Iron extraction (%)
pyrite	1
Pyrite with iron	57
MCTP	87

The results proved that iron addition during mechanochemical treatment has main role in the enhancement of pyrite leachability. The iron addition can impose microstructural changes to pyrite as amorphization degree increases and crystallite size reduces during mechanochemical treatment accelerating pyrite reactivity. In atomic scale, the iron atoms (belong to iron powder) can affect the strength of existed bonds among Fe and S atoms in pyrite structure and make them more weakened. Also, the iron addition can completely destroyed some atomic bonds between constituent elements of pyrite by formation of new troilite phase during mechanochemical treatment. Thus, iron addition and troilite formation during the incomplete mechanochemical reaction are responsible for promoting reactivity of mechanochemically treated pyrite.

3.3 Preparation of nano zero-valent iron (NZI)

As mentioned before, the titration of sodium borohydride technique was used for precipitation of NZVI form obtained leach liquors. For the nano zero-valent iron characterization, images of iron nanoparticles were recorded with FE-SEM and phase identification was conducted using XRD analysis. Figure 5 illustrates the FE-SEM image of the iron nanoparticles in which the representative iron particles size is around 50 nm (x:41, y:53 nm). The image verifies that the most of the particles are less than 100 nm.

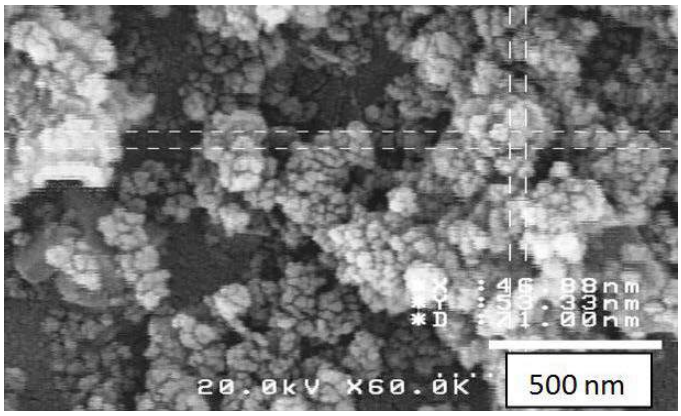

Figure 5. FE-SEM image of aggregations of the zero-valent iron particles nanoparticles

The XRD pattern of the nanosized iron particles is shown in Figure 6. The phase analysis indicates that both iron (JCPDS No. 6-696) and iron oxide (JCPDS No. 25-1402) phases are detectable in the final product. The detected phase of iron oxide can be ascribed to the preparation and maintenance conditions where oxygen was not removed completely. The iron oxide can be considered as a protective shield for the zero-valent iron particles improving their performance (Yuang-Pang et al., 2006). The aim of our paper is far from comprehensive characterization of the iron nanoparticles.

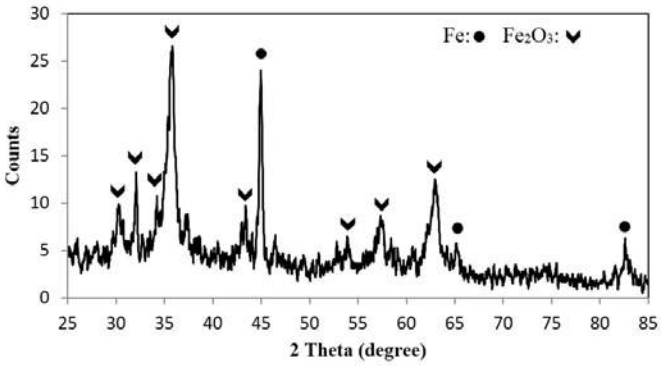

Figure 6.XRD pattern of the zero-valent iron nanoparticles

4 CONCLUSION

The main achievements of this paper are as follow. The mechanochemical treatment can improve reactivity of pyrite during leaching test with 1M sulfuric acid at ambient temperature. The NZVI is prepared from leach liquors produced during hydrometallurgical processing of pyrite.

Also, the following conclusions can be concluded from the obtained results.

1- XRD patterns indicated that during mechanochemical treatment, new phase of troilite is detected along with previous phases of iron and pyrite.

2- Unit cell volume of pyrite and added Fe increased during mechanochemical treatment by formation of vacancies.

3- It was also proved that the crystallite size reduced and amorphization degree increased during mechanochemical treatment of pyrite in favor of reactivity promotion.

4- The iron extraction from pyrite was about 1 % after 5 h leaching at ambient temperature by 1M sulfuric acid. By using mechanochemical pretreatment, the iron extraction increased to 87 %.

5- Finally, NZVI particles were prepared from obtained leach liquors. According to FE-SEM image, the particle size of the NZVI was less than 100 nm. Also, the XRD analysis proved that the NZVI powders were protected by an iron oxide shield.

Recovery of Indium From Zinc Oxide Flue Dust

Wei Liu, Honglin Luo, Wenqing Qin, Yongxing Zheng, Kang Yang, Junwei Han
School of Minerals Processing and Bioengineering, Central South University, Changsha, Hunan, China

ABSTRACT The main purpose of this study was to extract indium from the zinc oxide flue dust (ZOFD), which contained 753 g/t indium. Two-stage leaching process to recover indium from the ZOFD was investigated. The conditions for neutral leaching were optimized at 60 °C for a leaching duration of 30 min with sulfuric acid concentration of 0.16 M and a liquid/ solid ratio of 10 mL/g. In the neutral leaching, zinc (> 95%) was selectively leached into the solution and indium (> 95%) was concentrated in the residue, which indicated the successful selective separation of zinc and indium. The dissolution rate of indium was more than 88% under the leaching conditions: temperature of 80 °C, sulfuric acid concentration of 0.8 M, liquid/solid ratio of 6 mL/g and reaction time of 2 h. The conditions in extraction of indium by di(2-ethylhexly)-phosphoric acid (D2EHPA) were optimized that organic phase: 20% D2EHPA and 80% kerosene, aqueous phase/oil phase ratio (A/O): 4 and initial acid concentration of the aqueous solution: 1-1.5 M, the fraction of extracted indium from solution was more than 95%, which is a significantly increase compared with less than 70% in traditional process. This work would contribute to provide a novel cleaning and efficiently process to separate and recover zinc and indium from zinc oxide flue dust, and prevent heavy metal pollution.

Keywords: Indium, zinc oxide flue dust, leaching, solvent extraction

1 INTRODUCTION

Indium is a rare and valuable metal, which is used mainly as indium tin oxide-films (84% in 2007) in liquid crystal displays (LCDs) (Alfantazi and Moskalyk, 2003; He et al., 2014; Kang et al., 2011; Virolainen et al., 2011). These indium tin oxide (ITO) films are composed of 90% of In_2O_3 and 10% of SnO_2. New types of solar panels containing indium are being developed and they may become an important application sector for indium in the future potentially increasing the demand for indium. However, indium represents a very minor percentage of the earth's crust, which is about 0.1 part per million, and does not occur in the native state. Sphalerite is the main mineral source for the zinc and indium production (Alfantazi and Moskalyk, 2003; Koleini et al., 2010; Lu et al., 2014; Zhang et al., 2010). So indium has to be recovered as a byproduct from other metallurgical processes, especially for the Zn-bearing byproduct, or from secondary raw materials.The typically traditional process for extracting indium from In-Zn concentrates includes the following steps (Alfantazi and Moskalyk, 2003; Koleini et al., 2010; Li et al., 2010; Zhang et al., 2010). Firstly, ferric is removed by the method of jarosite, and indium goes into jarosite. In order to recovery indium, jarosite residue is dissolved using hot sulfuric acid solution. In this method, indium is directly extracted from leach solution by di-(2-ethylhexyl) phosphoric acid (D2EHPA)(Batchu et al., 2014; Darvishi et al., 2007; Haghshenas Fatmehsari et al., 2009; Kang et al., 2011; Virolainen et al., 2011). Generally, in this method the leach solution to solvent extraction process is contained relatively high concentrations of indium. The

recovery ratio of indium is low in this method, and serious pollutions are produced, such as low concentrate of sulfur dioxide and large quantity of ferric oxide residues.

Therefore, the purpose of the present study was to explore the new process (Fig.1) for recovering indium from zinc oxide flue dust. In this two stages leaching process, it was tried to firstly enrich indium by pre-leaching zinc and acidic leaching indium and then use solvent extraction with D2EHPA as an extractant to separate and concentrate indium from its acidic solutions.

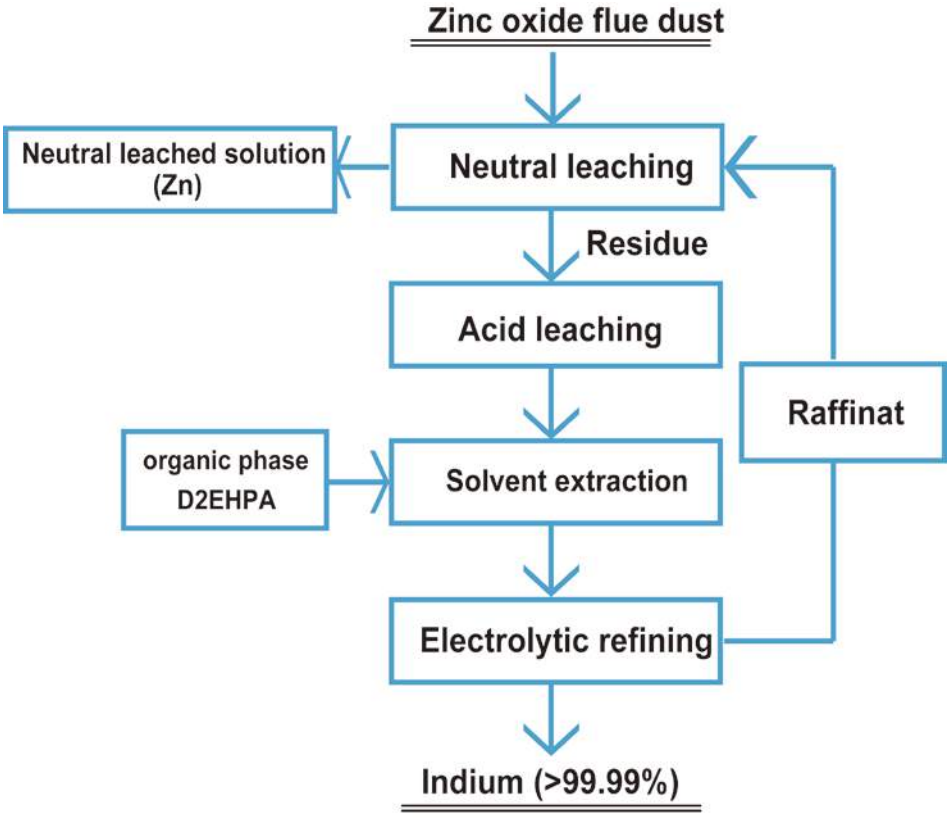

Figure 1. Schematic two-stages leaching flow diagram to recover indium.

2 MATERIALS AND METHODS

2.1 Materials

The zinc oxide flue dust used in the research was produced at the lead smelting Co.'s (Henan, China). The main metals in the flue dust are lead and zinc with some cadmium and indium (Table 1).The commercial D2EHPA (Henan, China) and the diluents, kerosene (Hunan, China), were used in the solvent extraction experiments. Analytical grade sulfuric acid and sodium hydroxide (Hunan, China) were employed in the leaching and solvent extraction

Table 1. Chemical compositions of zinc oxide flue dust (mass fraction,%)

F	Na	S	Cl	K	Fe	Cu	Zn	Cd	In/g·t^{-1}	Sn	Pb	Bi
0.603	5.159	5.095	34.029	7.948	0.648	0.058	15.596	0.349	753.408	0.41	20.255	0.392

2.2 Analytical Techniques

The X-Ray Diffraction (XRD) and Scanning Electron Microscope (SEM) of the flue dust are shown in Fig. 2, and Fig.3, respectively. These analyses indicate that the raw material was primarily zinc and lead compounds, such as ZnO, PbS and ZnS, and have a small particle size. The metals (Fe, Zn, Cd and In) concentrations in solid samples were analysed by means of the oxidation-reduction titration with EDTA and aqueous samples were determined by Inductively Coupled Plasma-Atomic Emission Spectrometry (ICP-AES).

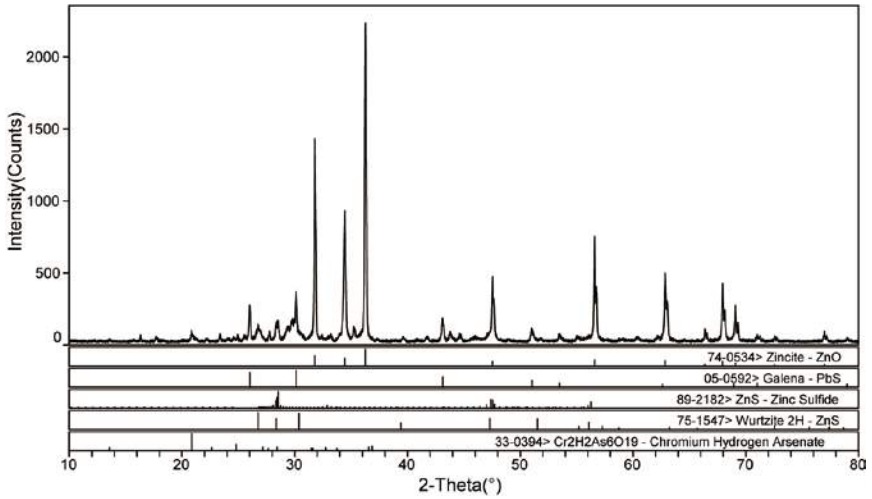

Figure 2. XRD of zinc flue dust

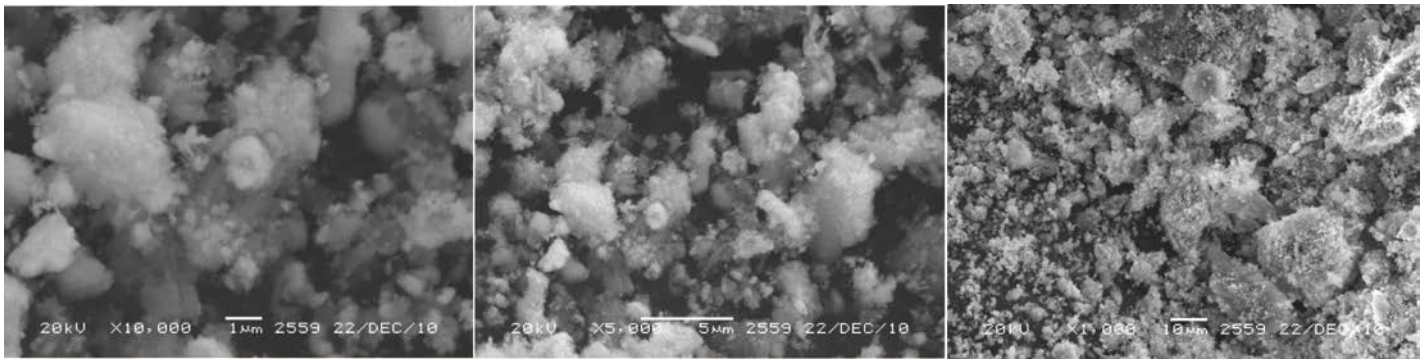

Figure 3 SEM micrographs of zinc oxide flue dust.

2.3.Leaching and Dissolution

For the study of the leaching of zinc oxide flue dust, the dissolution experiments were carried out in a 1 L glass flask reactor in thermostatically controlled water bath, equipped with mechanical stirrer and thermometer. The temperature could be controlled within ±0.1°C. Deionized water and sulfuric acid or sodium hydroxide were used to prepare the leach solutions when the temperature reached the pre-set value. Experiments were carried out at stirring speeds of 500 rpm. The leached residues were withdrawn after various times. In these experiments, the effects of reaction temperature, liquid/solid ratio, sulfuric acid concentration and reaction time were considered. The second leaching stage feed was the neutral leached residue.

The fractions of leaching extraction E_L is defined as follows:

E_L=

where

c_0=initial concentration of the metal in zinc oxide flue dust, %

W_0=initial weight of the zinc oxide flue dust added of the leach solution, g

c=concentration of the metal in the leached residue, %

W=weight of the leached residue, g

2.4. Solvent Extraction

A batch of experiments was carried out in a flask containing equal volumes (100 ml) of aqueous and organic solutions. The mixture was agitated at a constant temperature with a mechanical shaker for 10 min. Samples were then retained in the flask for 2 hours to allow complete separation of the phases through a separation funnel.

The effects of organic phase composition, aqueous phase/oil phase ratio (A/O), and the initial acid concentration of the aqueous solution were considered.

The fraction of solvent extraction E_E is defined as follows:

E_E=

where

c_0=initial concentration of the metal in aqueous phase, mg/L.

c_{aq}=equilibrium concentration of the metal in aqueous phase, mg/L.

3 RESULTS AND DISCUSSION

3.1. Leaching and Dissolution

3.1.1. Neutral leaching

3.1.1.1. Effect of temperature

The effect of reaction temperature from 30 to 80 °C on the extraction rate was studied while other conditions were constant. The extraction rate of zinc was partly dependent on temperature (Fig.4). Notably, the leaching efficiencies of zinc were higher compared with indium. At above 60 °C, 90% of zinc was leached into the solution. In the following neutral leaching experiments, the solution temperature was chosen to be 60 °C.

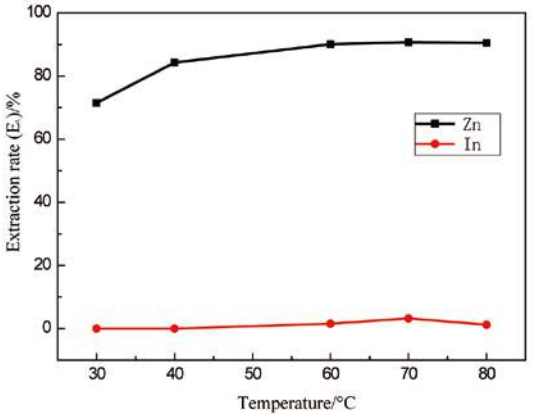

Figure 4. Effect of temperature on zinc extraction and indium extraction in neutral leaching (0.16 M H_2SO_4; liquid/solid ratio: 10mL/ g; reaction time: 2h).

3.1.1.2. Effect of liquid/solid ratio

The effect of the liquid/solid ratio from 5 to 15 mL/g on the extraction rate was studied when other conditions were constant. The extraction rate of zinc was strongly dependent on the liquid/solid ratio (Fig.5). At the ratio of 5 mL/g, about 45% of zinc was extracted, and 90% was extracted at 10 mL/g. At above 10 mL/g, the extraction rate of zinc was slightly higher, but that of indium notably increased, probably because the leaching efficiencies of zinc and indium were improved as the liquid/solid ratio increased. The optimal result was obtained at the liquid/solid ratio of 10 mL/g.

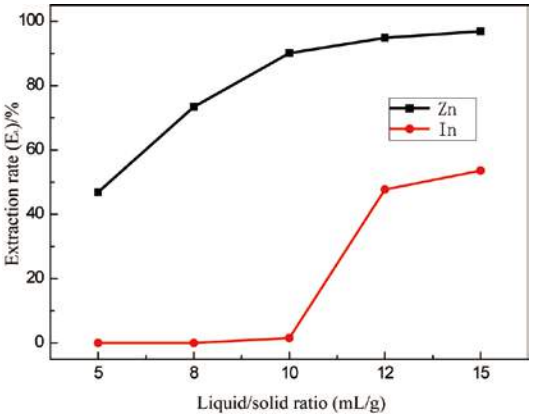

Figure 5. Effect of liquid/solid ratio on zinc extraction and indium extraction in neutral leaching (0.16 M H_2SO_4; 60 °C; reaction time: 2h).

3.1.1.3. Effect of sulfuric acid concentration

The effect of H_2SO_4 concentration (0.1, 0.13, 0.16, 0.19, and 0.22 M) on the dissolution of ZOFD was investigated. The H_2SO_4 concentration strongly affected the leaching rate (Fig.6). The leaching efficiencies of zinc and indium were improved as the H_2SO_4 concentration increased. The zinc extraction increased to 90%, when the concentration of H_2SO_4 was 0.16 M. However, the indium extraction was promoted with the increased concentration of H_2SO_4.

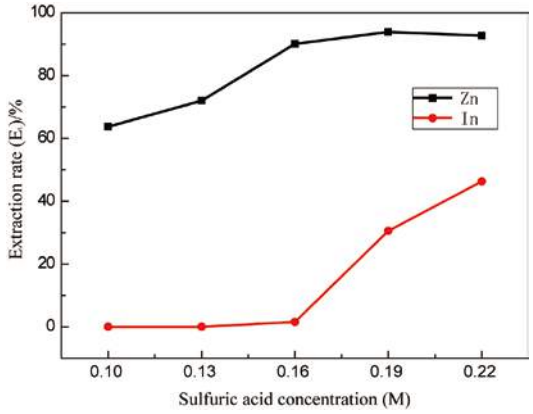

Figure 7.a Effect of the sulfuric acid concentration on zinc extraction and indium extraction in neutral leaching (60 °C; reaction time: 2 h; liquid/solid ratio: 10 mL/g).

3.1.1.4. Effect of reaction time

The effect of reaction time (0.5, 1, 1.5, 2, 2.5 and 3 h) on the dissolution of ZOFD was studied. The zinc extraction was slightly improved with time, and the indium extraction was nearly 0 when the reaction time was 3 h (Fig.7), indicating that the leaching efficiencies of zinc were high and the indium was not leached in these conditions. Considering the economy, the optimal result was obtained at the reaction time of 30 min. Under the optimal condition, the concentrations of zinc and indium were 75.05 g/L and 12 mg/L in the solution, respectively. In the industrial process, such solution can recover zinc through synthesis of zinc carbonate ($ZnCO_3$).

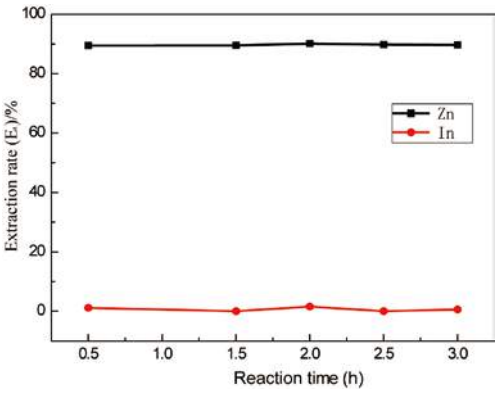

Figure 7.b Effect of the reaction time on zinc extraction and indium extraction in neutral leaching (60 °C; 0.16 M sulfuric acid; liquid/solid ratio of 10 mL/g).

3.1.2. Acid leaching

The acid leaching materials were the residue from the first leaching stage. Table 2 shows the chemical compositions. In the first leaching stage, zinc was selectively leached into the solution and indium was concentrated in the residue.

Table 2. Chemical composition of the residue from the first leaching stage (mass fraction, %)

S	Fe	Zn	In/g·t^{-1}	Pb
7.21	4.32	1.36	1254	32.51

3.1.2.1. Effect of temperature

The effect of reaction temperature from 30 to 90 °C on the extraction rate was studied while other conditions were constant. Notably, the leaching extractions of zinc and indium were high within this temperature range (Fig.8). At 80 °C, about 80% of indium was leached into the solution. In the following acid leaching experiments, the solution temperature was chosen to be 80 °C.

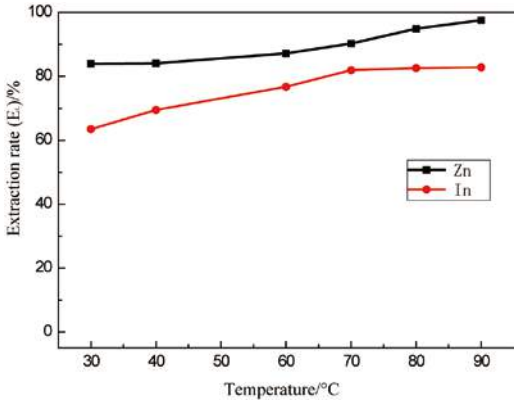

Figure 8. Effect of temperature on zinc extraction and indium extraction in acid leaching (0.7 M H_2SO_4; liquid/solid ratio: 4mL/ g; reaction time: 2h).

3.1.2.2. Effect of liquid/solid ratio

The effect of the liquid/solid ratio from 3 to 7 mL/g on the extraction rate was studied while other conditions were constant. The extraction rate of indium was improved with the increased liquid/solid ratio (Fig.9). At the ratio of 3 mL/g, only 60% of indium was extracted into the solution, but it was promoted to 80% at 6 mL/g. Above 6 mL/g, the extraction rate of indium was slightly higher. The optimal result was obtained at the liquid/solid ratio of 6 mL/g

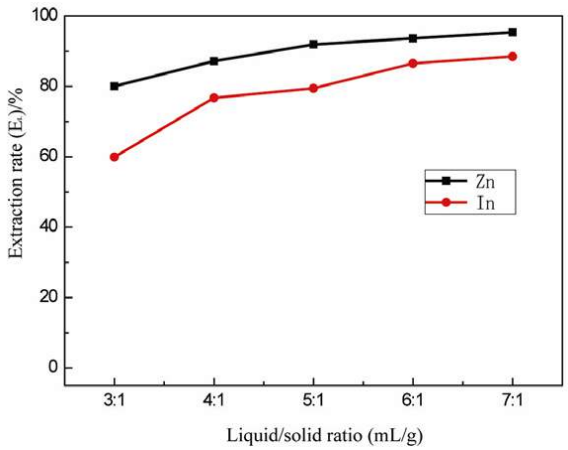

Figure 9. Effect of liquid/solid ratio on zinc extraction and indium extraction in acid leaching (0.7 M H_2SO_4; reaction temperature: 80 °C; reaction time: 2h).

3.1.2.3. Effect of sulfuric acid concentration

To investigate the influence of H_2SO_4 concentration on the dissolution of neutral leached residue, the experiments were carried out using solutions containing different initial H_2SO_4 concentrations (0.5, 0.6, 0.7, 0.8, and 0.9 M). The H_2SO_4 concentration strongly affected the indium extraction (Fig.10). The indium extraction was 80% for 0.8 M H_2SO_4.

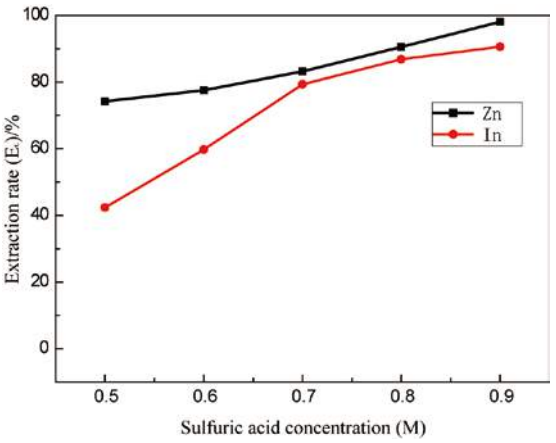

Figure 10. Effect of the sulfuric acid concentration on zinc extraction and indium extraction in acid leaching (80 °C; reaction time: 2 h; liquid/solid ratio: 6 mL/g).

3.1.2.4. Effect of reaction time

The effect of reaction time (0.5, 1, 1.5, 2, and 2.5 h) on the dissolution of neutral leached residue studied was studied. The indium extraction was improved with the extension of time (Fig. 11). After 2 h of agitated leaching,
88.65% of indium was extracted into the solution, and the solution contained 0.3 M H_2SO_4, 560 mg/L indium, 3.55 g/L zinc and 12.21 g/L iron, and the acid leached residue contained 191 g/t indium.

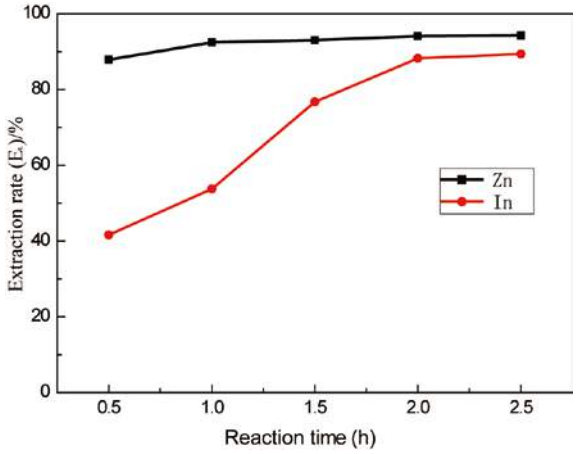

Figure 11. Effect of reaction time on zinc extraction and indium extraction in acid leaching (80 °C; 0.8 M sulfuric acid concentration; liquid/solid ratio 6 mL/g).

3.2 Solvent Extraction

The solution from the acid leaching extracted indium through solvent extraction with D2EHPA, and the selective extraction of indium was much higher at high acid concentration. The divalent heavy metal ions, such as Zn^{2+}, Cd^{2+} and Fe^{2+}, extracted by D2EHPA should be at a low acid concentration. However, the solvent extraction behavior of impurity ion, Fe^{3+} was the same as indium ion when D2EHPA was used. The aqueous solution was first purified to remove Fe^{3+} by addition of iron power, and Fe^{3+} was detected using potassium rhodanide.

3.2.1 Effect of the component of organic phase

In the D2EHPA-kerosene system, the D2EHPA concentration varied from 5 to 30 vol.% in the organic phase. The extraction percentage of indium was improved with the increased D2EHPA concentration (Fig.12). The extraction percentage was improved from 85% at 5% D2EHPA to more than 93% at 20% D2EHPA. However, the density of organic phase was intensified with the increased D2EHPA concentration, and the phases could not be separated within short time. Considering the economy and efficiency, the optimal result was obtained for the components of organic phase: 20% D2EHPA and 80% kerosene.

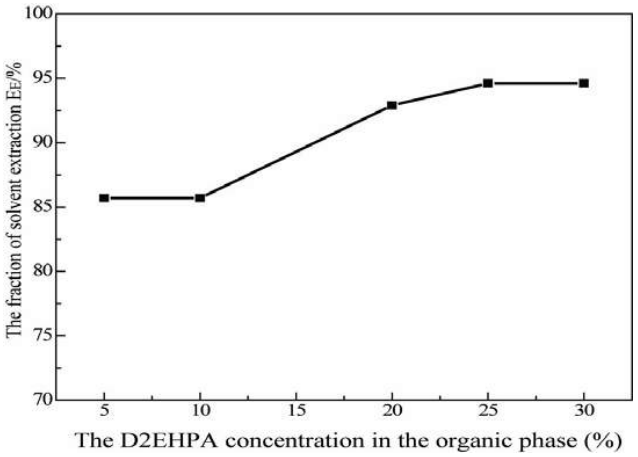

Figure 12. Effect of the D2EHPA concentration in the organic phase on indium solvent extraction (A/O:6; initial concentration of acid in aqueous phase: 1.2 M).

3.2.2 Effect of the volume phase

The effect of A/O (2, 4, 6 and 8) at the same condition was studied. The extraction percentage of indium was improved along with the increased A/O (Fig. 13). At A/O=8, about 80% of indium was extracted into the organic phase, and the extraction percentage was improved to more than 95% at A/O=2 or 4. However, the concentration of indium in the organic phase was low, and phase separation time was long when A/O=2. The following solvent extraction experiments were carried at A/O=4.

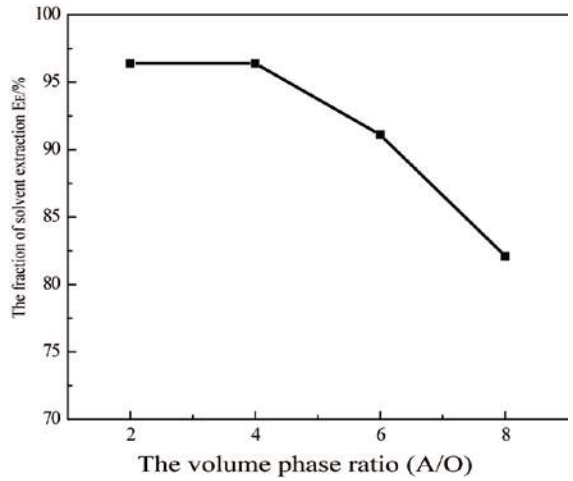

Figure 13. Effect of the volume phase ratio on indium solvent extraction (organic phase: 20% D2EHPA and 80% kerosene; initial concentration of acid in aqueous phase: 1.2 M).

3.2.3 Effect of the initial acid concentration

The effect of the initial acid concentration in the aqueous solution to the indium extraction was studied. The indium solvent extraction mechanism can be simplified as:

$$In^{3+}+3[H_2A_2]_0 \rightarrow [InA_3 \cdot 3HA]_0+3H^+$$

(where A is D2EHPA)

H^+ was released from the indium solvent extraction with D2EHPA. The decreased initial acid concentration in the aqueous solution could improve the extraction process. However, the impurity ions were hydrolyzed when the acid concentration decreased to a certain degree, which made the solution emulsifiable and the phases inseparable.

The extraction percentage of indium decreased along with the increased initial acid concentration (Fig.14). With 0.5 mol/L acid, the solution experienced slight emulsion and no obvious delamination. The extraction percentages sharply decreased when the acid concentration increased to more than 2 mol/L. The initial acid concentration should be controlled within the range 1 to 1.5 mol/L in the aqueous phase. Under these optimal conditions, the extraction percentage of indium was 94.6%; the raffinate at pH 2 contained 30 mg/L indium, and it could be used as an acid adjustment in neutral leaching to reduce the discharge of waste water quantity and sulfuric acid amount.

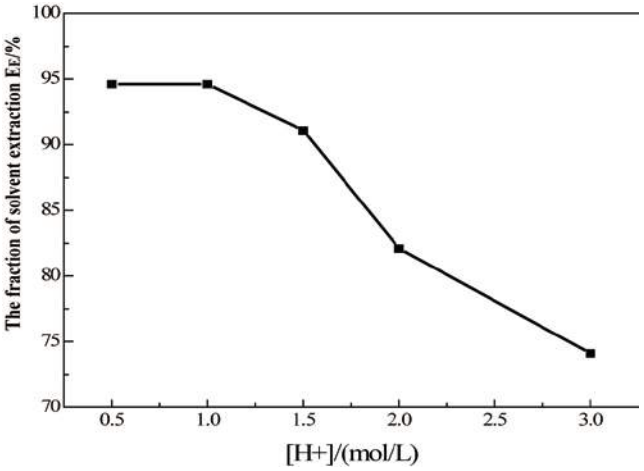

Figure 14. Effect of the initial concentration of acid in the aqueous phase on indium solvent extraction (organic phase: 20% D2EHPA and 80% kerosene; A/O:4).

4. CONCLUSIONS

The zinc oxide flue dust was leached by two stages. In the neutral leaching, zinc was selectively leached into the solution and indium was concentrated in the residue, indicating that the selective separation of zinc and indium was realized. In the acid leaching, indium in the neutral leached residue was efficiently leached into the solution. The dissolution rate of indium was more than 88%. The recovery of indium from the aqueous solution by solvent extraction was investigated, considering the effects of organic phase composition, aqueous phase/oil phase ratio (A/O), and the initial acid concentration of the aqueous solution. The fraction of extracted indium was more than 95%, which is a significantly increase compared with less than 70% in traditional process.

ABSTRACT Electronic wastes are the mixture of various metals such as Cu, Sn, and Pb as well as platinum group metals (Au, Ag, and Pt). The recovering of electronic waste is an important subject not only due to the waste treatment but also for recycling of valuable materials. In the present work, leaching process of Cu, Sn and Pb from electronic wastes was carried out using Fluoroboric acid as the leaching agent. Several factors including concentration of acid, temperature, liquid-solid ratio, and concentration of H_2O_2 as oxidizing agent were statistically studied. The obtained experimental results, showed the optimal condition of the process.

Keywords: Electronic waste; Leaching; Fluoroboric acid, Hydrogen Peroxide

1 INTRODUCTION

Nowadays, electrical/electronic waste reach its alarming growth rate (Ongondo et al., 2011). Currently, the major treatments on such waste are the reuse, remanufacturing, and recycling of them (Cui and Zhang, 2008). Electronic wastes are composed of valuable metals, particularly copper as well as aluminum and gold (Ongondo et al., 2011). Hydrometallurgical process can facilitate the recovery of precious metals from E-wastes (Agrawal et al, 2010). Leaching is the process for extracting soluble constituents from a solid with a solvent in the first step of hydrometallurgical processes (Cui and Zhang, 2008). Various leachants such as nitric acid (Oishi, 2007), hydrochloric acid (Lu and Dreisinger, 2013) and sulfuric acid (Vagili et al, 2003) have been used for the leaching of metallic sources. In the case of copper recovered from nitric and sulphuric acid leaching solution, a significant amount of copper deposit as Cu_2O. Furthermore, in the case of hydrochloric and sulphuric acid solution it was found that $PbCl_2$ Precipitate is formed (Masavetas et al, 2009). Additionally there are some impurities such as silver in chloride solution (Lu and Dreisinger, 2013). A process for E-wastes recovery by leaching and solvent extraction is explored in the present study. This investigation was carried out by using Fluoroboric acid as a leaching agent. The influence of temperature, and solid to liquid were examined with the help of CCD.

2 MATERIALS AND METHODS

2.1. Reagents And Analytical Methods

All chemicals in this experiment were of analytical reagent grade. Water was double

distilled. Hydrogen peroxide, used in this study was purchased from MERCK Company. HBF4 utilized as a leaching agent which was supplied by MERCK Company. Atomic adsorption spectroscopy (Varian, type AA240) for analyzing the concentration of Cu(II) ions was used in the experiments.

3 RESULTS AND DISCUSSION

3.1 Model Fitting

Table 1 lists the values of copper dissolution percentage after 180 minutes of leaching at each of the 28 combination of factor levels generated by the principles of RSM with the values ranging from as low as 0.29 to as high as 0.96. The results of the ANOVA are presented in Table 2; the low P- values for the regression ($P<0.001$) and the fact that the lack of fit of the model was not significant ($P>0.05$) indicates the suitability of the model the value of the regression coefficients are presented in Table 3. Based on regression coefficients calculated for the response (Table 3) a polynomial regression model equation that fitted 90% of the variation in the data was proposed as:

$$\text{Cu recovery} = 66.13 + 4.70\ L/S - 1.57\ T + 6.306\ HBF_4 - 7.31\ (L/S)^2 + 0.07\ T^2 - 9.313\ (HBF_4)^2 + 0.679\ L/S \times T \quad (1)$$

2.2. METHOD

Physical pretreatment was performed by crushing printed circuit boards (PCB) with the aim of changing the wastes to the size less than 1mm. The received solid from crushing treatment was mixed with a certain amount of HBF4 in a stirring reactor accompanied by injection of hydrogen peroxide with known concentration and constant mass flow for 3 hours. Then the solution was sent to the filtering system for solid/liquid separation.

Response surface methodology (RSM) was employed to survey of Temperature, L/S and H_2O_2 volume on copper recovery. A central composite design (CCD) was adopted in this work to study four factors at three levels. Ten experimental runs consisting of 4 star points (star distance is 0) and 2 center points were generated with 4 factors and 3 levels by the principle of RSM using MINITAB Release 15. The CCD matrix conducted which includes the levels employed for the different factors, is presented in Table 1.

Table 1. Central composite design arrangement and response (Cu dissolution).

3.2 Effects of Parameters: Analysis of Response Surfaces

According to equation (1), an increase in L/S values and temperature results in an increase in the Cu recovery at the end of 180 minutes of leaching. In the cases where interaction between factors is statistically significant, surface plots give more complete information regarding the effect of a factor on the response. The curvature of the surface presented in Fig. 1 suggests that L/S × T have interaction with each other in the leaching process. This is further confirmed by the results presented in Table 3.

As it can be seen in Figure 1, the effect of L/S on the Cu dissolution is more significant at high temperature. It was also observed that the excessive accretion of L/S ratio do not have a considerable effect on copper dissolution, after reaching to the optimum point

As it can be seen in Figure 2, the effect of L/S and HBF_4 has an optimum value on the Cu dissolution. An increasing on of L/S and

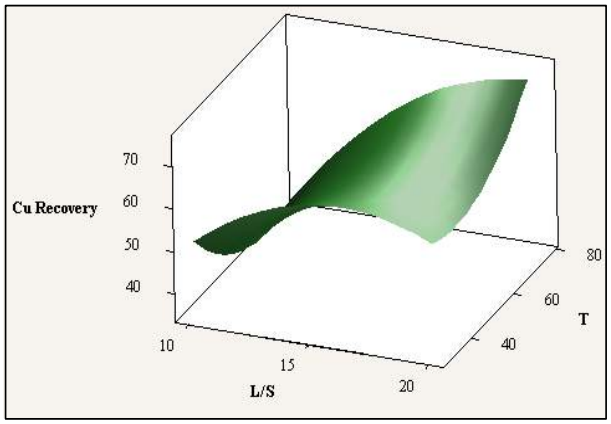

Figure 1. Surface plots for Cu recovery with respect to L/S and T.

HBF_4 increases the copper recovery at the first step and after optimum condition decreases the copper recovery. The surface plot of the effect of temperature and HBF_4 on copper recovery is shown at Fig 3. As seen as in Fig 3, the effect of temperature and HBF_4 on copper recovery show a saddle curve and by increasing of temperature, the copper recovery decreases to obtain a minimum value and then increases by increasing of temperature.

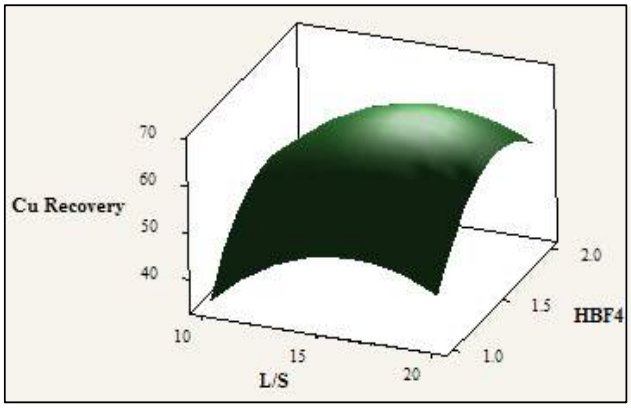

Figure 2. Surface plots for Cu recovery with respect to L/S and HBF_4.

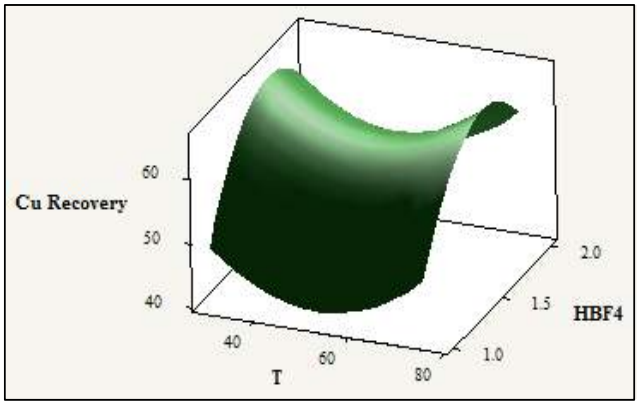

Figure 3. Surface plots for Cu recovery with respect to $HBF_4$and HBF_4.

4 CONLUSION

In this paper, CCD coupled with RSM was used to study the interaction between factors in Cu dissolution process from E-waste leaching by using HBF_4 with the following results:

- According to the statistically developed model, an increase in L/S and T, results in an increase in the Cu dissolution. In addition, it was found that L/S and T have interaction with each other in the E-waste leaching process.
- The effect of L/S on the Cu dissolution is more significant at high Temperature.
- The effect of temperature and HBF_4 on copper recovery shows a saddle behavior.
- -The maximum recovery of Cu that can be achieved after 180 minutes of leaching of WEEE, in a 3 L reactor running at 210 rpm is 0.75 under the following conditions: L/s: 20, Temperature: 70 ^{O}C and HBF_4: 1.62 SR.

ABSTRACT The electronic waste (E-Waste) contains such precious metals as gold, silver, and platinum. In addition to the Platinum group metals, large amounts of copper, tin and lead are present in E-Waste. For an effective recovery of precious metals, it is essential to recover these metals. It is also important from an economic perspective. In this paper, separation of copper from tin and lead by solvent extraction is studied. Fluoroboric acid and LIX984N was used as leachant and organic solvent, respectively. Effective factors such as the concentration of organic solvent, pH, temperature and concentration of copper on the extraction of copper were investigated. Combined and separate extraction curves for Cu, Sn and Pb were plotted using pure reagents. Finally, the optimal condition for the purification was determined**.**

Keywords: Electronic waste, Solvent extraction, LIX984N, Fluoroboric acid

1 INTRODUCTION

Wastes from electrical and electronic equipment (WEEE) are a waste category that is growing rapidly (Jha and Lee, 2006). This fact requires efficient WEEE recycling strategies (Bertram et al., 2002). Furthermore, WEES contains metals with high commercial value, as well as other hazardous or toxic elements. WEEE is regarded as an important source for recovery of valuable metals (Lee et al., 2004). Because of the complex composition of the e-waste, recovery treatment for all metals may not be possible, however precious and valuable metals such as gold, silver, copper, lead, zinc, and tin can be recovered by the hydrometallurgical route (Agrawal et al., 2010). Copper is the major metallic component in the E-wastes; hence a process for selective recovery of copper by leaching and solvent extraction is explored in the present investigation. Several commercially available solvents such as LIX 64, LIX 84, LIX 6022, LIX 860, and LIX 984N is capable of recovering copper by solvent extraction. However, for extraction of copper from chloride solution LIX 984 N shows more promise (Lu and Dreisinger, 2013).

Present study focuses on the recovery of copper from E-waste concentrate by Fluoroboric acid dissolution and selective extraction of copper from leach solution by using LIX 984N as a solvent diluted in the kerosene.

2 MATERIALS AND METHODS

2.1 Reagents and Materials

All chemicals in this experiment were of analytical reagent grade. Water was double distilled. Commercial LIX 984N was provided by Recovery of nonferrous Metals

Company, which was diluted in industrial kerosene after treatment with Sulfuric acid. HBF_4 and ammonia solution 25%, (extra pure, Mojallali chemicals) were used for adjusting the pH value.

2.2 Instruments and Analytical Method

Mettler Toledo precision pH meters, and the atomic adsorption spectroscopy (Varian, type AA240) for analyzing the concentration of Cu (II) ions were used in the experiments.

2.3 Method

Batch experiments were carried out in a flask containing equal volumes (20 mL) of aqueous and organic solutions. Then, the produced mixture was transferred to a 250 mL separation funnel. The two layers were allowed to settle and separate. pH of aqueous layer was measured and the concentration of Cu(II) in an aqueous solution was determined by atomic adsorption spectroscopy.

Agitation was carried out for 30 min to assure equilibrium conditions, even though equilibrium could have been achieved in less than 10 min (Kim & Lee & Jung & Kim & Kim, 2005).

Organic solutions were prepared by diluting different percentages of LIX 984N (10%, 20%, and 30%) in kerosene.

3 RESULTS AND DISCUSSION

3.1 Effect of pH on Extraction of Cu (II)

The extraction was carried out with an aqueous solution of 2g/l Cu(II) and the organic phase containing 20% (v/v) LIX 984N diluted in kerosene at 25ºC. The effect of pH on the extraction of these metals was investigated in the pH range 0.8 – 2.5 using the O/A phase ratio of 1:1. pH and concentration of Cu ions in an aqueous phase was determined.

Figure 1 represents the extraction percent of copper in different pH values. It is evident that the percentage of extraction was increased for extraction of copper with increase in the equilibrium pH, and maximum extraction (~99%) was obtained at equilibrium pH 3.

3.2 Effect of LIX 984N Concentration in the Organic Phase on Extraction of Cu (II)

In this study, for evaluating the effect of the extractant concentration on extraction of copper from the leach liquor at O/A phases ratio 1:1, experiments were conducted with 10%, 20%, and 30% (v/v) LIX 984N in kerosene at 25℃ (Figure 2).

It was observed that the percentage extraction of copper increased at higher LIX values. Consideration high costs and consumption of the organic phase, a 20% (v/v) LIX 984N concentration in kerosene was chosen for all experiments.

3.3 Effect of Temperature

To determine the effect of temperature on the extraction of copper, experiments were performed at three different temperatures (10, 25 and 60 ℃). Figure 3 shows the copper extraction versus pH. As can be seen from Figure 3, the percentage of extraction curve shifted to the left with increasing temperature. It can be concluded that the copper extraction was endothermic process; however extraction rate increases with increasing temperature.

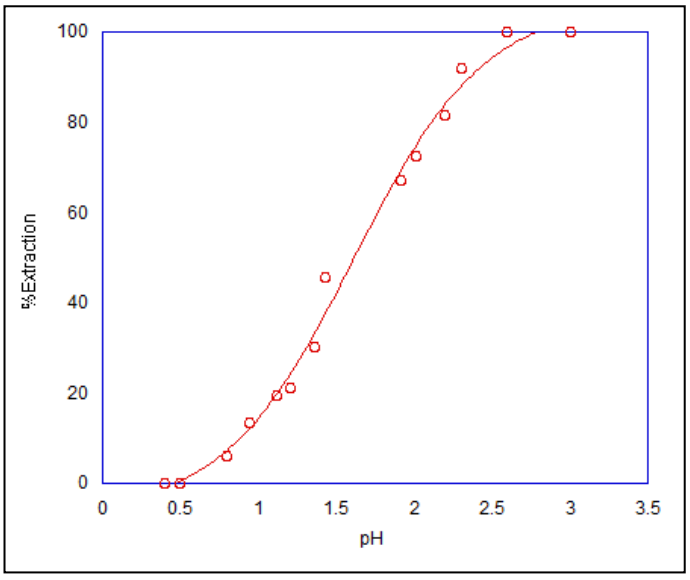

Figure 1. Effect of pH of the HBF_4 on extraction of Cu from leach solution using LIX 20% at 25ºC.

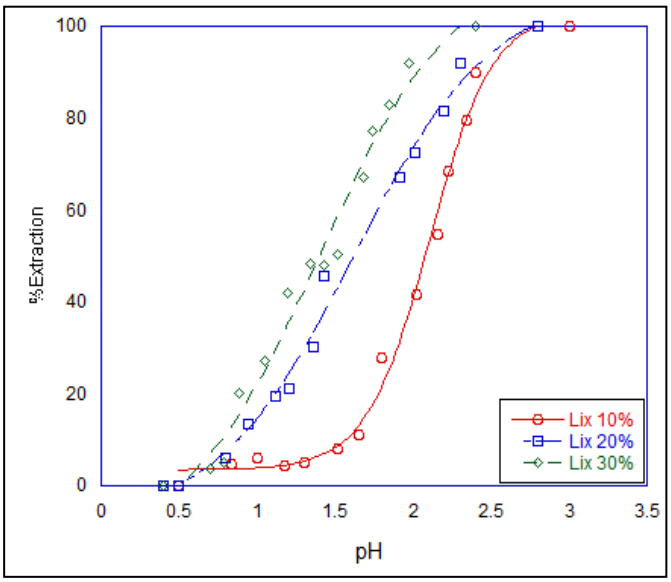

Figure 2. Percentage of extraction of copper from HBF_4 leach solution versus pH in different LIX concentration.

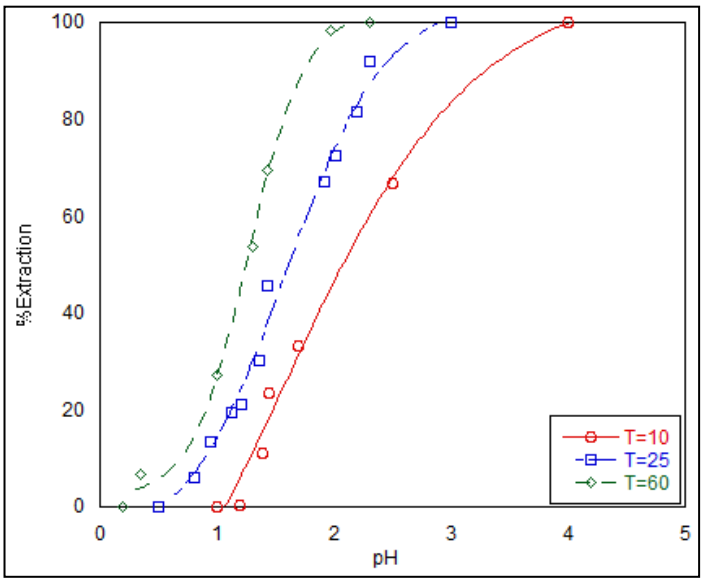

Figure 3. Percentage of extraction of copper from HBF_4 leach solution versus pH in different Temperatures.

4 CONCLUSION

In this paper, different parameters were studied for extraction of copper from an acid medium, such as pH, concentration of the organic phase and temperature. In consideration of cost and overall efficiency, it was shown that the extraction of copper is preferable to be carried out with an organic solution containing 20% (v/v) LIX 984N which was diluted in kerosene, in ambient temperature. The pH-%E curves of extraction showed that the percentage extraction of copper increased with increasing equilibrium pH and extractant concentration**.**

Selective Zinc Recovery From a Valuable Iranian Zinc Plants Residue Using a Facile Selective Alkaline Leaching Method

P. Ashtari, P. Pourghahramani
Mining Engineering Faculty, Sahand University of Technology, Tabriz, Iran

ABSTRACT Large amounts of three different kinds of zinc plants residues are annually generated in Iran. Hot filtercake (known as HFC) is one of them which could be used as a promising secondary resource of zinc, cobalt and manganese. Unfortunately, despite its valuable elements, HFC isn't treated and the most of its hazardous constituents are easily exposed to the environment. For the first time, in this paper, zinc was selectively leached from HFC employing alkaline leaching. Secondly, it was tried to optimize leaching through L16 taguchi experiments design to obtain the maximum recovery of zinc. In addition, the effect of each affecting parameter was studied.

Keywords: Selective zinc recovery, Zinc plant residue, Selective alkaline leaching

1 INTRODUCTION

Zinc is mainly extracted from primary resources. A part of zinc is also obtained from different secondary. Waste materials could be used to recover valuable elements or it may be stock piled. But, stringent environmental regulations concerning waste disposal cause to impose expensive disposing costs. During metallurgical processes, a large amount of several solid wastes including flotation tailings, slags, slimes, filtercakes (filtering residuals), etc. are produced. Nowadays, a proper process is strongly required for zinc production from secondary recourses, especially wastes (Huhtala, 1997; Jha et al., 2001).

In the Iranian hydrometallurgical zinc plants (leach-electrolysis process), a great amount of wastes are often produced. One of them contains Zn, Mn, Ca and Co which known as hot filtercake (HFC). Due to its heavy metals, HFC could harm humans, animals, and plants. Evaluating the impacts of releasing of toxic heavy metals from such waste materials to surface and ground water shows that they can be one of the reasons for particular concern (Altundogan et al., 1998). High metal content in secondary resources could be considered as a good source for supplying Zn, Mn and Co. In this purpose, if a proper process could be developed, the HFC also can be considered as a very important resource for production of such elements (Altundogan et al., 1998).

Metal extraction from metallurgical wastes often requires hydrometallurgical treatment (Rao, 2011). Alkaline leaching has some advantages compared to acidic leaching. Alkaline leaching is usually used to extract valuable metals selectively from secondary resources. Aluminum, zinc and some other amphoteric metals can selectively dissolve in alkaline solution; however, acidic leaching commonly results to collective dissolution with low selectivity. Even though, in some cases, by manipulating the effective parameters, the recovery of undesirable elements in acidic leaching could be controlled, but, solution impurities usually increase (because of high metal content in secondary resources) and purification processes have to be done, inevitably (Gupta and Mukherjee, 1990). A relatively clean and impurity-free leach solution can be obtained by alkaline leaching and the complex purification and impurities removal

processes are avoided. Because of the insolubility of iron, calcium, manganese and cobalt compounds in sodium hydroxide solutions, the main advantage of sodium hydroxide leaching is its good selectivity between those compounds and zinc. Consequently, NaOH leaching could be a suitable leaching procedure for leaching of amphoteric hydroxides or oxides.

The previous studies have implied that the solubility of some specific amphoteric elements in strong caustic alkaline solution decreases in the following sequence Zn > Pb > Al > Cr (III) > Cu. Cr (III), Cu and Cd dissolve negligibly in the presence of zinc and lead. The solubility of lead is decreased provided that the zinc concentration in caustic pregnant solution is almost high (Stafanova and Aromaa, 2012).

So far, many researches have been reported zinc extraction form various secondary resources using acidic leaching (Ahmed et al., 2012; Dvořák and Jandova, 2005; El-Nadi et al., 2007; Ognyanova et al., 2009; Ruşen et al., 2008; Safarzadeh et al., 2009; Sayilgan et al., 2009) and alkaline leaching (Dutra et al., 2006; Moradkhani et al., 2012; Nagib and Inoue, 2000; Shin et al., 2009; Xia and Picklesi, 2000). However, few papers have been devoted for zinc recovery from HFC.

The objective of this study is to investigate the selective leaching of zinc from HFC in the alkaline medium. The main aim was to evaluate the effects of various leaching affecting parameters on zinc dissolution from HFC. Optimization process of the leaching study was conducted according to L16 taguchi experimental design to determine the optimum leaching condition for zinc extraction.

2 MATERIALS AND METHOD

2.1 Materials

The initial hot filtercake (HFC) sample was obtained from ALVAN zinc plant, Zanjan, Iran. In order to remove the trapped pregnant solution resulted in deficient filtering and separate the soluble salts, the as-received wet HFC was first washed with distilled water several times. The pre-treated HFC was dried in the oven at 95 °C 24 h. For leaching experiments, pure NaOH from merck was used.

2.2 Experimental Procedure

The leaching experiments were conducted in a two neck glass reactor of 250 ml volume equipped with a condenser and mechanical stirrer having a digital controller unit and a thermostat which controlled the temperature of the reaction medium within ±0.5 ˚C. Seventy five milliliters NaOH solution at a given concentration was decanted into the reactor. When the desired temperature of the reactor content was reached, a predetermined amount of HFC was added into the solution while the content of the vessel was being stirred at a certain speed. After 30 minutes, the content of the vessel was filtered and the filtered liquor was then analyzed by atomic absorption spectroscopy for Zn, Pb and cadmium (and some other impurities). Experimental parameters and their levels determined in the light of preliminary tests are given in Table 1.

Table 1. Experimental parameters and their levels.

Process parameter	Designation	Level 1	Level 2	Level 3	Level 4
Temperature (°C)	A, T	50	70	90	105
NaOH concentration (M)	B, C_{NaOH}	3	5	7	9
solid to liquid ratio (g/cc)	C, S/L	1/5= 0.2	1/10= 0.1		
stirring speed (rpm)	D, R	500	800		

Based on L16 ($4^2\times2^2$) taguchi fractional orthogonal array (OA) four process factors are considered to determine their best levels in order to optimize the zinc extraction from HFC (ZnE[1]). Two parameters (C_{NaOH} (NaOH concentration) and T (temperature)) in four levels and two parameters (S/L (solid

[1] ZnE is abbreviated form of zinc extraction (%)

weight/solution volume) and R (stirring speed)) in two levels applied in this study are listed in Table 1. For analysis the data obtained, Minitab® 16 Statistical Software was used.

3 RESULTS AND DISCUSSION

3.1 PHFC Characterization

Chemical composition of PHFC is presented in Table 2. Size analysis revealed that the HFC particles are -150 µm.

Table 2. Chemical composition of PHFC.

Element	Zn	Mn	Co	Ca	Pb	Cd	Fe	other
wt. %	10.5	15.4	2.2	7.5	1.4	0.3	2.5	trace

The XRD pattern of PHFC is shown in Fig. 1. As shown, different kinds of hydrous calcium sulfate like gypsum (CaSO4·2H2O) and plaster of pairs (2CaSO4·½H2O) were the major crystalline phases in HFC. Other phases included manganese oxide (MnO2), zincite (ZnO), quartz (SiO2) and cobalt oxide (Co3O4). But, intricate composition of HFC, likewise very fine particles and low degree of crystallinity made phase assessment more difficult.

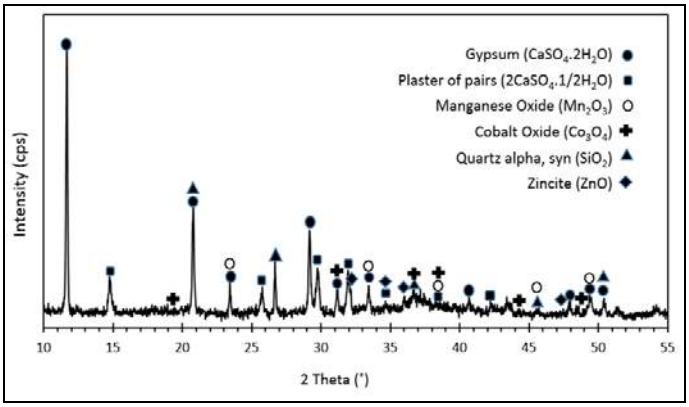

Figure 1. XRD pattern of the HFC sample.

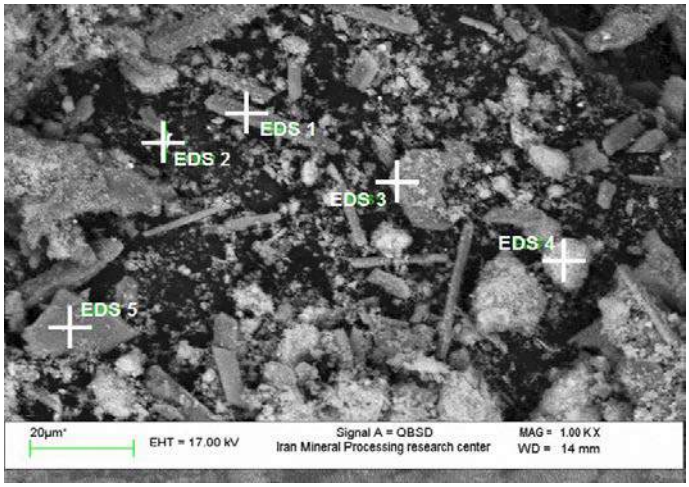
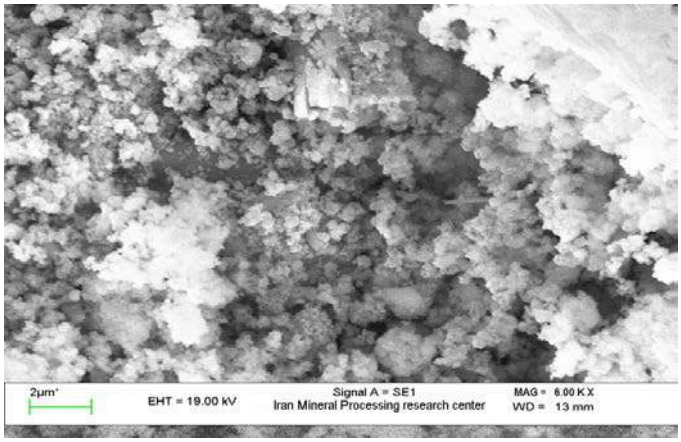
SEM-EDS analysis was used to find more information. As shown in Figure 2a, the only crystalline particles which have relatively large grains (compared to other particles) viz. EDS1, EDS3 and EDS5 points contain Ca and S, confirming the presence of calcium sulfate phases. Zn, Mn and Co could be observed instantly on the some fine particles with varying ratios of zinc, manganese, cobalt, calcium and oxygen. High-resolution image of fine surface morphology is also shown in Figure 2b. It was concluded that most of the particles are in sub-micron sizes and fine particles aggregate on surface of larger crystalline particles.



(a) Backscattered electron mode



(b) Secondary electron mode

Figure 2. SEM micrograph of PHFC.

3.2 Zinc dissolution from HFC with alkaline medium

Based on the XRD analysis of PHFC sample, the main zinc bearing phase is zincite (ZnO). Among the all phases presents in HFC, ZnO was the only phase could be dissolved in alkaline medium. Our preliminary experiments showed that lead and cadmium have not leached, remarkably. So, the leaching process could be completely selective for zinc. It is thought that zincite dissolves in alkaline medium according to the reaction below:

$$ZnO_{(s,\ in\ HFC)} + 2NaOH_{(aq)} + H_2O \rightarrow Na_2Zn(OH)_{4(aq)} \quad (1)$$

Preliminary experiments showed that reaction time has no significant effect on the

leaching recovery and it seems that 30 minutes could be enough to get equilibrium. For the evaluation of the effect of other parameters on the zinc dissolution from HFC, the collected data were analyzed by using Minitab®16 Statistical Software. The results of all experiments as well as their operational condition are summarized in Table 3.

The intensity of the effects of parameters on the zinc dissolution are given at Figure 3. The principal intention was to maximize the response parameter ZnE to the greatest extent. Accordingly, as seen at Figure 3 "*A*4 (T = 105 °C), *B*4 (C_{NaOH}= 9 M), *C*1 (S/L = 0.1 g/cc) *and D*2 (R = 800 rpm)" combination resulted to the most outstanding zinc extraction recovery. This could be concluded based on the mean of process response. At the suggested optimum level of parameters, the confirmation test revealed that 83.4 % of the zinc could be extracted. This value is higher than all our observed values in Table 3.

Table 3. Taguchi L16 (42×22) results for zinc extraction (ZnE).

Experiment no.	A T (°C)	B C_{NaOH} (M)	C S/L (g/cc)	D R (rpm)	ZnE (%)
1	50	3	0.2	500	13.1
2	50	5	0.2	500	54
3	50	7	0.1	800	71.9
4	50	9	0.1	800	71.4
5	70	3	0.2	800	20.9
6	70	5	0.2	800	52.1
7	70	7	0.1	500	70.5
8	70	9	0.1	500	72
9	90	3	0.1	500	48
10	90	5	0.1	500	62.8
11	90	7	0.2	800	58.4
12	90	9	0.2	800	67.4
13	105	3	0.1	800	65.1
14	105	5	0.1	800	63.1
15	105	7	0.2	500	61.9
16	105	9	0.2	500	69.2

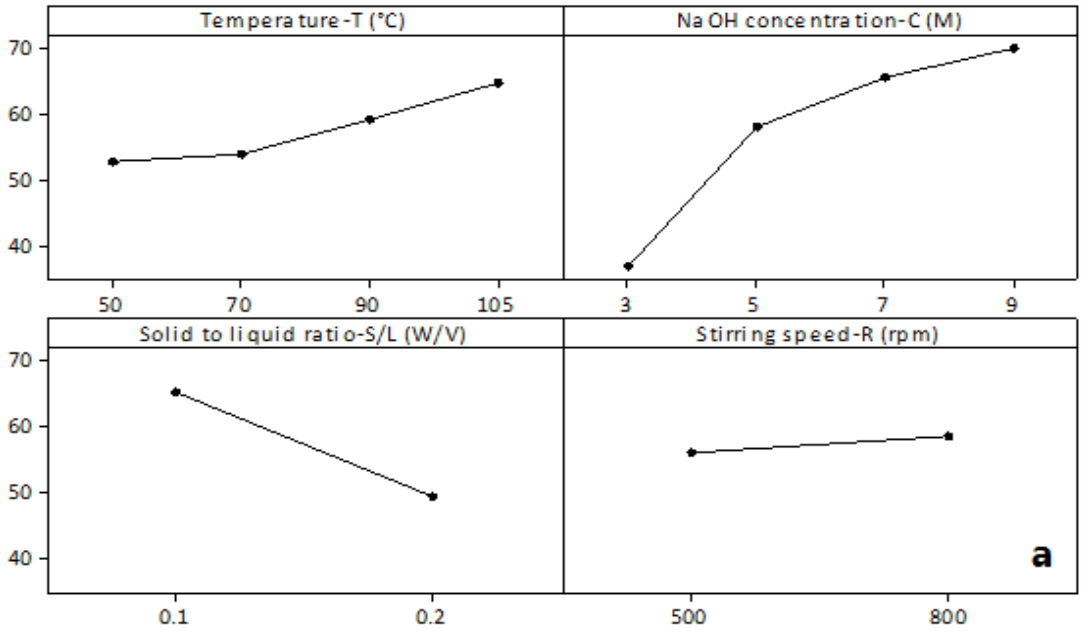


Figure 3. Main effects plots of each parameter for means of the zinc extraction (ZnE).

3.3 Response Plots For Various Affecting Parameters On Zinc Leaching Recovery From HFC

To show the simultaneous effects of parameters on zinc recovery, response plots was used. Figure 4a shows the relationship between NaOH concentration and solid to liquid ratio at a temperature of 55 ˚C and 500 rpm stirring speed. The presented arrow shows the maximum direction of variation (highest gradient) of zinc recovery. As seen, the arrow is more inclined to NaOH concentration axis. It means that with comparison to solid to liquid ratio, zinc

dissolution was more influenced by NaOH concentration. As before mentioned, this result was proved with taguchi method, previously. At the other hand, as it is obvious at Figure 4a, zinc recovery could be increased by decreasing solid to liquid ratio as same as increasing NaOH concentration.

Figure 4b shows the relationship between NaOH concentration and temperature at a solid to liquid of 1/10= 0.1 (W/V) and 500 rpm stirring speed. As seen, at low temperature (T < 65 ˚C), temperature has no significant effect on zinc recovery. In this region, NaOH concentration affects zinc recovery, lonely. But, at high temperature (T > 65 ˚C), the effect of temperature increased and the direction of arrow was more inclined to temperature axis. Thus, it must be considered that at temperature above 65 ˚C, the effect of temperature on zinc dissolution is significant as well as NaOH concentration.

4 CONCLUSION

In the present study, L16 Taguchi method was employed for design of experiment to determine the effective parameters on zinc extraction from HFC. Based on the experimental results and given analysis, at the optimum operating condition (T = 105 °C, C_{NaOH}= 9 M, S/L = 0.1 g/cc and R = 800 rpm), approximately 83.4 % of zinc was leached selectively in NaOH solution. The most important parameter in the zinc alkaline leaching is NaOH concentration. Zinc extraction due to alkaline dissolution of HFC also increase when solid to liquid ratio decreases and temperature increases. Stirring speed has no reasonable effect. It was shown that the alkaline leaching of HFC is an efficient method to recover zinc selectively. High amount of HFC zinc content could be extracted with alkaline leaching.

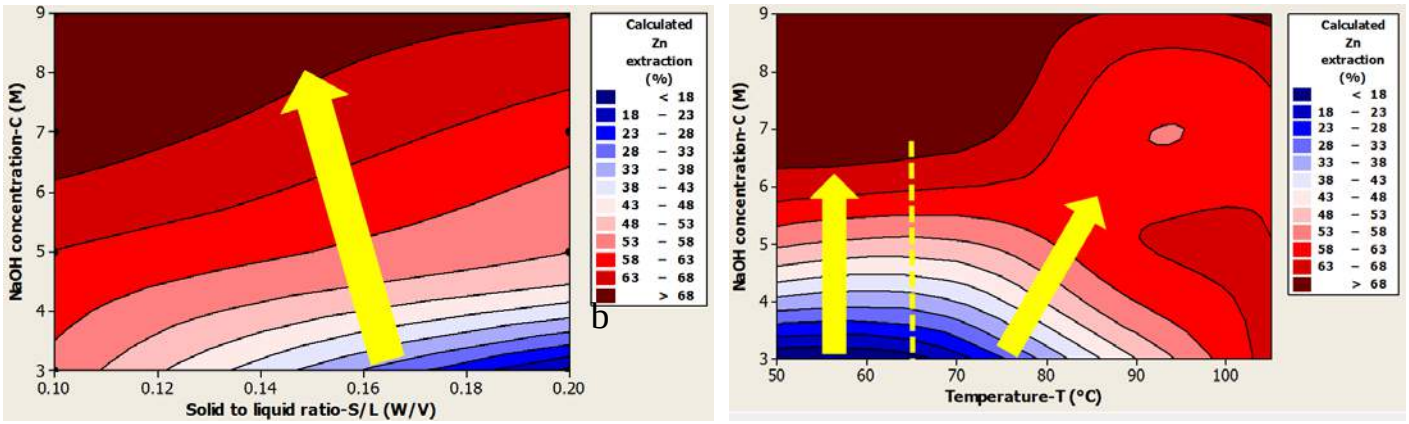

Figure 4. Contour plots of the interactive effect for zinc recovery: (a) effect of NaOH concentration and solid to liquid ratio at constant temperature 55 ˚C and stirring speed 500 rpm and (b) effect of NaOH concentration and temperature at constant solid to liquid ratio 1/10 (W/V) and stirring speed 500 rpm.

Taguchi method can successfully be applied to optimize the zinc alkaline dissolution from HFC.

ABSTRACT Mixer settler equipment is widely used for solvent extraction process. The aim of this project is betterment of settler performance that leads to clean phase separation, minimizing the loss of reagents and declining surface area of the settlers. Computational fluid dynamics provides a convenient way to achieve exact details about fluid flow through solving differential equations by numerical methods. Settler of Sarcheshmeh copper complex in Iran is selected for this survey. Geometry of settler is designed in Gambit software and then computational fluid dynamics simulation based on Euler-Euler two-phase method applied to study aqueous-organic dispersion. Experimental measurements have been used to validate accuracy of simulation results. Flow simulation, separation of phases and the effect of ratio of phases on separation pattern have been investigated. By analyzing the mentioned parameters, the optimized ones are achieved.

Keywords: CFD, Settler, Solvent extraction

1 INTRODUCTION

Solvent extraction process is widely used in many fields such as petrochemical and pharmaceutical industries as well as hydrometallurgy of copper, cobalt, nickel and zinc. Liquid-liquid extraction is a process for separating components in solution distributing them between two immiscible liquids. This technique is used for treatment of complex ores and recovery of non-ferrous metals (Ying and Mikiya, 2009). Using Mixer settler equipment is a convenient method for operating solvent extraction processes in hydrometallurgy industry. The main advantages of this equipment are: strong operational loads, easy operation and maintenance and simple start-up (Shabani and Mazahert, 2012). The function of the mixer is to provide an adequate combination of mixing and dispersion for the desired degree of extraction (Shabani and Mazahert, 2012). After complete mixing, the homogenous combination of phases enters the settler to be separated by gravity force. Figure 1 shows a schematic of mixer-settler equipment. Stanbridge and Sullivan (1999) showed that feed arrangement distribution has a great effect on settler performance (Stanbridge and Sullivan, 1999). In their results, optimum conditions of flow in the settler can be obtained by uniform feed distribution along the width of the settler. Miller (2006) reported that performance of a settler can increase up to 30–50% by improving the feed distribution and coalescence systems (Miller, 2006). These systems also increase settler performance when an emulsion band is not present due to fast breaking emulsions. In order to control the flow entrance to settler, vertical plates called “picket fence” are used. Any improvement in understanding of hydrodynamics and flow pattern within a mixer-settler unit would enable effective design of the mixer-settler equipment and this is provided by using CFD simulation. By CFD simulation, not only the experimental

tests are not required to be done to find out optimum conditions of mixer-settlers but also it leads to a decrease in operation costs.

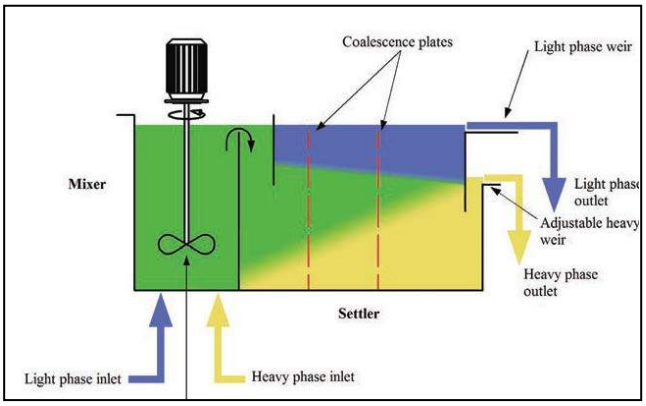

Figure 1. Schematic of mixer settler equipment.

A CFD model of a mixer-settler requires these to be selected, amongst others, an appropriate grid resolution, discretization scheme, impeller rotation model and turbulence model. The selection of these, largely numerical considerations, can have a dramatic influence on both the accuracy of the CFD simulation and the associated computational expenses. This is particularly important when performing CFD simulations of large industrial vessels (engineering studies) as the number of control volumes in the grid increases enormously with increasing the size of mixer-settler (Miller, 2006; Sadeghi et al., 2011). The aims of the present work are as follows: Flow simulation, separation of phases and investigating the effect of ratio of phases on separation patterns.

2 MATERIAL AND METHODS

2.1 Governing Equations

The equations are solved through Finite volume method in ANSYS CFX 14.5. The CFD simulation involves the continuity equation for incompressible flow and time averaged navier-stocks equations. Droplet coalescence and break up model is implemented in the ANSYS CFX.

2.1.1 Continuity equations

The continuity equations for continuous (c) and dispersed (d) phases are as follows (Versteeg, and Malasekara, 2007; White, 1991):

$$\nabla(\rho_c \alpha_c U_c) = 0 \quad (1)$$

$$\nabla(\rho_d \alpha_d U_d) = 0 \quad (2)$$

Where ρ, α, and U are density, volume fraction and mean velocity vector respectively.

2.1.2 Momentum equations

The time averaged governing equation for a steady, incompressible, turbulent flow form as (Versteeg, and Malasekara, 2007; White, 1991):

$$\rho_c[\nabla(\alpha_c U_c U_c)] = -\alpha_c \nabla P + (\mu_c + \mu_t)\nabla^2(\alpha_c U_c) + S_{M.} \quad (3)$$

$$\rho_d[\nabla(\alpha_d U_d U_d)] = -\alpha_d \nabla P + (\mu_d + \mu_t)\nabla^2(\alpha_d U_d) + S_{M.d} \quad (4)$$

Here μ, μ_t, P and S_M are dynamic viscosity, turbulent viscosity, pressure and source term respectively. U_c and U_d are the time averaged mean vectorial velocities.

2.1.3 Other equations

The k-ε turbulent model has been used to calculate the turbulent viscosity. Where k and ε are turbulent kinetic energy and turbulent dissipation rate respectively (Sadeghi, et al., 2011; Ansys Cfx 14.5 Users' Guide, 2013).

Fluid flow field calculation has been carried out through standard K- ε turbulence model. K- ε is one of most established turbulence model which is successfully used by the other researchers, for simulating similar cases. The turbulence model includes buoyancy, drag, lift and turbulent dispersion force (Sadeghi, et al., 2011; Ansys Cfx 14.5 Users' Guide, 2013). Buoyancy, drag and lift effect are considered respectively as follows:

$$F^{buo} = (\rho - \rho_\circ)g \quad (4)$$

$$F^{drag} = \frac{1}{2}|U_{rel}|U_{rel}A_p C_D. \quad (5)$$

$$F_d^{lift} = \alpha_d \rho_c C_L (U_c - U_d) \times \nabla U_c. \quad (6)$$

2.2 Calculation Process

In order to analyze the flow pattern in settler, a case study has been selected for verifying the simulation results with experimental data; so the settler of Sarcheshmeh copper complex was chosen for this task.

Settler tank was designed and meshed by Gambit software as shown in figure 2. Settler is rectangular with one entrance for fluid. Type of mesh and distance between the nodes hugely influence the time of mixing equations and the reliability of the results. Considering the cubic shape of the tank, Hex dominant mesh was selected. In curved or near picket fence areas, nodes with less distance were used with 400000 cells, according to Sadeghi et al. Research for settler tank, 500000 and 600000 cells were examined and concluded that with 600000 cells, results of simulation are not dependent on the number and shape of the cells. Flow pattern was investigated in settler tank and finally the results were validated by Sadeghi et al. data (Sadeghi, et al., 2011; Sadeghi, et al., 2011).

For investigating the interaction of two fluids, two phase Euler-Euler model was used because of its good results in condition that volume ratio of disperse is not negligible. Hydrostatic pressure by atmosphere is considered in the volume of settler tank. Entering volumetric rate of flow according to the operating condition was considered 1100 m^3/hr. Stationary situation applied on the walls.

By a camera which is connected to a computer, minimum and maximum sizes of droplets were calculated 100 and 2000 micrometers respectively.

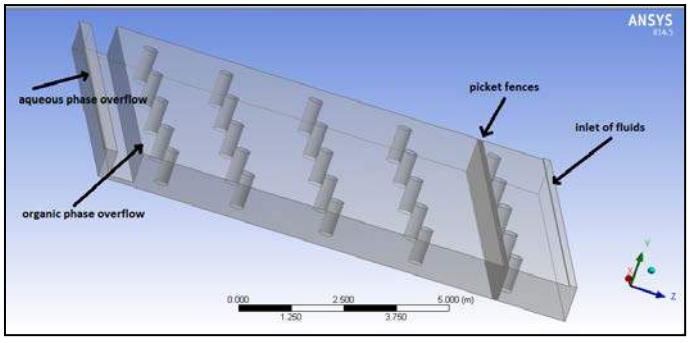

Figure 2. Schematic of settling tank.

Settler equipment of Sarcheshmeh includes two separated outlets for aqueous and organic phases in which the exhausting condition of tank is considered as pressure outlet in atmosphere constant pressure. In inlet valve, ratio of flow rate of phases according to the operational condition was set by 0.95.

For assessing the flow pattern, it was supposed that inlet fluid consists only of water by 1100 m^3/hr flow rate. Continuity and momentum balance equations were modeled. At first, the tank was empty so for studying the way of filling it by fluid was done by two phases; air and water.

According to the Sadeghi et al. research data for these dimensions, 500000 cells are appropriate and are correspondent with experimental data. After meshing, the geometry was referred to Ansys Fluent software. Velocity of inlet was set 1100 m^3/hr and volume ratio of organic to aqueous phase was considered 0.95.

Since the phases are isotherm and there is no heat transformation in volume of settler, solving heat transformation equations was ignored. Time-transient type of simulation was selected and time steps size for calculation and reserving the results was applied by 0.01 Sec. Total time of calculations according to inlet fluid, inlet area and total volume of tank, was adjusted by 200 second. In modeling at the start point, the volume fraction of water was 0 and the total volume consisted of air and at the entrance it was 1. For converging the results, sum of squared residuals method was used by 10^{-4} criteria.

There are some spaces in settler which eddy currents occur. These currents not only reduce the efficiency of fluid distribution in settler, but also aggravate the separation of phases, Hence, diminishing these areas results in decreasing the costs and performing the gravity separating reactors.

This simulation was done in three dimentional, unsteady state, turbulent flow, incompressible and without transformation of heat and mass conditions. Reynolds numbers based on hydraulic diameter in launder and settling tank were 93000 and 11000 respectively. For this reason turbulent

flows were considered in this simulation.

3 RESULTS AND DISCUSSION

3.1 Simulation of Flow and Investigating Separation of Phases

One of the significant factors of flow pattern is volumetric rate of flow. Figure 3 shows the volume ratio of organic phase at different height of settler. Desirable separation is obtained when the separation layer is less and organic phase is thick. Figure 4 and 5 show the distribution of phases in 2 views.

Volumetric rate of inlet influences the collision of droplets and separation of phases. For analyzing this parameter at different inlet volumetric rate by 375, 550, 1000, 1500, 1200, 2200 and 3600 m^3/hr were examined. The approach of separation of phases shown in figure 6 to 10. As these figures indicate, by choosing inlet volumetric rate near to 1000 m^3/hr, the separation improved among other velocities. Figure 11 shows organic volumetric ratio at different inlet volumetric rate.

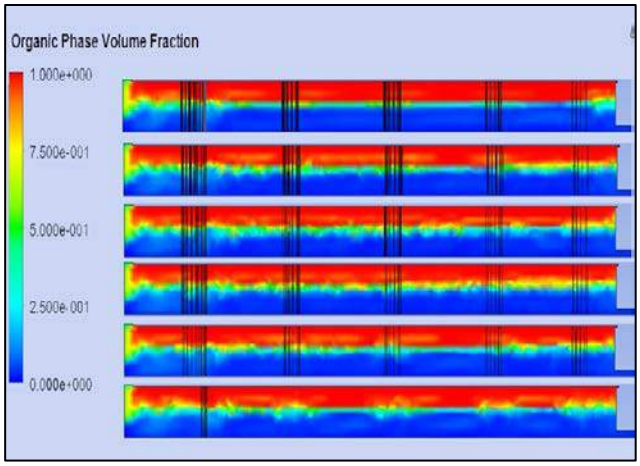

Figure 9. Pattern of separation in 1200 m3/hr inlet volumetric rate.

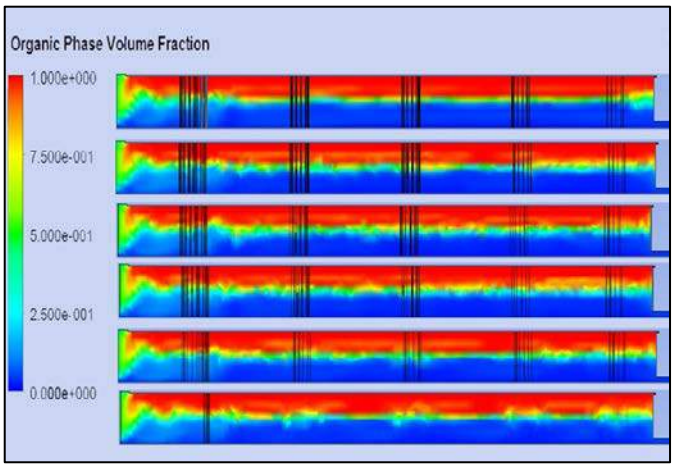

Figure 10. Pattern of separation in 1500 m3/hr inlet volumetric rate.

3.2 Studying Ratio of Phases on Separation Pattern

Volumetric ratio of organic phase to aqueous phase was set 0.95 in all simulations. One of the effective parameter affecting on separation could be volumetric ratio. For analyzing effect of this factor, different volumetric ratios with optimum volumetric rate of flow were examined. These ratios were equal to 0.5, 0.25, 0.1, 2, 4 and 10. Results were compared with ratio of 0.95 as shown in figures 12 to 17.

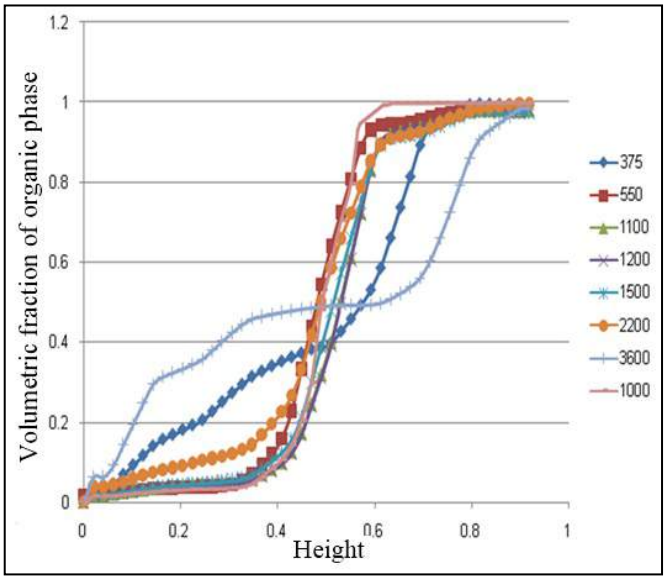

Figure 11. Organic phase volume fraction in different heights (m) of settler and in the presence of different inlet flow rates.

Simulation results of separation pattern in settler volume show that by changing volumetric ratio of organic to aqueous phase

in input valve, the separation pattern becomes distorted, and the separation layer increases. So, ratio equal to 0.95 was considered as optimum ratio. Figure 18 shows volumetric ratio of organic phase in 0.6 m height from the bottom of the settler.

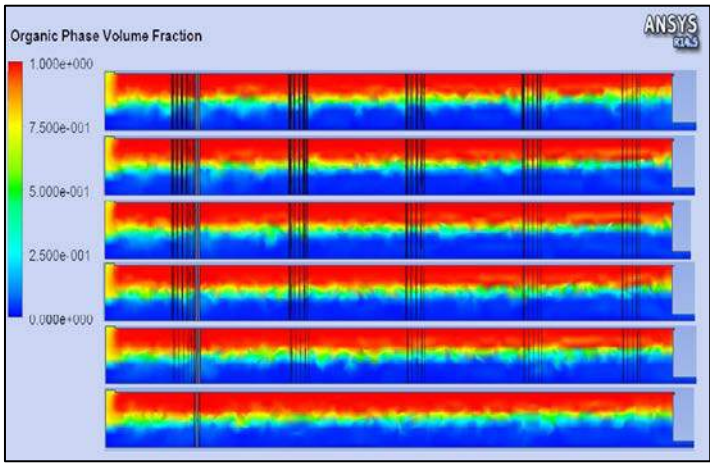

Figure 12. Separation pattern in volumetric ratio 0.5.

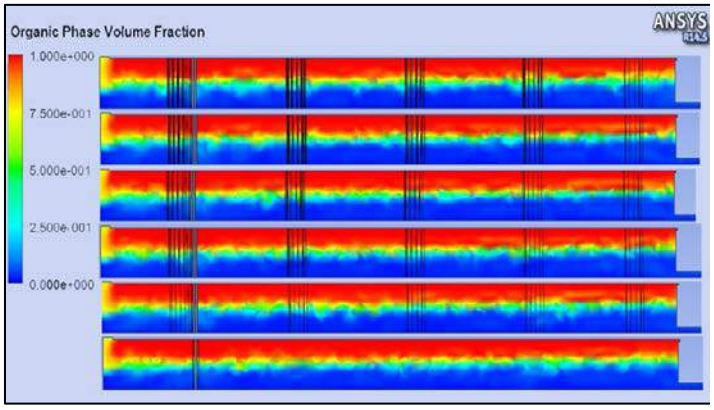

Figure 13. Separation pattern in volume ratio 0.25.

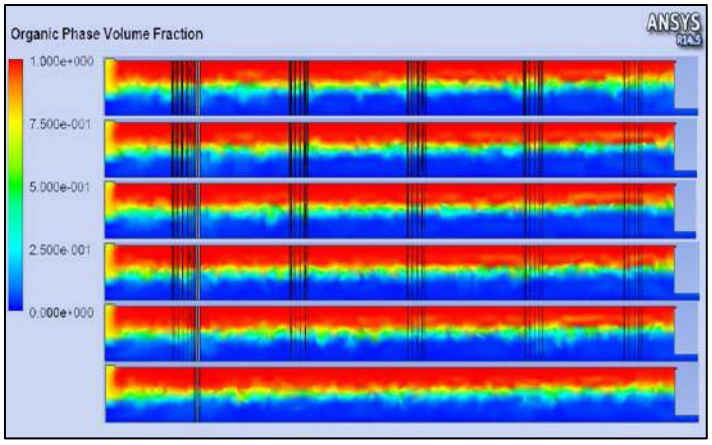

Figure 14. Separation pattern in volume ratio 0.1.

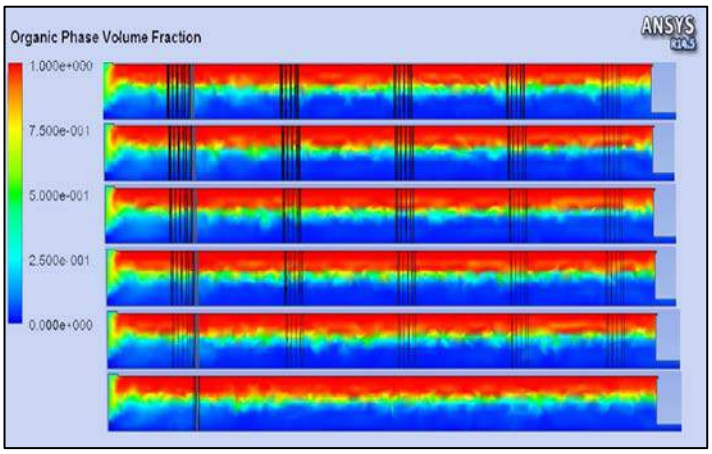

Figure 15. Separation pattern in volume ratio 2.

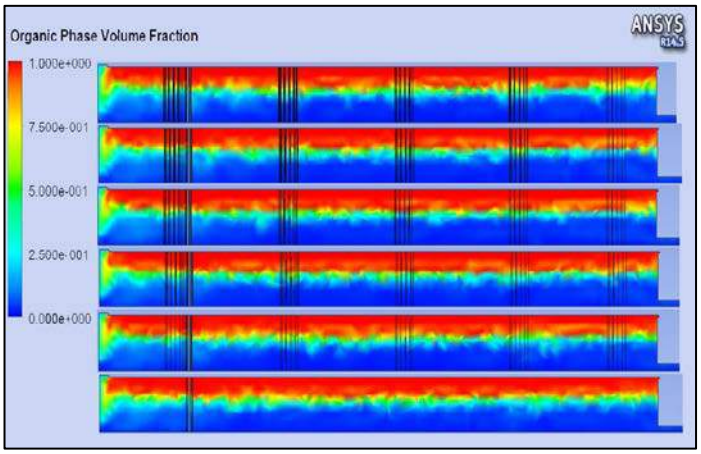

Figure 16. Separation pattern in volume ratio 4.

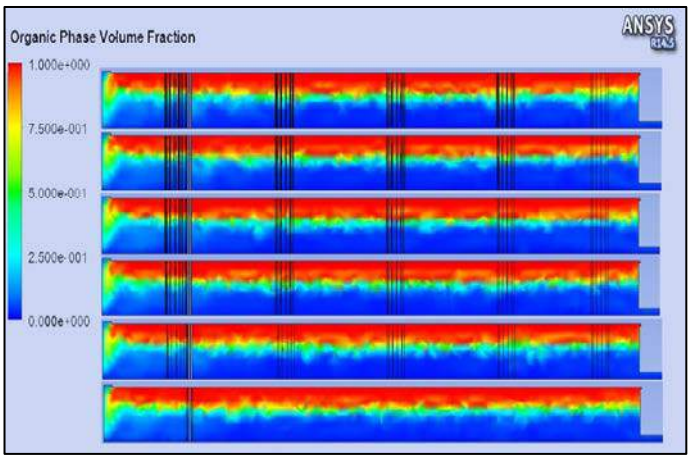

Figure 17. Separation pattern in volume ratio 10.

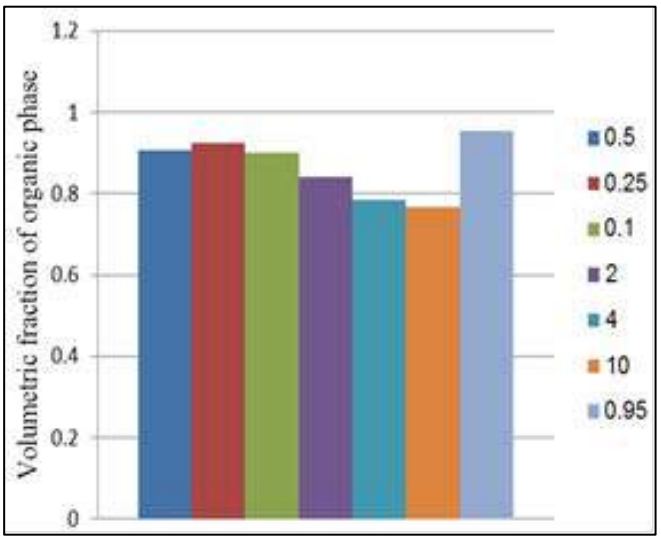

Figure 18. Volumetric fraction of organic phase in 0.6 meter height in different volumetric ratio.

4 CONCLUSIONS

Demanded separation is obtained when the separation layer is less and organic phase is thick. Different inlet volumetric rates by 375, 550, 1000, 1500, 1200, 2200 and 3600 m^3/hr were simulated and it was concluded that by decreasing inlet volumetric rate to 1000 m^3/hr, the separation improved among other velocities. For analyzing the effect of ratio of phases, different volumetric ratios in presence of picket fence with optimum volumetric rate of flow were examined. These ratios were equal to 0.5, 0.25, 0.1, 2, 4 and 10. By changing volumetric ratio of organic to aqueous phase in input valve, the separation pattern became distorted, and the separation layer increased. So, ratio equal to 0.95 was considered as optimum ratio.

ABSTRACT Selenium is well known for both an essential and toxic role in lives of human beings and animals. Actually, very few extraction methods have been available for selenium (IV) so far. In the present study, the mechanism of selenium extraction in hydrochloric media by solvent extraction was carried out in two steps. First, extraction of selenium by triisobutyl phosphate was employed and then in the next step, Dodecanol was used as a modifier. The effect of concentration of acid, concentration of TIBP in the organic phase, pH, temperature, contact time, aqueous to organic volume ratio, and Dodecanol as a modifier on the extraction of selenium (IV) was studied.

Keywords: Solvent extraction; Selenium (IV); Triisobutyl phosphate; Dodecanol

1 INTRODUCTION

It is well known that selenium is both an essential and toxic trace element for man and animals with an upper intake limit of 400 μg/day (Sarger, et al., 2011). Selenium has many applications in electronic and metal alloy industries, and the largest use of it is in glass and ceramic manufacturing, it is also used in chemical industry, rubber industry and pharmaceuticals (Chowdhury and Sanyal 1993; Sarger, et al., 2011; Swapnil, et al., 2013). Solvent extraction is commercially used for recovery of precious metals, such as gold, silver, selenium, tellurium and etc. from copper electrorefining anode slimes (Abdollahy and Shafaei 2004, Gupta 2009). Very few extraction methods of selenium (IV) are available in the literature (Sarger, et al.,2011). The extraction and back extraction of selenium (IV) with N503 was studied by (Li, et al., 2012). This investigation proved that the extraction efficiency of Se (IV) is 100% by two times of extraction. (Aeungmaitrepirom, et al., 2001) studied the solvent extraction of Se (IV) by diaminocalix[4]arene. They came to the conclusion that Selenium (IV) was extracted into chloroform as (LH_2^{2+}, Cl^-, $HSeO_4^-$) and [$(LH_2^{2+})_2$, $2Cl^-$, SeO_4^{2-}] species at pH 2.6. While the extraction of Se (VI) was severely decreased as pH increased. (Chowdhury & Sanyal 1993) used tributyl phosphate (TBP) as an extractant for investigating the solvent extraction of selenium (IV), and this study was followed by studying the separation of selenium (IV) and tellurium(IV) using 1.1M TBP in kerosene as an extractant. N-n-octylaniline was also used by (Sargar, B.M., Anuse 2001) for the extraction of Se (IV) from dilute hydrochloric acid media. This method offered sequential separation of selenium (IV) from tellurium (IV). This paper surveyed the affecting parameters such

as the concentration of TIBP, pH, acid concentration, and modifier on extraction of selenium (IV) systematically, and estimated the thermodynamics of the overall extraction process.

2 MATERIALS AND METHODS

2.1 Reagents and Materials

All chemicals in this experiment were of analytical reagent grade. Water was double distilled. The Se (IV) solution was prepared by Selenium dioxide which was purchased from Merck Company. The triisobutyl phosphate (TIBP) was provided by Recovery of nonferrous Metals Company was diluted in kerosene after treatment with Sulphuric acid. Dodecanol was purchased from MP Biomedical Netherland Company which was used as a modifier. Ammonia solution 25% extra pure was employed for adjusting the pH of the system which was purchased from Mojallali Company.

2.2 Main Instruments and Analytical Method

Mettler Toledo precision pH meters, EUTECH instruments ORP meter (Oxidation Reduction Power meter) for measuring voltage of solutions, and the atomic adsorption spectroscopy (Varian, type AA240) for analyzing the concentration of Se (IV) ions were used in the experiments.

2.3 Method

Aqueous solution of Se (IV) of 0.05 Mwas made by dissolving appropriate mass of Selenium dioxide, in the stoichiometric value of hydrochloric acid and diluted to volume with double distilled water. Organic solutions were prepared by diluting different percentages of TIBP (10%, 20%, and 30%) in kerosene. In the second step of experiments organic phase containing 20% (v/v) Dodecanol as a modifier and 20% (v/v) TIBP was prepared which was diluted in kerosene. Aqueous solution and organic solution were shaken for 30 minutes in the mechanical shaker then the produced mixture was transferred to 250 mL separatory funnel. The two layers were allowed to settle and separate. pH of aqueous layer was measured by pH meter, and the concentration of Se (IV) in aqueous solution was determined by atomic adsorption spectroscopy.

3 RESULTS AND DISCUSSION

3.1 Choice of Diluent

Considering the important role of diluents in solvent extraction, due to their influence on the efficiency of process, the choice of diluent is one of the consequential steps in solvent extraction process. On the basis of (Chowdhury and Sanyal, 1993) investigations, distribution coefficient of nonpolar diluents is higher than polar diluents in TBP system. The results of their studies illustrated that kerosene and hexane are the best diluents in the mentioned system. In this investigation kerosene was chosen because of its low cost, minimum toxicity, and availability.

3.2 Effect of pH on Extraction of Se (IV)

The extraction was carried out with an aqueous solution of 0.05 M Se (IV) and organic phase containing 20% (v/v) TIBP diluted in kerosene at 25℃. pH and concentration of selenium ions in aqueous phase was determined. Figure 1 represents the extraction percent of selenium in different pH values. As it is shown in the figure, there are some irregular changes in comparison with usual sigmoid graphs of pH-%E for solvent extraction processes.

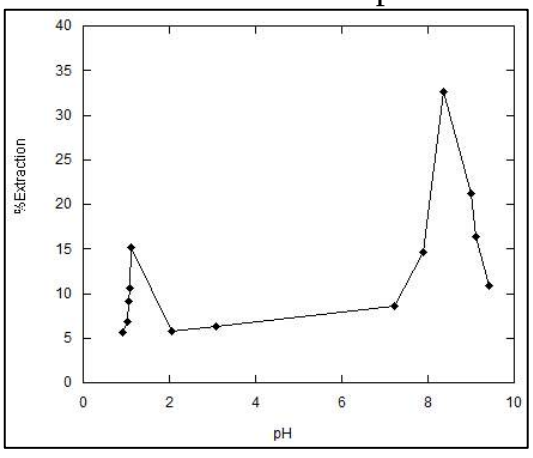

Figure 1. Effect of pH on extraction of selenium.

The considerable difference in represented graph is the sudden and severe accretion in the percent of extraction at the pH of 8.5. To find out the reason of the difference, the Pourbex graph of selenium in the hydrochloricmedia and ORP graph (Figure 2) of aqueous solutions in different pH values was taken into consideration. Evaluation of two graphs came into considerable and reliable results that can justify the unusual pH-%E curve of selenium.

Results illuminated that Se occurred in two complex forms, as SeO_3^{2-} and SeO_4^{2-}before and after the pH of 8.5, respectively. So that selenium could be in its tetravalent state before and after the mentioned pH, and in its hexavalent state at the pH of 8.5. Therefore, it can be denoted that selenium has its maximum extraction at TIBP system in its hexavalent state.

3.3 Effect of TIBP Concentration in the Organic Phase on Extraction of Se (IV)

In this study, the effect of the concentration of extractant TIBP was also examined with 5%, 10%, 20%, 30% and 40% (v/v) TIBP in kerosene at 25℃. Figure 3 shows an increase in Se extraction with an increase in TIBP concentration, but as it is clear, there is no significant enhancement in extraction of selenium by increasing the concentration of TIBP in organic phase. Figure 3 also illustrates that there is a severe accretion at the pH of 8.5 in all considered TIBP concentrations. Thus, in regards to the acquired pH-%E, and taking cost and consumption of the organic phase into account, a 20% (v/v) TIBP concentration in kerosene was chosen for all experiments, even though the higher TIBP concentrations showed a little higher extraction efficiency.

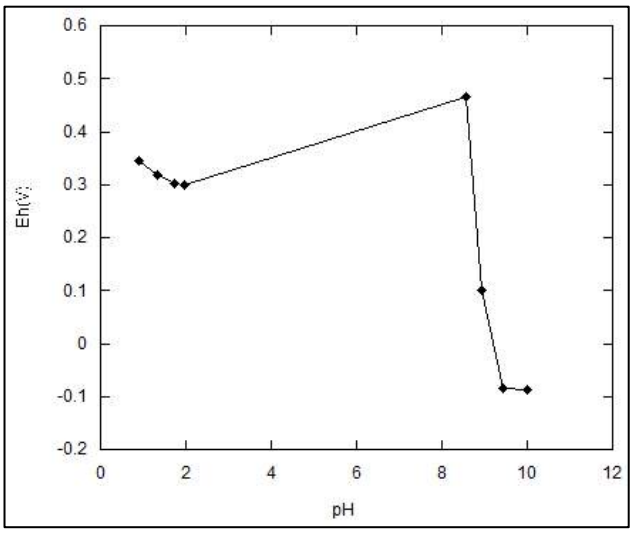

Figure 2. ORP graph of selenium extraction with 20% (v/v) TIBP.

3.4 Effect of Acid Concentration on Extraction of Se (IV)

The extraction was carried out with an aqueous solution of 0.05M Se (IV) and an organic solution containing 20% (v/v) TIBP in kerosene. The results presented in figure 4 imply that the extraction of Selenium (IV) does not have a considerable accretion by increasing the concentration of acid in the aqueous solution.

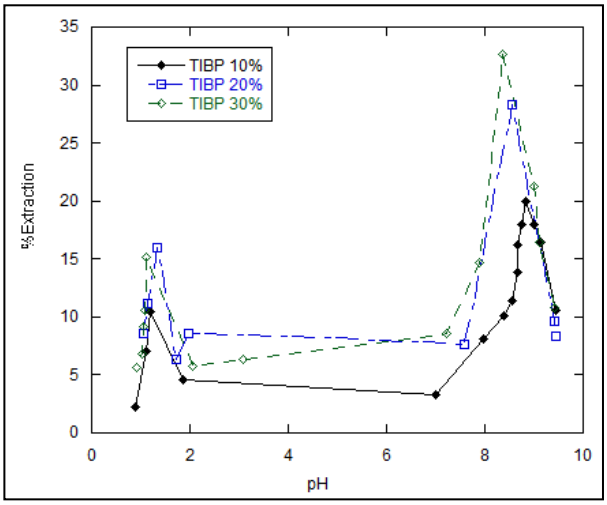

Figure 3. Effect of TIBP concentration on extraction of selenium.

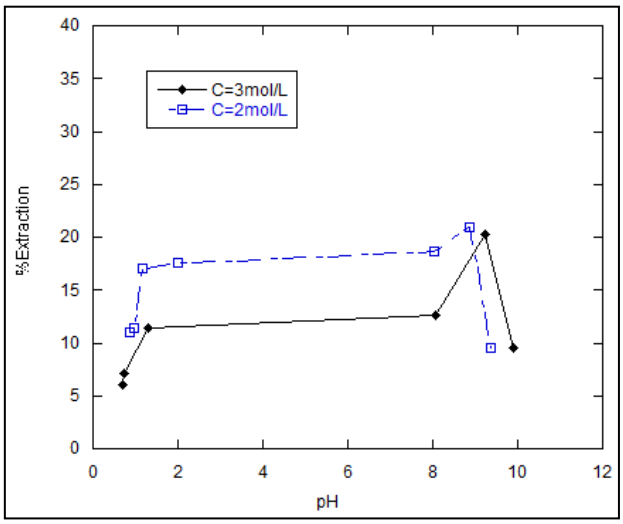

Figure 4. Effect of acid concentration on Se (IV) extraction at 25℃ and 20% (v/v) TIBP.

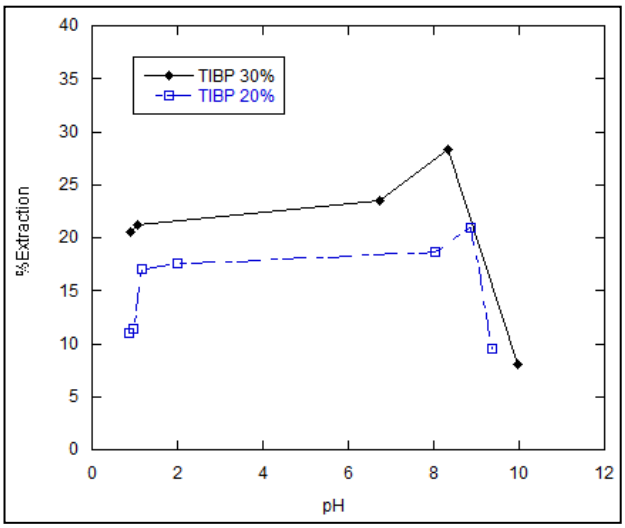

Figure 5. Effect of acid concentration on selenium extraction at 25℃and acid concentration of 2 mol/lit.

But it is shown in the figure 5 that by increasing acid concentration in aqueous solution and TIBP concentration in the organic solution from 20% (v/v) TIBP and to 30% (v/v) TIBP simultaneously, the maximum amount of extraction percentage is enhanced from almost 20% to 30% which can be considered as a useful parameter for improving selenium extraction efficiency.

3.5 Effect of Dodecanol as Modifier on Extraction of Se (IV)

In the second step of this study, Dodecanol was used as modifier for extraction of selenium in order to enhance the extraction percentage of Se (IV). The process was carried out with 20% (v/v) versus pH in the presence of Dodecanol and Dodecanol and 20% (v/v) TIBP in kerosene at 25℃. Figure 6 shows extraction percentTIBP in the organic phase. As it is clear in the figure, the extraction percent increased intensely at pH less than 1, whereas at pHs close to zero the extraction percent can be increased up to 99%. It can be concluded that the modifier's effect on extraction of Se (IV) is positive at lower pH and negative at higher pH.

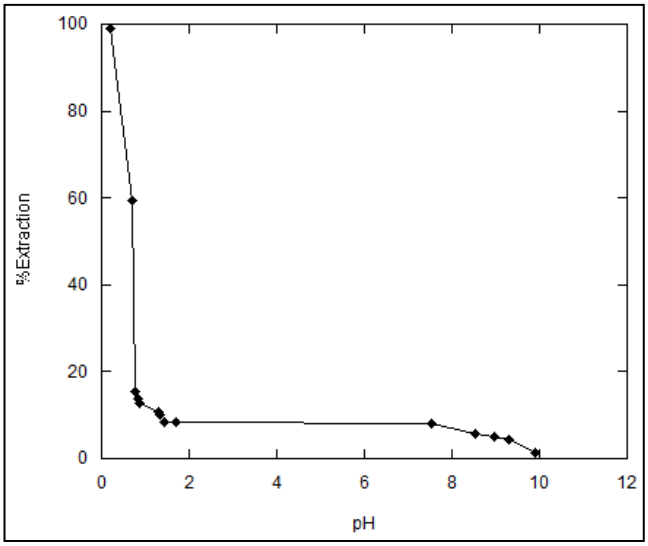

Figure 6. Effect of Dodecanol on etraction of selenium by TIBP at 25℃.

4 CONLUSION

In this paper, different parameters were studied for extraction of selenium species from an acid medium, such as pH, concentration of organic phase, and modifier. Considering cost and overall efficiency, it was shown that the extraction of selenium is better to be carried out with an organic solution containing 20% (v/v) TIBP diluted in kerosene, and ambient temperature. The pH-%E curves of extraction of selenium (IV) showed different behavior in the considered system. There was a severe accretion in extraction percentage in the pH of 8.5 which occurred as a result of the species of

selenium's alteration at the mentioned pH. Changing of different parameters did not have a considerable impact on enhancement of selenium extraction in TIBP system while using Dodecanol as a modifier has a significant effect on extraction of selenium by using Dodecanol, the extraction of selenium has a severe increase, specifically, at the pHs less than 1. Thus, the effect of modifier is positive at lower pH and negative at higher pH.

Study of the Zircon Processing Aiming the Recovery of Zirconium and Silica

C.A. Ferreira, T.S. Formiga, C.A. Morais
Centro de Desenvolvimento da Tecnologia Nuclear – CDTN/CNEN Belo Horizonte, Minas Gerais - Brazil

ABSTRACT The zircon ($ZrSiO_4$) is the most abundant mineral of zirconium and the main source for the production of metallic zirconium, its compounds and alloys. The alkaline fusion with sodium hydroxide is the most widely used process in the chemical opening of zircon to obtain the metal zirconium. The present work describes the influence of the process variables in the alkaline fusion, zirconium dissolution from fusion product and in silica recovery steps. In the study of silica and zirconium dissolution two routes were investigated: the traditional alkaline an acid leaching and a new route in which just the acid leaching was used. In the alkaline fusion step, results showed that with a reaction time of 45 min, a NaOH/sample ratio of 1.3 is sufficient to achieve a complete fusion reaction. The leaching experiments showed that the direct acid leaching (new route) was able to obtain a good zirconium and silica separation. From a molten mass of zircon containing 31.8% ZrO_2, 14.1% SiO_2, 47.8% Na_2O and 5 % humidity, in the alkaline leaching a dissolution of approximately 73% of silica, a liquor containing about 20 g/L silica and a residue with 85% ZrO_2 and 10 % SiO_2 was obtained. In the direct acid leaching of the molten mass using HNO_3 as leaching agent, a dissolution of approximately 97% ZrO_2 and a residue containing 92% SiO_2 were obtained, with a mass reduction of approximately 80%.

Keywords: Zircon, silica and zirconium dissolution, leaching

1 INTRODUCTION

The zircon (ZrSiO4) is the most abundant mineral of zirconium and the main source for the production of metallic zirconium, its compounds and alloys. Zircon is a tetragonal zirconium orthosilicate and the chemical composition of the mineral mass contains approximately 65% of ZrO_2, 32% of SiO_2, and other elements at low concentrations, such as Hf, Fe and Ti (Habashi, 1997; Manhique et al, 2003; Bertolino et al, 2008). Due to high thermal and chemical stability, the decomposition of zircon requires drastic conditions. Different methods are used for the mineral decomposition, such as thermal or chemical decomposition at high temperatures. The alkaline fusion with sodium hydroxide is the most widely used process in the chemical opening of zircon to obtain the metal zirconium. This fusion occurs at temperatures between 550-700 °C. During the alkaline fusion, zirconium silicate ($ZrSiO_4$) is converted into sodium zirconate and sodium silicate. Also, the decomposition of zircon generates large ammounts of sodium silicate, along with zirconium oxide, according to Equation 1 (Abdel-Rehim, 2005).

$$ZrSiO4 + 4NaOH \rightarrow Na2ZrO3 + Na2SiO3 + H2O \quad (1)$$

The variables that affect the characteristics of the product of the fusion are: mass ratio, temperature and reaction time (ABDEL-Rehim, 2005; ZOLFONOUN et al 2010). According to BISWAS et al, 2010, considering the reaction presented in Equation 1, it is possible to form other products, besides zirconate and sodium silicate, such as Na_4SiO_4, $Na_2Si_2O_6$, $Na_6Si_2O_7$, $Na_4ZrSi_3O_{12}$.

Silica recovery from zircon is an alternative concerning the environmental and economic issue, since silica is an inorganic

material that can be widely used in a variety of applications such as resins, molecular sieves, catalyst carriers, as raw material in the glass, and electronic industry, amongst other applications. This removal is generally accomplished by alkaline leaching using water as a leaching agent. In this step there is a very high consumption of water and a highly pollutant effluent having a high content of silica is produced. An alternative method evaluated in this work was the leaching of sodium zirconate, keeping the silica insoluble. This new route can reduce the cost of the process with satisfactory results.

In this work, the influence of the following variables were investigated:

- alkaline fusion step: NaOH/sample ratio, temperature and reaction time;
- alkaline leaching: solid percentage, temperature and reaction time;
- acid leaching: acid concentration, temperature and reaction time.

In the study of silica and zirconium dissolution, two routes were investigated: the traditional alkaline an acid leaching and a new route in which just the acid leaching was used.

2 METHODOLOGY

2.1 Reagents

The sample of zircon concentrate used in this work was provided by the Nuclear Industries of Brazil - INB. Prior to this study, the decomposition of the zircon concentrate by alkaline fusion with sodium hydroxide was performed. In the study of the separation of Zr/Si; 100 kg of zircon concentrate was melted, generating approximately 200 kg of molten mass (alkaline melt product). The sample was homogenized and reduced to fractions of different masses in order to enable the laboratory experiments and the chemical characterization. The sodium hydroxide used was of commercial grade (99% w/w) and the nitric acid (HNO_3) was of analytical grade. Distilled water was used for alkaline leaching as well as for solutions preparation.

2.2 Experiments Methodology

The zircon fusion experiments were carried out by using iron crucible in a furnace at the specified temperature and time. The alkaline fusion efficiency was investigated through X-ray diffraction, where the unreacted zircon and fusion products phases were identified.

The leaching studies were performed in a 250 ml beaker using mechanical agitation at controlled temperature. After the reaction time stated, the pulp was vacuum filtered using buchner funnil and kitasato. After filtration, the solid was transferred for drying in an oven at 110°C. Then the residue was weighted and the volume of the filtrate was measured and sent to chemical analysis. The metals present in the residue and in the leaching liquor were analyzed by Energy Dispersive X-ray Fluorescence Spectrometry - EDXRF - using an X-ray spectrometer of dispersive energy brand SHIMADZU, model EDX-720. The nitrate content in the liquor was determined by molecular absorption spectrophotometry in the ultraviolet region (302nm) using an UV – visible spectrometer, brand VARIAN model Cary 50 conc.

The new route experiments were conducted similarly to previous experiments. Experimental conditions are shown in Table 1. Experiments 1 to 3 were carried out in order to precipitate the solubilized silica and experiments from 4 to 6 were the continued leaching of the waste generated in the previous experiments. The experiment number 7 was similar to previous experiments, but without drying the residue after the first leaching. In experiment 8 was conducted a sequential leaching without the separation of the first reaction residue, as follow: in a beaker was added 40 ml of HNO_3 3.0 mol/L, left under stirring for a period of 4 hours and then added 85 mL of HNO_3 3.0 mol/L to complete the zirconium dissolution.

Table 1. Experimental conditions of direct acid leaching

Test	H_2O (ml)	Sample mass (g)	HNO_3 3mol/l (ml)
Zrlac-T1	10	10,0	25
Zrlac-T2	20	20,0	44
Zrlac-T3	30	30,0	58
Zrlac-T4	10	4,7	45
Zrlac-T5	10	9,4	85
Zrlac-T6	10	16,1	144
Zrlac-T7	40	20,0	40+85
Zrlac-T8	40	20,0	40+85

3 RESULTS AND DISCUSSION

3.1 Chemical Characterization

The chemical composition of the main components of the zircon concentrate and of the molten mass (fusion product) of zircon used in the experiments of recovery of silica is shown in Table 2 below.

Table 2. Chemical composition of zircon before and after the alkaline fusion

Species	Sample/Content (%)	
	Zircon	**Fusion Product**
ZrO_2	65.0	31.8
SiO_2	29.0	14.1
HfO_2	1.33	0.57
Na_2O	-	47.8
H_2O	-	5.70
Er_2O_2	0.58	-
Y_2O_3	0.18	-
Al_2O_3	2.22	-
TiO_2	0.94	-
Fe_2O_3	0.53	-
BaO	0.58	-

3.2 Alkaline Leaching

The chemical opening of zircon performed through fusion with sodium hydroxide produces a strongly alkaline molten mass. This allows to use water as the leaching agent for the dissolution of the sodium silicate formed during melting. In the study of silica dissolution with water (alkaline leaching) the following process parameters were investigated: solids percentage (sample/water ratio) temperature and reaction time.

Variation of the solids percentage and the temperature

The influence of the solids percentage and temperature on the sodium silicate dissolution was investigated for percentages of 10%, 15%, 20% and 30% at temperatures of 25°C and 70°C with a reaction time of two hours. The results are presented below in Table 3.

Table 3. Effect of the percentage of solids in the dissolution of sodium silicate generated in the alkaline fusion of zircon

Percentage of Solids	Temperature (°C)	Dissolution (%)
10	25	73
10	70	76
15	25	75
15	70	73
20	25	72
20	70	72
30	25	71
30	70	72

As can be seen in Table 3, the influence of the percentage of solids and the temperature on the dissolution of sodium silicate was not significant. However, one can observe a slight tendency towards higher dissolution in solids percentages between 10 and 15%. In the intervals investigated, the dissolution of the silicate ranged from 71 to 76%,

considering an experimental error of about 4%, it can be said that the dissolution of the silicate present in the fusion product is not influenced by temperature.

Reaction time

The reaction time was investigated ranging from 1 to 6 hours, within a percentage of solids of 10% and at room temperature. The results showed that there was only a slight variation in the percentage of the silicate dissolution – 73 to 76%. Considering the small difference in the silicate dissolution obtained in this step of the study, the reaction may be conducted with 1 hour of stirring at room temperature.

Final products of the alkaline leaching

At the end of the experiments presented in this paper, an alkaline liquor containing approximately 15 g/L of Si and a residue containing 89% of ZrO_2 and 6.7% of SiO_2 was obtained. The silicon present in the liquor was precipitated through acidification with hydrochloric acid 5.0 mol/L up to pH 1.0. The chemical composition of the alkaline solution, the residue of leaching and silica obtained in the neutralization liquor is given in Table 4. The mass reduction in the alkaline leaching was approximately 45%. The dissolution of the residue of the alkaline leaching with HNO_3 generated a liquor containing around 50g/L Zr, 2.5 g/L Si, 3.5 g/L Na, 1.0 g/L Hf and 0.2 g/L Fe. The yield of the dissolution of Zr and Hf from the residue of the alkaline leaching was 97%.

Table 4 – Chemical characterization of the products of the alkaline leaching

Species	Sample/Content (%)		
	Alkaline Liquor (g/L)	**Residue of leaching (%)**	**Silica (%)**
SiO_2	31.1	6.73	95.3
ZrO_2	0.09	89.4	2.30
HfO_2	0.002	0.96	0.09
Na_2O	67.1	0.98	0.57
Fe_2O_3	-	1.14	0.04
TiO_2	-	0.54	-
CaO	0.08	0.26	0.20

3.3 Acid Leaching

As shown in Table 3, the residue of the alkaline leaching had a SiO_2 content of 6.7%, which is not desirable in the process. Therefore, another process route was investigated; the dissolution of Zr without previously removing the silicon. The dissolution of Zr was made by leaching with HNO_3 in a beaker using mechanical stirring at controlled temperature. The process variables investigated were: acid concentration, temperature and reaction time.

Variation of the concentration of HNO3 and temperature

The influence of the concentration of HNO_3 in the dissolution of zirconium from the fusion product was investigated at the range of 4 mol/L to 12 mol/L at three different temperatures: 25°C, 50°C and 70°C. The experiments were performed in triplicates and the results are shown in Figure 1. As seen in Figure 1, there is an increased dissolution of Zr as the temperature increases. The influence of temperature is more significant for lower concentrations of HNO_3 (4.0 mol/L). The dissolution of silica was below 2% for all the concentrations of HNO_3 investigated. The subsequent experiments were carried out in acidity of 12 mol/L. The high acidity of HNO_3 is justified by the fact that in the next stage of the study, which comprises the separation of Zr/Hf by solvent extraction, is performed at high acidity. The behavior of Hf was similar to that of Zr and therefore was not reported in Figure 1.

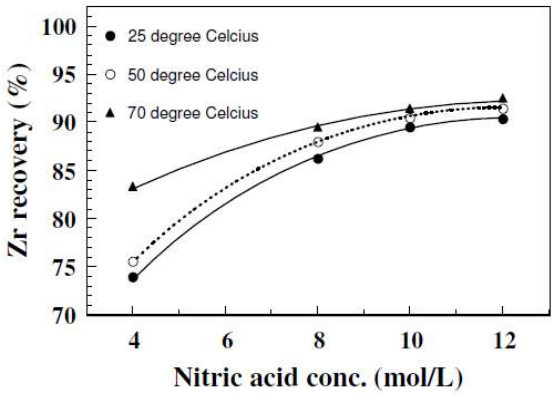

Figure 1 Influence of temperature and HNO_3 concentration in the dissolution of zirconium.

Reaction time

The reaction time was varied from 0.5 to 4 h, using a HNO_3 concentration of 12.0 mol/L (ratio acid/water of 3:1) at a temperature of 70°C and using a percentage of solids of 10%.

The experiments indicated a progressive increase in the dissolution of the zirconium with an increase of time, however negligible. For the reaction time of 30 min. (0.5 h), the dissolution of Zr was approximately 89% and 95% for the time of 4 hours. The results are shown in Table 4 below. The dissolution of Si was lower than 2% in all experiments.

Table 4 Effect of reaction time on the SiO_2 and Zr dissolution

Time (h)	Zr Dissolution (%)	Hf Dissolution (%)	Si Purity (%)
0,5	88,7	85,6	84,2
1,0	91,5	89,4	85,5
1,5	92,0	91,2	86,5
2,0	92,7	92,7	86,7
2,5	94,0	92,0	88,7
3,0	92,9	91,6	87,0
4,0	94,9	93,5	89,3

New Route (direct acid leaching)

The new route is presented as a great option for the dissolution of zirconium present in the material. This methodology reduced one step in the process, and did not need the prior dissolution of silica by alkaline leaching neither the zirconium precipitation with ammonium sulfate.

In preliminary studies (experiments 1 to 3), a low zirconium dissolution was observed, because the amount of added acid was not sufficient for a complete zirconium dissolution. This low zirconium dissolution can also be noted for experiments 4 to 6 due to the low solubility of the second leaching step residue, observed by the sample mass (first leaching residue) and the residue mass obtained in these experiments.

From a molten mass of zircon containing 31.8% ZrO_2, 14.1% SiO_2, 47.8% Na_2O and 5 % humidity, in the alkaline leaching a dissolution of approximately 73% of silica, a liquor containing about 20 g/L silica and a residue with 85% ZrO_2 and 10 % SiO_2 was obtained.

After optimization of the direct acid leaching of the molten mass using HNO_3 as leaching agent, a dissolution of approximately 97% ZrO_2 and a residue containing 92% SiO_2 were obtained, with a mass reduction of approximately 80%.

4 CONCLUSION

The previous dissolution of the sodium silicate by acid leaching before the dissolution of the zirconium, is already being used industrially, however the drawback of this route is the high water consumption, as water plays an important role in the sustainability of the environment. The route of zirconium leaching without the prior leaching of sodium silicate has the advantage of demanding lower water consumption besides saving one step in the purification of zirconium.

The leaching experiments showed that the direct acid leaching (new route) was able to obtain a good zirconium and silica separation. As shown in these results, the zirconium dissolution increased considerably when compared with previous experiments.

ACKNOWLEDGEMENTS

The Authors are grateful to FAPEMIG, FINEP, CNPq and CAPES for the financial support and also would like to thank CDTN's technicians involved in this study, mainly Luiz C. da Silva and Liliane P. Tavares.

ABSTRACT Lithium extraction from a lepidolite concentrate was studied by roasting in the presence of the additives S+CaO or FeS+CaO and subsequent leaching by water. Thermodynamic models were used to forecast the dependence of the roasting process on various parameters (e.g., temperature, molar ratios of S/Li and Ca/F). Simulations and preliminary experimental results showed that various Li-compounds (e.g., $LiKSO_4$, Li_2SO_4) were formed and that SO_2 and SO_3 played a significant role in lithium liberation. Moreover, addition of Fe seems to greatly benefit lithium extraction: roasting in the presence of S+CaO and FeS+CaO resulted in extraction of up to 23.1% and 75.4% Li, respectively. The absence of Fe during roasting appears to cause formation of spodumene ($LiAlSi_2O_6$) and eucryptite ($LiAlSiO_4$), which could hinder formation of other, water-soluble lithium compounds. Addition of CaO led to a decrease in the liberation of HF gas.

Keywords: Lepidolite, lithium, roasting, leaching

1 INTRODUCTION

Lithium, the lightest metal, is used for many industrial applications, such as electric vehicles, batteries, ceramics, glass, lubricating greases, air treatment, metallurgy, polymers, pharmaceuticals, and primary aluminum production. The global total demand of lithium in industries has been increasing every year. The world total of mine production in 2011 was 34100 million tons, increasing to 37000 million tons in 2012 (USGS 2013).

Lepidolite sulfation during the roasting process has the purpose to form new Li compounds, which dissolve in water. Prior experimental work confirmed the efficiency of this method by using lepidolite in combination with various compounds: Na_2SO_4, K_2SO_4 and CaO (Yan et al 2012b), Na_2SO_4 and CaO (Luong et al 2013); $FeSO_4.7H_2O$ and CaO (Luong et al 2014), and Na_2SO_4 + $CaCl_2$ (Yan et al 2012a).

The present study investigates the effects of using S and FeS with CaO as the additives for roasting lepidolite and reports preliminary results.

2 EXPERIMENTAL

2.1 Material

The lepidolite (1.55 wt. % Li) used in this study was collected in the La Vi area, Quang Ngai province, Vietnam, where it occurs a major component of an albite granite. Chemical and mineral compositions of the lepidolite concentrate are shown in Table 1 and Figure 1.

2.2 Equipment and Chemicals

Major components of the concentrate and leach liquors were determined by X-Ray Fluorescence (XRF) and atomic absorption spectroscopy (AAS), respectively.

Table 1. Chemical composition of lepidolite (wt. %)

SiO_2	Al_2O_3	Fe	Mn	Mg	Ca	Na	K	Cs	Rb	Li	P	F
54.67	25.10	0.25	0.39	0.6	0.71	1.16	6.82	0.063	0.8	1.55	0.12	2.91

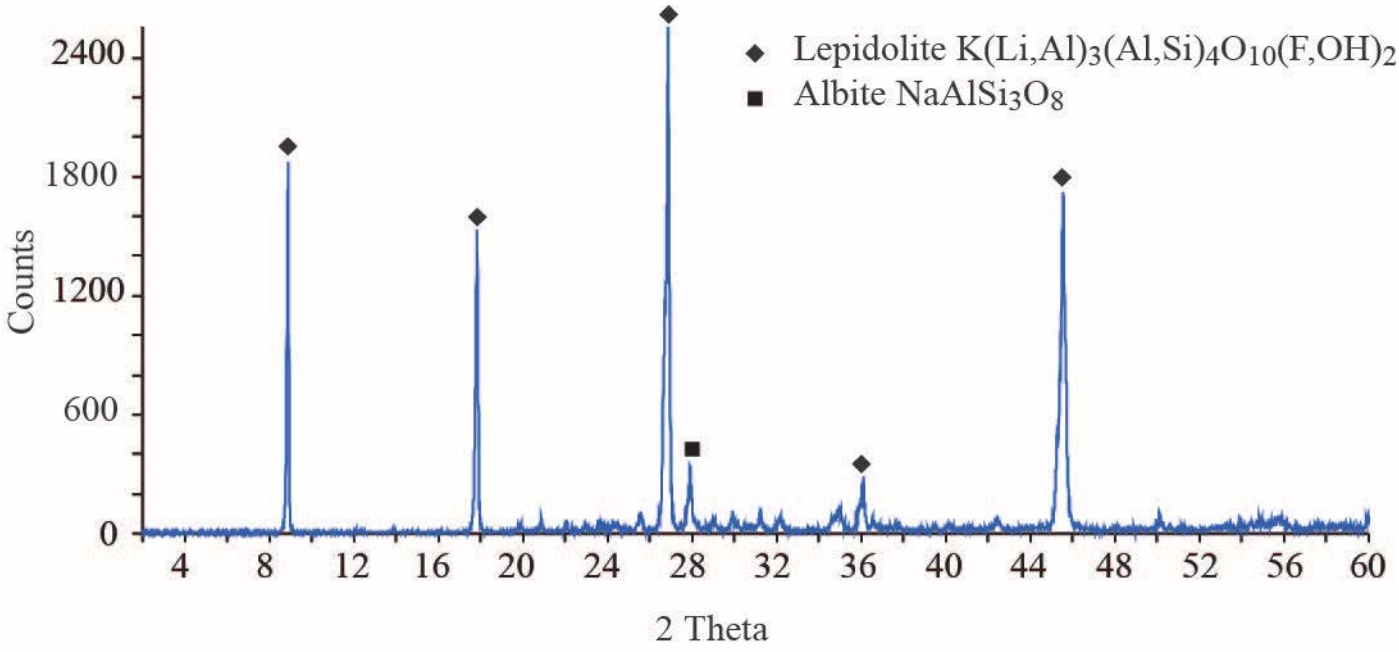

Figure 1. XRD pattern of lepidolite

Minerals contained in the lepidolite concentrate were identified by X-ray diffraction (XRD), followed by Rietveld refinement using the BRUKER Topas 4.2 software.

Roasting tests were carried out in a tube furnace with a gas supply system, whereas leaching was conducted by using hot plates with magnetic stirring bars.

All chemicals used were of analytical grade and were purchased from Merck and Alfa Aesar.

2.3 Experimental Techniques

The lepidolite and the additives were first mixed at specified molar ratios of S/Li and Ca/F. The mixtures were then placed in the furnace for roasting at various temperatures and durations. Calcines obtained after roasting were cooled down to ambient temperature, followed by being finely ground. The pulverised calcines were subsequently leached in distilled water at different temperatures, mass ratios of water/calcine and time. The flowchart of the process is illustrated in Figure 2

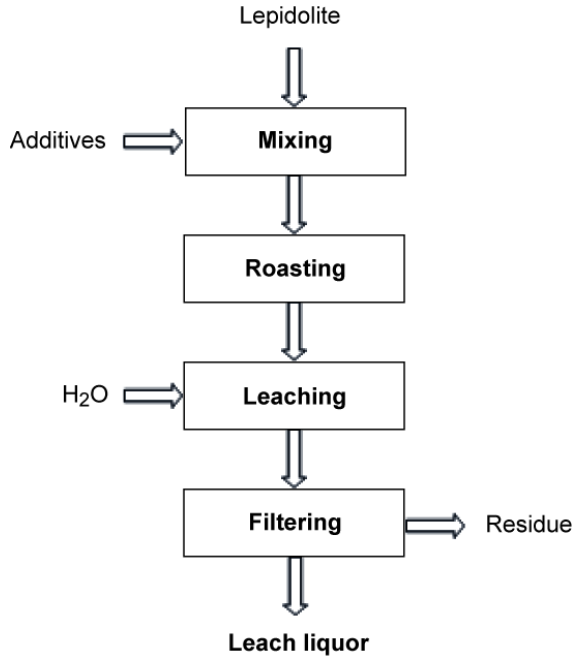

Figure 2. Flowchart of lepidolite processing.

3 RESULTS AND DISSCUSSION

3.1 HSC Modelling

The outcome models of roasting lepidolite and the additives simulated by the HSC software (Outotec 2011) were shown in Figure 3. Roasting lepidolite with the mixture of S and CaO resulted in $LiKSO_4$ and Li_2SO_4 as major solid compounds with a minor amount of $LiAlSiO_4$. A similar result was also indicated when FeS was used, but in addition other compounds of Fe including Fe_2O_3, Fe_2O_3(G), $LiFeO_2$ were created. In both cases, high quantities of SO_2 and SO_3 were liberated in parallel with the presence of HF and LiF gases. Luong et al 2014 suggested that SO_2/SO_3 formed during the decomposition of $FeSO_4.7H_2O$ played a key role in the extraction of lithium from lepidolite based on HSC modelling and LOI (loss on ignition) obtained from experiments. Similarly, roasting lepidolite with S or FeS would also create SO_2/SO_3 gases generated through oxidation as observed in Figure 3. A gas-solid interaction of the gases with lepidolite was therefore also believed to be a factor controlling the extraction of Li in the form of $LiKSO_4$ and Li_2SO_4 in this study.

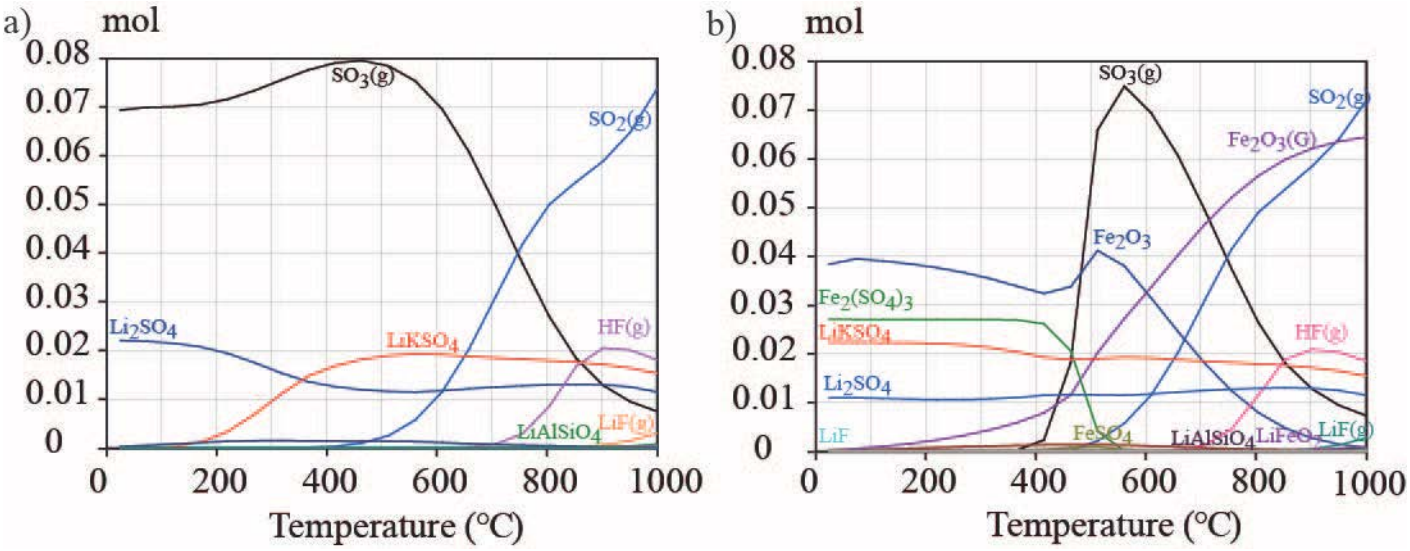

Figure 3. HSC models for roasting of a) lepidolite and S, b) lepidolite and FeS at S/Li molar ratio of 3/1. *Abbreviation*: G = gamma, g = gas.

3.2 Extraction of Lithium from Lepidolite

To investigate the role of SO_2/SO_3 gases on the extraction of lithium, both open and closed roasting systems were performed as described in Luong et al 2014. An S/Li molar ratio of 3/1 was applied for mixtures of the concentrate with S or FeS. There was an indication that roasting in the closed system at 800°C-950 °C resulted in ~5-16 % Li extraction when S was used as the additive. The recovery of lithium was sharply increased when S was replaced by FeS, in which case ~57 % of Li was extracted at 850-900 °C. However, using the open system for roasting of lepidolite and the additives could greatly enhance the amount of soluble lithium compounds created as well as reduce the amount of thermal energy required for the optimal extraction of lithium. As shown in Figure 4, a maximal Li recovery of ~75.4 % was attained at temperature of 750 °C after 1.5 h roasting using mixtures of lepidolite and FeS. Meanwhile, the improvement in Li extraction from lepidolite-S mixtures seemed to be negligible.

The effect of roasting manners on Li extraction seemed to be incompatible with that obtained from Luong et al 2014, in which roasting in the closed system yielded higher extractions of Li. However, the behaviour of S and FeS is different from $FeSO_4.7H_2O$ indeed. Heating of $FeSO_4.7H_2O$ could directly liberate SO_2 during its decomposition, which

subsequently interacts with lepidolite to release Li. In contrast, S and FeS first needed to be oxidised to form SO_2/SO_3 that required ventilation for a supply of oxygen.

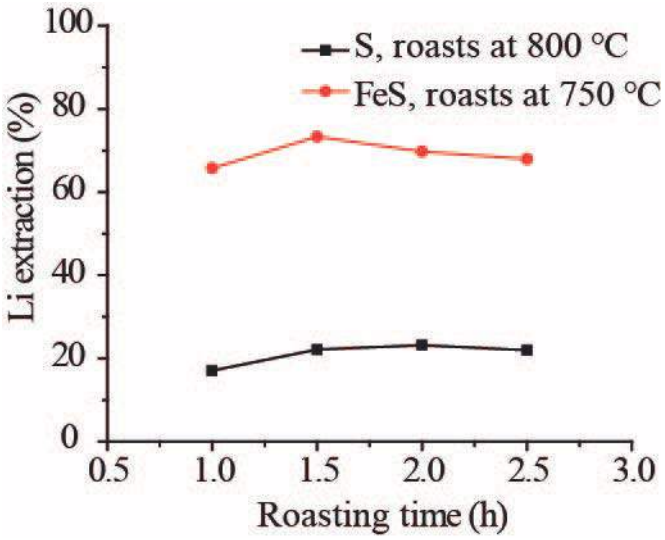

Figure 4. Effect of roasting time on Li extraction from lepidolite-S and lepidolite-FeS mixtures at S/Li molar ratio of 3/1. Leaching at 85 °C for 2h, using water/calcine mass ratio of 5/1.

On the other hand, the gases created could be rapidly lost before reacting with lepidolite if no cap was used to cover crucibles. As a result, the maximal extraction of Li, as obtained by Luong et al 2014 when iron sulphate was utilised, could not be achieved. Finally, roasting in the open system was more suitable for mixtures of lepidolite and either S or FeS.

The use of CaO as secondary additive during sulfation roasting of lepidolite lowers the amount of HF gas liberated due to the formation of CaF_2, as also reported by Luong et al 2014 and Yan et al 2012b. A Ca/F molar ratio of 1/1 was found to effectively decrease the liberation of HF gas with an insignificant influence on the lithium extraction in this study.

Microscopy and electron probe microanalysis (EPMA) were used to observe the external morphology of calcines obtained from roasting. Lepidolite seemed to be slightly decomposed when being roasted with S. Only the rim of lepidolite particles was metamorphosed during roasting while their surfaces were contaminated by the additives (Fig. 5a). In contrast, lepidolite was obviously affected by FeS, causing a conversion to new compounds as shown in Figure 5b.

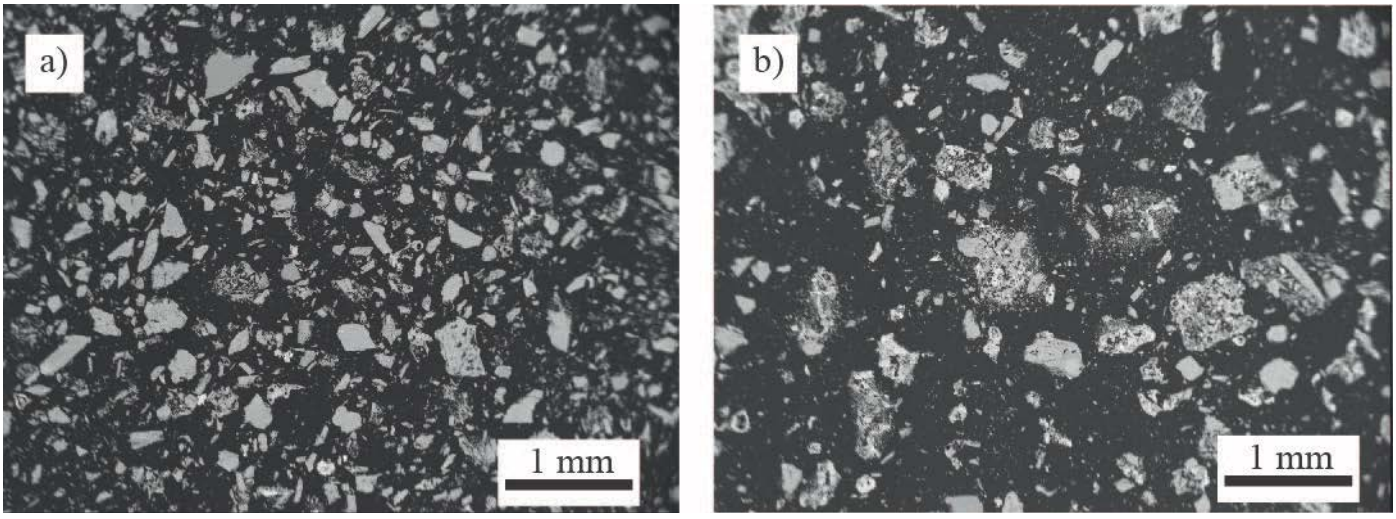

Figure 5. BSE images of calcines roasted at S/Li molar ratio of 5/1 and a) at 800 °C for 2h using S, b) at 750 °C for 1.5h using FeS.

XRD patterns of calcines obtained from roasting of lepidolite and the additives using the optimal conditions are shown in Figure 6. It was noticeable that lepidolite was still present in the calcine after roasting with S as seen by its clear peaks (Fig. 6b). Other compounds such as CaF_2 and $CaSO_4$ were formed due to the addition of CaO.

Meanwhile, lepidolite seemed to have completely disappeared when FeS was utilised, resulting the dominance of Fe_2O_3 peaks (Fig. 6c). The existence of Li_2SO_4 and $LiKSO_4$ in the calcines was also found, but these phases exhibit poor crystallinity. Thus, the effectiveness of FeS compared to S on the extraction of lithium from lepidolite was evident.

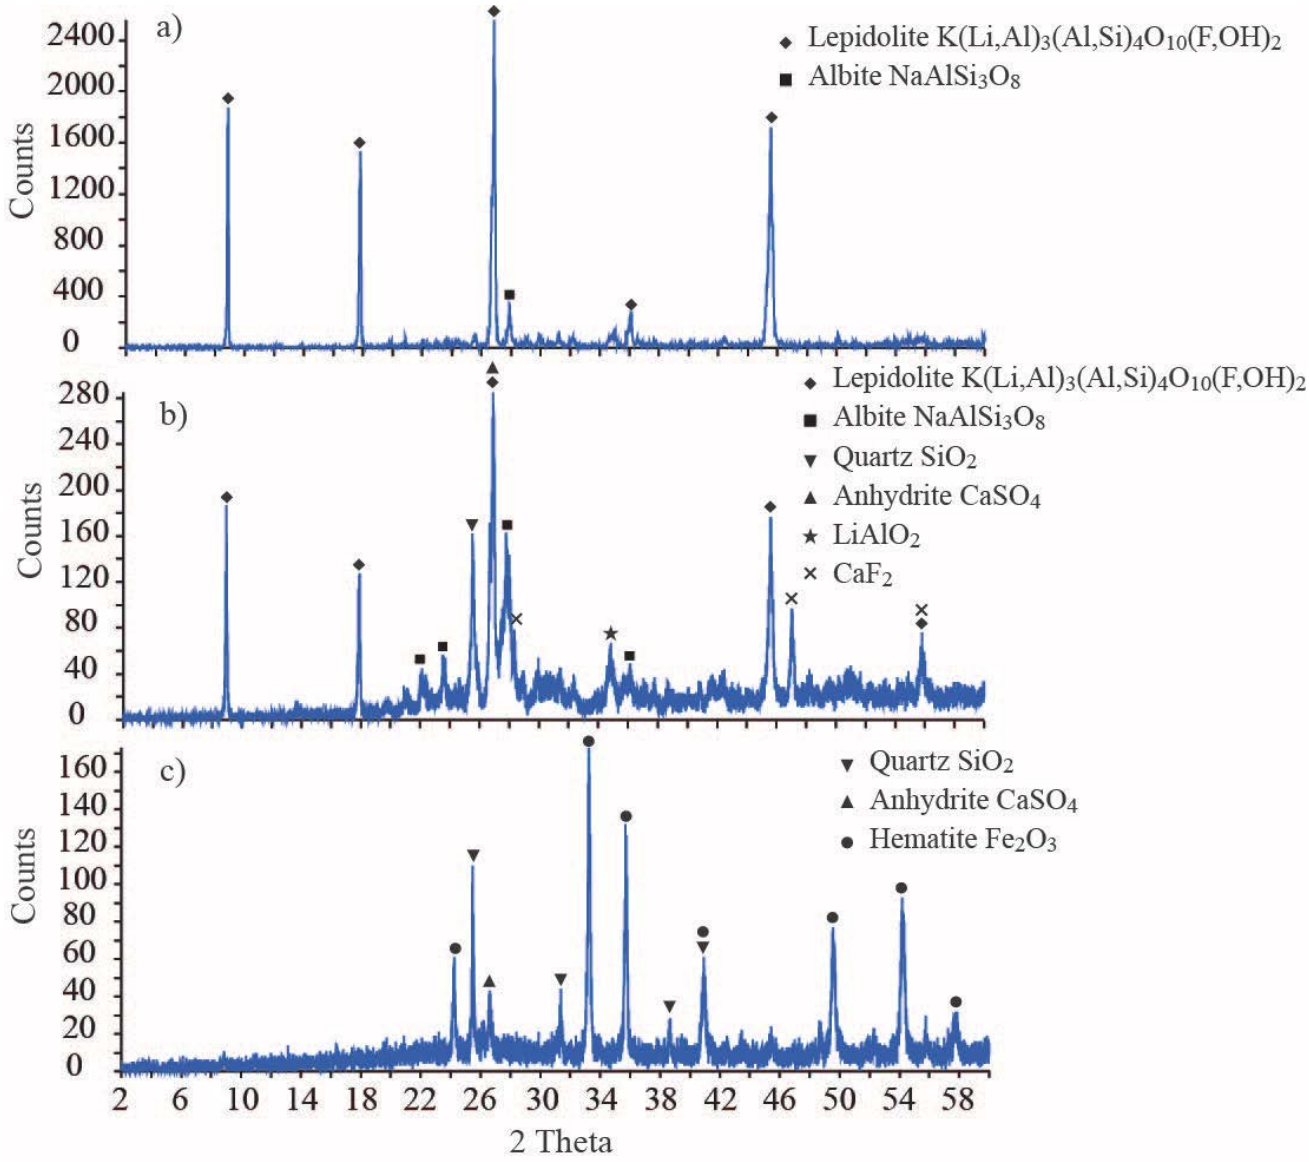

Figure 6. XRD patterns of a) lepidolite, b) calcine at 800 °C for 2h using S, c) calcine at 750 °C for 1.5h using FeS. Roast using S/Li molar ratio 5/1.

4 CONCLUSIONS

The extraction of lithium from lepidolite via sulfation roasting and water leaching was experimentally performed based on HSC thermodynamic models. It was found that using FeS as the additive could extract a maximum of ~75 % Li from lepidolite in the open roasting system. Sulphur (S) was found to be an unsuitable additive for the recovery of Li due to a low extraction obtained (~23 %). The usefulness of FeS compared to S was confirmed by EPMA and XRD. The role of CaO in lowering the formation of HF gas was also tested.

5 ACKNOWLEDGEMENTS

Comparison of Two Consolidation Methods of Waste Fill in Longhole Open Stoping

S.B. Avcı, İ. Erdem
Eldorado Gold, Efemcukuru Gold Mine, İzmir, Turkey

ABSTRACT: Longhole Open Stoping and Drift & Fill are commonly utilized mining methods in underground metal mines in Turkey. Both of these methods are employed at Efemcukuru Gold Mine. The primary mining method of Efemcukuru Gold Mine is drift and fill due to being appropriate for selective mining. As a secondary mining method, longhole open stoping is used because of its high production rate, low dilution and low operating costs. In this method, standard drilling-blasting and material handling operations are utilized as indicated in the technical methodology. Also the backfilling stage can be changed according to the stope conditions. Generally paste fill is used in backfilling operation at Efemcukuru Gold Mine. However for longhole open stoping, the backfilling operation is generally done by waste fill material in order to disposal of development waste.

The purpose of this paper is regarding the usage of waste fill material in the longhole open stoping method. Subsequently this requires a suitable consolidation method of the waste material in order to produce from the next stope.

Keywords: Longhole open stoping, drift and fill, Efemcukuru Gold Mine

1 INTRODUCTION

Efemcukuru Gold Mine is located approximately 20 km southwest of İzmir/Turkey as one of the ongoing operations of Eldorado Gold Corporation (Fig. 1). Efemçukuru is an intermediate sulfidation epithermal gold deposit hosted within Upper Cretaceous phyllite and schist at the western end of the Izmir-Ankara Suture Zone in SW Turkey.

Figure 1. Location of Efemcukuru Gold Mine.

The orebody is crosscut by hornfels, phyllites and rhyolite dikes. The primary vein is the Kestane Beleni which is the focus of ore production in the first step of the mine life. The secondary vein is known as Kokarpinar that outcrops approximately 450m northeast of the Kestane Beleni Vein (Fig.2). There are three types of orebody generated inside the Kestane Beleni vein, which are South Ore Shoot (SOS), Middle Ore Shoot (MOS) and North Ore Shoot (NOS).

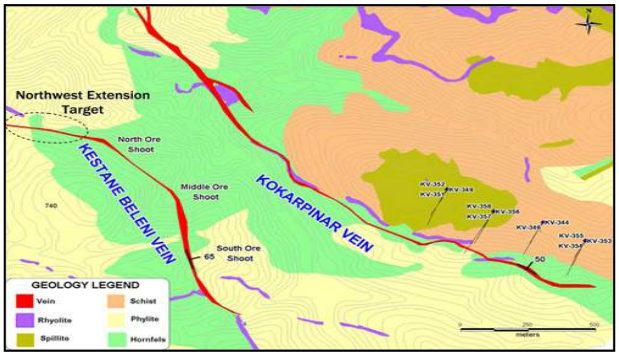

Figure 2. Geological Map of Efemcukuru Site.

2 MINING METHODS

There are mainly two underground mining methods based on 100% extraction with minimum or no dilution. These are the drift & fill and the longitudinal longhole open stoping mining methods. The Drift & Fill mining method is used as the primary mining method since it enables selective mining. As a secondary mining method, longitudinal longhole stoping is used where suitable ore and host rock properties are available. Important factors for selecting the mining method can be listed as below;

- Orebody characteristics; size, shape, dip angle, strike
- Host rock conditions; RQD, ground support requirements, structures
- Grade of ore, mining dilution and recovery

Level by level these factors are analyzed to determine the appropriate mining method. The decision of the mining method for a level is carried out by the long term mine planning engineer and designs are kept up-to-date annually as part of the life of mine process.

2.1 Drift & Fill Mining Method

The Efemcukuru Gold mine employed drift-and-fill mining method as the primary ore production method. The Kestane Beleni vein is the current working orebody and has varying thickness throughout its strike. Drift and fill is a cost intensive method of mining that is done in areas where rock conditions are challenging (Fig. 3). Rather than opening a large excavation in soft rock conditions which may be difficult to hold, ore is taken out by a number of stopes that are mined along the ore strike and then filled with paste fill at the closure phase of the stop.

The orebody is accessed from three ramp systems from the footwall. The main levels are at 80 m vertical intervals with sublevels at 20 m. Footwall drifts are driven from the level accesses across to the orebody and crosscuts are driven from the footwall drives as lifts (C1, C2, C3, and C4) with approximately 45 m length and inclination of %17. The production stopes are driven approximately 5 m height and 4.5 m width. The shape of a stope generally follows the shape of the orebody, from which the side walls can be 55 to 60 degrees, angled according to the hanging wall inclination. The length of the sill drifts depend on the thickness of the orebody and its grade.

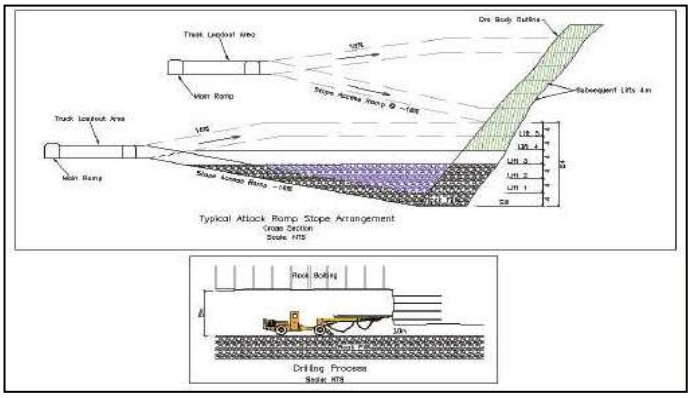

Figure 3. Sample Scheme for Drift & Fill Mining Method.

The average length of the production stopes is approximately 75 m from the crosscut to the left and right sides of the orebody, which indicates the interval between the crosscuts entrances from footwall drives. In the drift & fill mining method, the backfilling material is paste fill at all C1, C2, C3 and C4 lifts.

2.2 Longhole Open Stoping Method

The secondary mining method utilized at the Efemcukuru Gold Mine is longhole open stoping. The longhole open stoping method can be applied in stable footwall and hanging wall conditions, suitable vein dip and thickness. Vertical stope production comprises of the extraction of a 15 m height between two drifts.

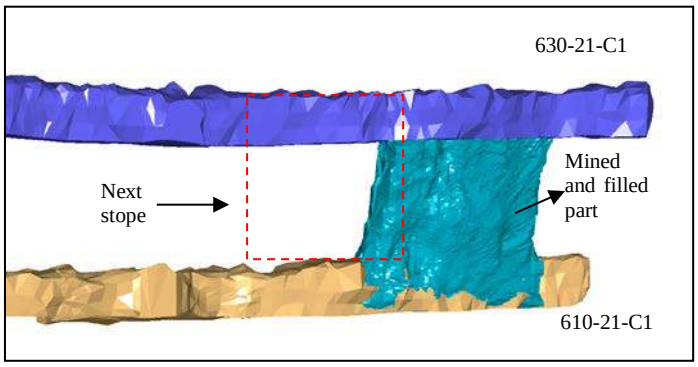

Figure 4. Longhole Open Stoping between 630-610 levels and the next stope to produce.

The minimum ore production width is 0.75 m and a maximum width of 6.5 m. In this mining method; first sill (C1) of the lower level and first sill (C1) of upper level are mined (Fig. 4). Then blast holes are drilled from C1 lower level to the upper level and blasted to create an initial opening named "slot". The slot is often the most difficult, and costly component of mining. After blasting the stope, the rest of the orebody is blasted towards to the slot void. Then, remote control LHDs muck the blasted material from the lower level. After the drilling-blasting and mucking operations, the filling takes place before commencing the initial stage of the adjacent stope. At Efemcukuru Gold Mine, the longhole stopes are generally filled with waste material for disposal of development waste.

Consolidation of the filled void is critical to provide a stable area and to prevent dilution when producing from the next stope.

3 FILLING AND CONSOLIDATION OPERATION OF MINED LONGHOLE STOPES

As the final step of the longhole open stoping method, waste fill is used as backfill material in the stope void. Waste fill is a loose rock material (generally from capital development) and has the potential to dilute future stopes. In order to consolidate the waste material to prevent dilution, two methods have been applied; (i) cement grouting with self-drilling bolts and (ii) consolidation of waste material by shock blasting.

3.1 Consolidation with Grouting Bolts

In Figure 4, the waste filled stope is indicated as the blue color and prior to commencing the ring blasting of the next stage, the filling material of the previous void must be consolidated. This process is undertaken by self-drilling bolts which are named "IBO Bolts". These bolts have sacrificial 51mm bits that enable grouting while drilling (Figure 5).

Self-drilling bolts are used for consolidation or reinforcement of loose material.

Figure 5. IBO Bolts Used in Consolidation Process.

The main applications of self-drilling anchors are slope stabilization, foundations with micropiles, and tunneling. In this operation, 2 m R32 bolts are used with couplings to extend the bolts to the lower level. The drilling length is varied, from 12 - 21 meters, therefore bolt usage also varies from hole to hole.

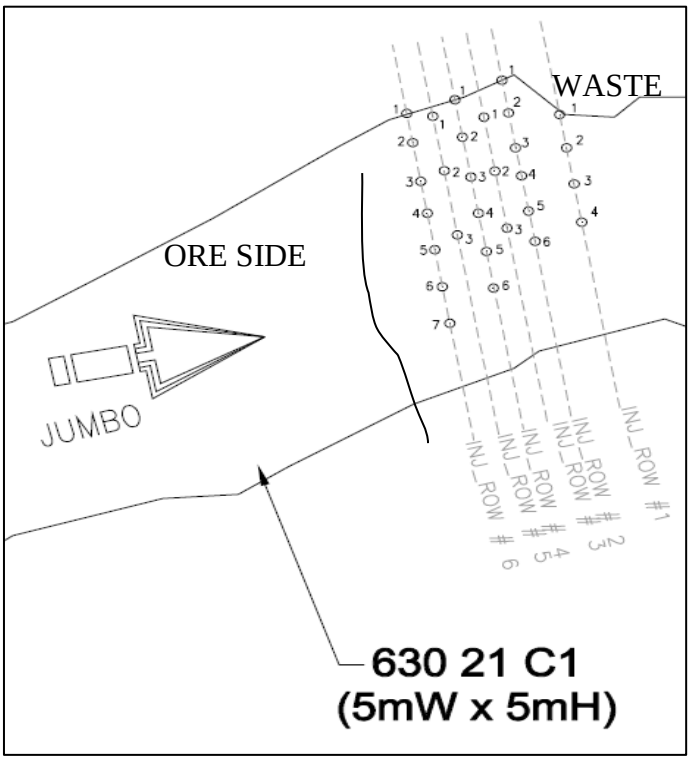

Figure 6. Upper Level Injection Row Plan.

The consolidation operation is designed with six rows of injection holes on the waste fill material (Figure 6). These rows are designed by slicing the solids of the upper and lower levels, and the solids of the cavity measurement (CMS) of the produced stope.

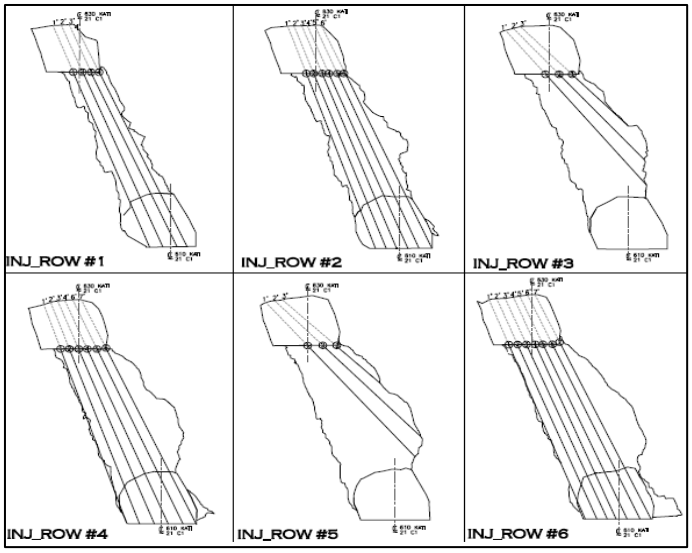

Figure 7. Row Designs, Section View

Injection rows commence from one meter behind the waste fill boundary at the waste side and with the exception of the first row, the interval between rows are designed as 0.5 m (Figure 7).

Self-drilling bolts are applied with jumbo, drilling and grouting is undertaken simultaneously with the use of an adapter attached to the jumbo drill rig and connected to a grouting pump (Figure 8).

Figure 8. Adapter attached to jumbo drill and connected to a grouting pump that sends grout into bolts while drilling.

Cement, self-drilling bolts, sacrificial bits and couplings were used as main consumables of the operation. For grouting; 720 liters of water and 1,000 kg of cement mixture is used for each hole.

Firstly, the jumbo drills the injection hole and simultaneously the grouting mix is pumped inside the hole. After each bolt, a coupling is placed and a bolt is attached to the coupling and the drilling-grouting operation resumes. While drilling continues, only rotation is applied due to working in loose ground. Bolts are inserted into the waste by grouting a row of injection holes, making a consolidated wall at the boundary of the waste fill/ore face.

Each hole is calculated to consume approximately 1,500 kg of cement to attain the required strength for a stable wall. In the first trial of this method, completing the injection drilling task took 14 shifts. In addition, at least four laborers were required to carry out the operation.

Figure 9. Finished consolidation work.

In figure 9, the completed view of the consolidation work is shown. In the figure, the solid wall contact is observed after the first blasting of the adjacent stope. In this operation, the consolidation of the waste fill material reduced the dilution percentage of blasted waste material.

3.1.1 Cost calculation

The cost of the operation is calculated and shown at Table I below (excluding labor).

Table 1. Cost Calculation of Grouting Bolts Method.

	Number of Holes	Number of Bolts	Coupling ea.	Bits ea.	Cement (ton)
Row1	4	40	36	4	6
Row2	6	60	54	6	9
Row3	3	18	10	3	3
Row4	6	60	54	6	9
Row5	3	18	10	3	3
Row6	7	70	63	7	10
TOTAL	29	226	227	29	40
Total IBO Bolt Set Cost			$		4,750
Total Cement Cost			$		5,700
TOTAL COST			***$***		***10,450***

3.2 Consolidation with Shock Blasting

The second method for consolidation of waste fill is the shock blasting method. In this method, only one row of holes is blasted to create shock on waste fill. This method designed to utilize elasticity of the waste fill structure. Before dumping the waste to the stope void, the method needs two different stoppers at the lower sill (Figure 10).

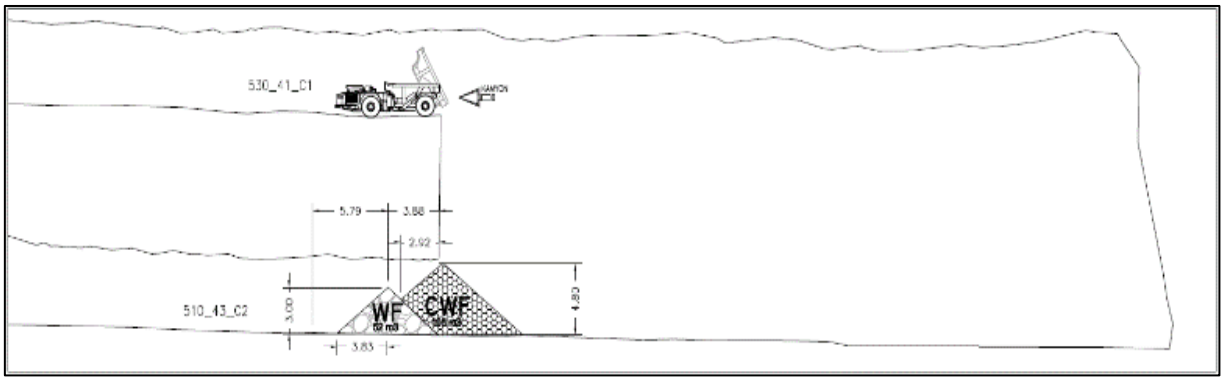

Figure 10. Providing stoppers.

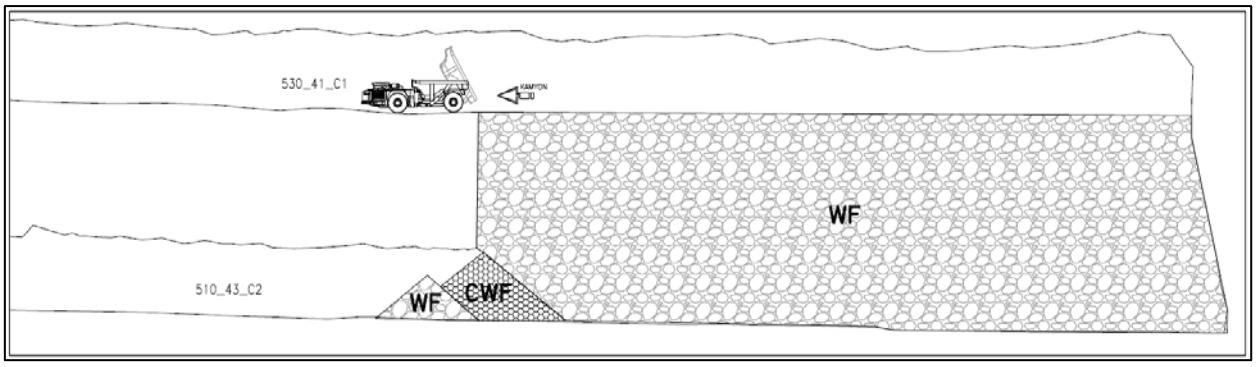

Figure 11. Filling with waste material.

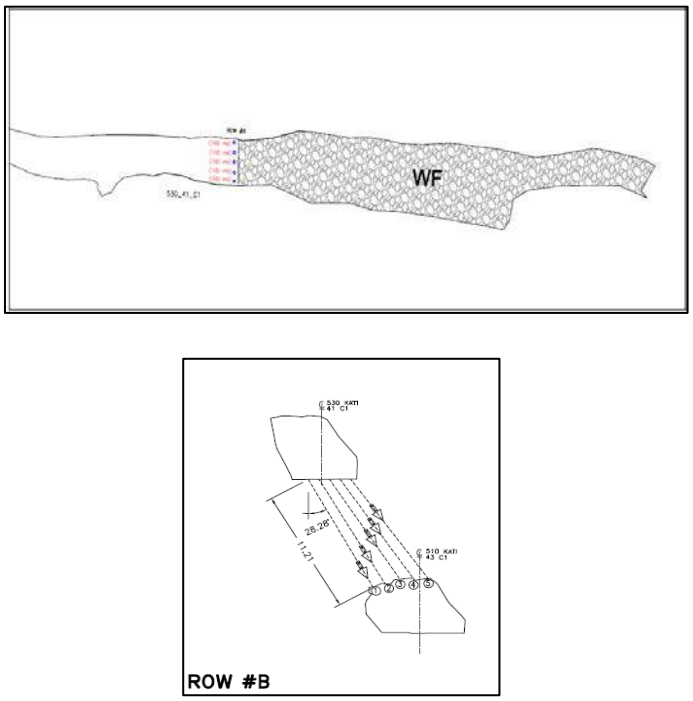

Figure 12. Blast hole design.

Illustrated at Figure 10, approximately 50 tons of 8% cemented waste fill (CWF) is pushed to the drawpoint of the stope void by remote control loader. Then a 3 m height of waste is dumped near the cemented waste fill. These two stoppers will prevent waste fill contamination at the lower level when blasting takes place.

Waste fill dumping starts from the upper level when the stopper construction is completed (Figure 11). Blast holes are drilled with an 86 mm diameter within 50 cm from the boundary of the ore and waste fill. The drill holes are drilled on the ore side.

Similar to the consolidation with grouting drill holes method, one blasting ring is designed by slicing the solids from the upper level, lower level and the solid of the orebody (Figure 12).

Drilling takes place over 2 shifts with the assistance of two laborers. Following the drilling, each hole must be stemmed with sand approximately 30 cm from the bottom and the top. Then the rest of the hole will be filled with ANFO after inserting the primer. In addition, each hole must blast at the same detonation sequence to break 50 cm thickness of ore and create an efficient shock effect towards the waste material.

After blasting the ring, an opened free slot surface must be covered with 20cm. thick shotcrete with the use of a SprayMec nozzle (Fig. 13).

In Figure 14, the completed view of consolidation work is shown. In the figure, the solid wall contact is observed after the shock blasting.

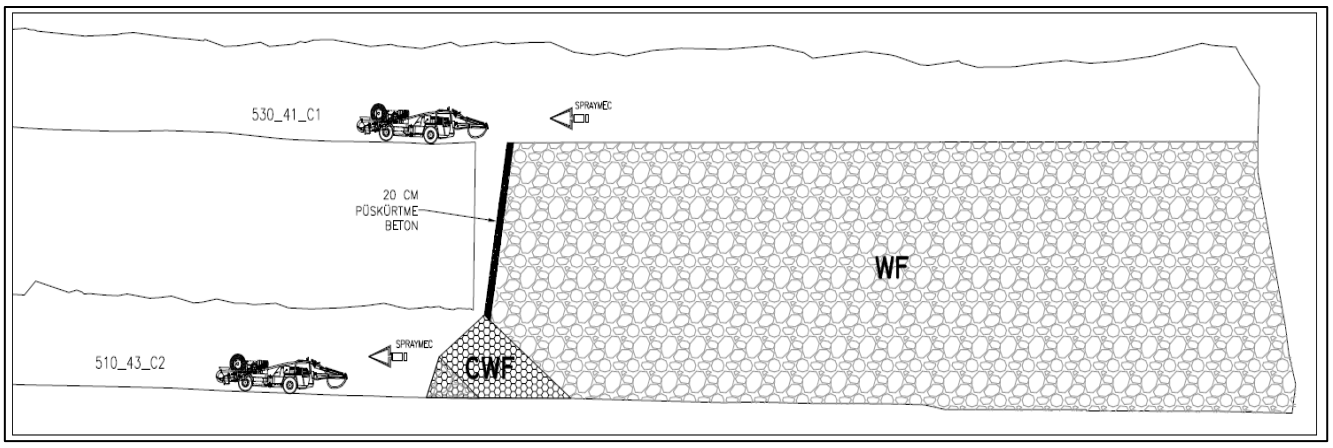

Figure 13. After blasting opened free surface must be cover with shotcrete.

3.2.1 Cost calculation

The cost of the operation is calculated and shown at Table II below (excluding labor).

Table 2. Cost Calculation of the Shock Blasting Method.

	Number of Holes	ANFO (KG)	Cement (ton)
RowB	5	225	3
Total ANFO Cost			$ 190
Total Cement Cost			$ 450
TOTAL COST			$ 640

Figure 14. Finished consolidation work.

4 CONCLUSIONS

Both of the consolidation methods were successful at their first trials. All of them give a stable working area in waste filled long hole stopes. As it is shown in the cost tables; the cement grouting method is timely, costly and more labor intensive job compared to the shock blasting method.

The shock blasting method is more cost effective, however it has the disadvantage of increased dilution to the ore at the initial blast.

ABSTRACT In this study, roasting and leaching of copper converter slag was carried out and the effects of their significant parameters were investigated. Minitab programing was put to use in design and analysis of these experiments. In roasting experiments the results show that roasting temperature has the greatest influence on solubility of Copper, while roasting time and grain size are in second and third place. Roasting slag with 237μ average grain size in 600 ° C with duration of 90 minutes was the best case of roasting. It resulted in 75.3% Copper recovery after leaching. Then in second stage, for obtaining optimum leaching parameters, all samples were prepared under previously mentioned roasting parameters and then went through leaching as its parameters were being manipulated. Best case was achieved when leached in boiling 150 gr/L acid, with L/S=10 and leaching time of 45 minutes which leads to Copper recovery of 92.2%.

Keywords: Roasting of copper, leaching of copper, optimization

1 INTRODUCTION

Copper is one of the earliest metals extracted by humans. As the time went by, it became more strategic and significant and today it has a wide spectrum of usage from simple ones like tools to the more complicated ones in the electrical and technological industries. The conventional method to extract Copper from sulfide ores using pyro-metallurgy have been used for decades and there are various furnaces with different percentages of copper in their products available for this mean. Slags from Inco Flash smelting contains <1% Cu, convertor slag 5% Cu, Noranda continuous submerged-tuyere converting 10% Cu, Mitsubishi top blown converting 14% and Outokumpu flash converting 20% Cu(W.G. Davenport, M. King, M.Schlesinger, A.K Biswas).

Nowadays, world faces lack of copper resources and even the remaining ones have very little amount of Copper (Less than 2%) while there are many secondary sources (copper slags) which were remained from pyrometallurgy furnaces mentioned above.
Recycling copper converter slag back to the flash furnace has been practiced in some plants and it leads to an increase in the matte grade (Antonioniet al., 1982). Dissolution behavior of Co, Cu, Fe, Ni, and Zn from smelter slag in aqueous sulfur dioxide has also been studied (Ahmed et al., 2000). Ausemelt top entry submerged lance technology is also used to recover Cu, Ni, and Co from slags (Hughes, 2000; Vernon and Burks, 1997). In some plants, flash smelting furnace slag (1.6–2% Cu) and converter slag (5–7% Cu) are cleaned in an

electric arc furnace, where coke is used as reductant and copper content of waste slag decreases to 0.5-0.8% (Kim, 1982, Suziki et al., 1982).

The purpose of this project was investigating of optimum parameters of roasting and leaching for slags from convertor of Non-Ferrous Metals Recycling Company of Rafsanjan (RFNR.CO). At first these slags were roasted and then were leached in Sulphuric acid solution. The effects of important parameters such as grain size, roasting time, roasting temperature, leaching time, leaching temperature, acid concentration and the liquid to solid ratio (L/S) on the copper recovery was determined by use of Minitab statistical computer program.

2 EXPERIMENTAL

2.1 Material

The slag sample used in this investigation came from convertor of Non-Ferrous Metals Recycling Company of Rafsanjan (RFNR.CO), which its important consisting elements are shown in Table 1 and Table 2 with two different micron average sizes.

As it can be seen, the mentioned slag has considerable amount of Cu and even Re which is a very valuable and expensive element as a rare metal.

2.2 Crushing and Grading

The crushing of slag was performed many times with three different crushers includes jaw crusher, cone crusher and roll crusher, and then was graded in to 8 categories.

Table 1. Important elements from XRF analysis for micron average size 237.

Element	Weight Percentage
Re	0.082
Al_2O_3	14
ZnO	2.25
NiO	0.28
Co_3O_4	0.032
CaO	11.1
SiO_2	34
MgO	8.7
Fe_2O_3	16.9
CuO	5.7

Table 2. Important elements from XRF analysis for micron average size 547.

Element	Weight Percentage
Re	0.091
Al_2O_3	14.1
ZnO	2.15
NiO	0.27
Co_3O_4	0.029
CaO	11.4
SiO_2	35
MgO	8
Fe_2O_3	16.7
CuO	5.4

2.3 Roasting of the Slag

Three different average grain sizes and four various roasting temperatures were given to Minitab statistical computer program as input. The result was 12 unique tests. Time of roasting was also considered as another parameter, so every mentioned test of Minitab result carried out in 9 various times, consequently, the total tests raised up to 108. For every test 20 gr of slag with a specific grain size average was poured into a stainless steel 316 container put into furnace with desired temperature and favorable time duration.

2.4 Leaching of the Slag

Leaching tests were designed to investigate the effect of acid concentration, liquid to solid ratio (L/S), leaching time and leaching temperature on the Copper recovery. By using the existing relation equations in the solution making, the required volume of solution (mixture of H2SO4 and distilled water) with specified concentration was poured into a beaker. The beaker was put on a hitter- stirrer so that its solution reaches to the desired temperature. Then the roasted slag and a magnet were added to solution and this time was considered zero time. Aluminum foil was also used to prevent vaporization. The leach liquor has been smoothed completely afterwards. In the end the final smooth solution was analyzed for Cu by titration and Fe by Atomic Absorption Spectroscopy (AAS).

3 RESULTS AND DISCUSSION

3.1 Effects of Roasting Parameters and Grain Size

The roasting process was conducted with slags included average grain sizes of 237, 392 and 547 µ. They each were roasted under temperatures 150, 300, 450 and 600 ° C with durations of 5, 10, 15, 20, 30, 45, 60, 90 and 120 min. 10 gr of each batch were leached under the same condition, 100 mL of Sulfuric acid solution with concentration of 100 gr/L.

It needs to be pointed out that solubility of Fe was very high (60- 97%) and also irregular, so, it was eliminated in consideration for optimizing the parameters. In conclusion, only the solubility of Cu is being considered as an important factor. Percentage of Copper solubility was calculated not according to the whole amount of Cu in the slag but based on dissolved Cu in the observer solutions. These amounts can be observed in table 3.

All leach specimens were analyzed and the results were compared for optimization of roasting parameters and grain size by use of Minitab software. Fig 1 shows the effect of grain size, roasting temperature and roasting time on solution of copper.

Generally, increasing of the temperature caused in enhancement of copper solubility. Usually roasting time increased copper solubility as well but recovery reached its peak at 90 and not 120 min. In most cases increasing grain size at first decreased and then increased solubility percentage of copper so effect of grain size is periodic and minimal. In conclusion it can be said that effect of temperature was more sensible and important than two other parameters.

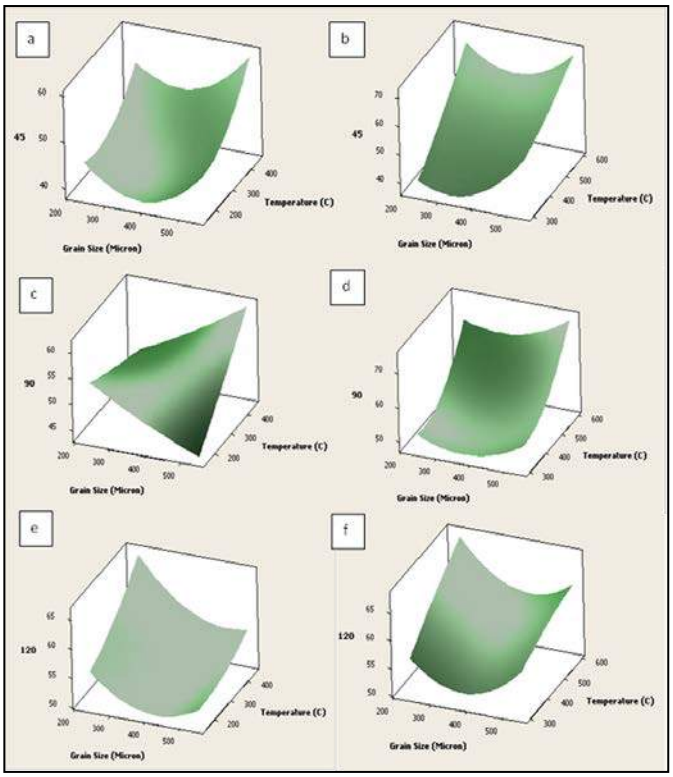

Figure 1. Effect of grain size, roasting time and temperature on solution of Cu:
a) 150 to 450 ° C and 45 min
b) 300 to 600 ° C and 45 min
c) 150 to 450 ° C and 90 min
d) 300 to 600 ° C and 90 min
e) 150 to 450 ° C and 120 min
f) 300 to 600 ° C and 120 min

With all considerations, the best copper recovery was obtained when roasting slag was performed with 237 µ average grain size in 600 ° C with time duration of 90 minutes which was equal to 75.3%. It is worth mentioning that the same average grain size of slag with the same condition of leaching, just without roasting, resulted into 45% copper recovery which obviously shows the importance of roasting process.

Table3. Amount of total Cu and soluble Cu in slags with various grain sizes.

Average Grain Size (µ)	Total Cu in slag (%)	Total Soluble Cu in slag (%)
237	5.7	4.9
392	-	5.2
547	5.4	4.7

3.2 Leaching in High Acid Concentrations

The optimum condition of roasting was considered for the rest of the experiments. As mentioned the slag with average grain size of 237 µ that was roasted in 600 ° C furnace as long as 90 minutes was selected and a set of experiments was designed for investigation of the leaching parameters.

Slag samples were leached in acids with 120, 150 and 180 gr/L concentration with liquid to solid ratios of 4, 7 and 10 which initially made 9 tests. Also time of leaching parameter was added by pulling out an approximately homogenous (same initial ratio of liquid to solid) leach liquor from the beaker with a syringe at times of 1, 5, 10, 15, 30, 45 and 60 min. The final 63 samples were analyzed for Fe and Cu and were compared together in order to optimizing leaching parameters.

Some of the samples in those 63 cases were observed in gelatinous state. This could be because of excessive leaching time and acid concentration which activated slag's consisting silica and solution of silica was the reason of the mentioned problem in 63 cases. In the end sample derived from leaching batch of 150 gr/L acid concentration, L/S=10 and leaching time of 45 min had highest copper recovery of 92.2%.

4 CONCLUSIONS

Primary lab-scale results show that an intensive Pyro metallurgical slag treatment before hydrometallurgical process leads to a further cleaning rate of the copper in copper slags.

This study has surveyed the effect of several parameters such as time of roasting, grain size, roasting temperature, acid concentration, ratio of liquid to solid and leaching time by use of MiniTab statistical computer program.

In conclusion, it was found that changes in grain size had no clear trend, and had staggering effect on copper recovery. With increasing in acid concentration and leaching time to the time which do not form silica gels in solution, usually copper recovery increased that was equal to 92.2%.

ABSTRACT In this investigation, the extraction of copper from converter slag via a pyro-hydro metallurgy process was statistically evaluated during a two-step roasting -leaching process. The optimum conditions for roasting including the average particle size, time and temperature, were determined and employed for all slag samples; then a leaching plan with low acid concentration with aim of the lowest level of iron and relatively high copper level, was examined. Optimum leaching parameters were also proposed as: liquid to solid ration (L/S) of 8, acid concentration of 45 g/L and temperature of 30°C. Under these conditions the recovery of copper was ~41%.

Keywords: Copper slag, leaching, acid concentration, L/S, Minitab, RSM.

1 INTRODUCTION

Steady depletion of the world's primary copper sources has led to secondary copper processing.

One of the most important secondary sources of copper is smelter slags. There are some hydrometallurgical methods presented in the literature for the treatment of slags, such as leaching in nitrate, perchloride, chlorate and sulfuric acid, ferric chloride, cyanide, ferric sulfate, and ammonia solutions (Lindblad & Dufresne 1974). Dissolution behavior of Co, Cu, Fe, Ni, and Zn from smelter slag in aqueous sulfur dioxide was also studied (Ahmed & Gbor & Ji 2000). Due to the amorphous structure of smelter slags, they cannot be efficiently leached with sulfuric acid and the formation of silica gel leads to difficulties for pulp filtration and crud formation during solvent extraction. However, this problematic issue could be overcome by the addition of hydrogen peroxide into the system (Banza & Gock & Kongolo 2002).

Acid roasting of slags followed by hot water leaching was also carried out to bring the metal values into solution (Arslan & Arslan 2002).

Roasting of the slag with sulphuric acid (Arslan & Arslan 2002, Sukla & Panda & Jean 1986), ammonium sulphate (Sukla & Panda & Jean 1986), ferric sulphate (Altundogan & Tümen 1997) or under reducing conditions prior to acid leaching (Anand & Das & Jena 1981) roasting of the slag under reductive conditions to produce Cu–Co–Fe–Pb alloy, electrolytic dissolution of the alloy in an ammonia-ammonium chloride solution, ammoniacal leaching of the slime and selective copper and Cobalt electrowinning (Rudnik & Burzyn´ ska & Gumowska 2002) was also reported in the literature.

In the present research, the slag obtained from the converter of Non-Ferrous Metals Recycling Company of Rafsanjan (RFNR.CO) was used. First the optimum parameters for particle size, roasting time and temperature were evaluated. Then tests were designed with low acid concentrations to minimize the solution of iron and give the best result in recovery of copper. Then the effect of L/S, temperature and acid concentrations was analyzed by use of Minitab statistical program.

2 EXPERIMENTAL

2.1 Material

The slag used in this study was obtained from convertor of Non-Ferrous Metals Recycling Company of Rafsanjan (RFNRCO). XRF analysis (Table 1) shows that mentioned slags have significant amount of CuO. The crushing of slag were carried out with three different crushers (jaw crusher, cone crusher, roll crusher) and then were graded in to 8 classes.

2.2 Roasting of the Slag

For this reason, 108 tests were designed by use of Minitab 15 using three different average particle size (237µm, 392µm and 547µm) at four roasting temperatures(150°C, 300°C, 450°C and 600°C), and different roasting times (5, 10, 15, 20, 30, 45, 60, 90 and 120 min). These tests were performed in a stainless steel 316 container.

Table1. Result of XRF analysis.

Sample no	Particle size	CuO (Wt%)
1	237 µm	5.70%
2	547 µm	5.40%

2.3 Leaching in High and Low Acid Concentrations

To evaluate the effect of acid concentration, liquid to solid ratio (L/S) and leaching temperature on copper recovery, 63 tests at high acid concentrations were designed. For this purpose, a mixture of H_2SO_4 and distilled water at the desired acid concentration was poured into a 100 ml beaker. To achieve the desired temperature, the beaker was put on a heater- stirrer and then the roasted slag was put into the beaker and a magnet was used for stirring. For low acid concentrations 18 tests were carried out with three factors at three levels by the principle of RSM using MiniTab 15 (Table 2.). Mechanical stirrer was used instead of magnetic stirrer. A stopwatch was used to measure the time of leaching. For prevention of vaporization, top of the beaker was covered with aluminum foil and distilled water was added periodically. After the completion of leaching, leach liquor was filtered.

2.5 Measurements and Analysis

The concentration of Cu and Fe was determined by Atomic Absorption Spectroscopy (AAS). It should be noted that due to the large number of tests, some of the Cu analysis were done by titration method using sodium thiosulfate.

3. RESULTS AND DISCUSSION

3.1 Effects of Roasting Parameters and Particle Size

According to the results obtained and their analysis by use of Minitab statistical computer program, as the temperature increase, copper recovery improves, and also the particle size has little impact on recovery of Cu. Best time for roasting of slag achieved at 90 minutes. Totally the effect of temperature in recovery of copper was greater in compare with particle size and time of roasting.

Table 2. Central composite design arrangement and responses (Cu and Fe dissolution concentration and recovery).

Sample no.	Central composite design arrangement			response (Cu and Fe concentration)		response (Cu and Fe recovery)	
	L:S	T	Acid	Cu (g/L)	Fe (g/L)	Cu Recovery %	Fe Recovery %
1	4	30	5	0.0	0.1	0.8	7.3
2	8	30	5	0.1	0.2	4.5	20.0
3	4	90	5	0.0	-	0.0	0.0
4	8	90	5	0.0	-	3.0	0.0
5	4	30	45	0.7	0.3	26.7	13.6
6	8	30	45	0.5	0.3	41.0	26.0
7	4	90	45	0.1	0.1	2.5	6.0
8	8	90	45	0.5	0.2	38.5	16.9
9	4	60	25	0.1	0.1	2.3	4.5
10	8	60	25	0.0	0.1	3.4	12.0
11	6	30	25	0.4	0.1	28.5	10.0
12	6	90	25	0.5	0.1	25.6	4.2
13	6	60	5	0.1	0.0	4.2	2.4
14	6	60	45	0.7	0.2	35.6	13.3
15	6	60	25	0.0	0.1	16.2	7.5
16	6	60	25	0.4	0.1	23.8	6.6
17	6	60	25	0.1	0.1	16.2	8.2
18	6	60	25	0.4	0.1	23.0	6.2

The average particle size of 237 µm, temperature of 600°C and time duration of 90 minutes were selected as the best condition for roasting.

The copper recovery after leaching, for 237 µm fraction was 75.3% which has about 30.3% increase in comparison with the sample without roasting that this shows the importance of roasting in these experiments.

3.2 Effects of Leaching Parameters

Slag used in this stage, was first roasted under optimum conditions acquired from the last stage (237 µm, 600 ° C, 90 minutes). Then two processes were designed for investigating the leaching parameters, one with high and the other with low acid concentrations.

3.2.1. Leaching in high and low acid concentrations

In this part, the effect of acid concentration, temperature, leaching time and L/S parameters for leaching experiments in recovery of copper was examined. At first, roasted samples were leached in 120, 150 and 180 g/L acid solutions at L/S ratios of 4, 7 and 10.

The results have shown that under the conditions of 150 g/L acid concentration, L/S of 10 and leaching time of 45 min the highest copper recovery of 92.2% was obtained.

Some tests were done with low acid concentrations too. For this purpose 18 tests were modeled by use of Minitab release 15 at three different temperatures: 30, 60 and 90°C; acid concentrations of 5, 25 and 45 g/L and also three levels of L/S: 4, 6 and 8.

In this study we tried to examine the Cu extraction, since the dissolution of Fe was significant, so the amount of both Cu and Fe were analyzed and Table 2 lists the values of solution of Cu and Fe after leaching.

Results illustrated that maximum recovery with 41% Cu in the 6th test as sample number is given in Table 2 (T=30°C, L/S=8, Acid Concentration=45 g/L). All of the results were analyzed with Minitab 15 and the following Figures obtained as output.

The values of the regression coefficients and P-values for Cu extraction are presented in

Table 3. It should be mentioned that the significance level employed in the analysis was 5%, so variables with P-values more than 5% are not statistically significant. Furthermore, the quadratic forms of the variables would not be statistically significant too. All of the linear and quadratic variables for Cu are statistically significant except T and its quadratic variables which mean that temperature has no effect on the extraction of Cu. On the other hand the extraction of Cu is affected by the L/S and acid concentration and their interaction.

Table 3. P values for Cu extraction.

Term	**Coef**	**P**
Constant	20.4	0.000
L/S	5.8	0.007
[Acid]	13.2	0.000
$(L/S)^2$	-12.1	0.001
$[Acid]^2$	5.0	0.584
L/S × [Acid]	5.5	0.018

P-values and regression coefficients for Fe dissolution are presented in Table 4. According to P-values shown in Table 4 all of the linear terms are statistically significant and on the other hand all of the quadratic variables except [Acid]*[Acid] are not statistically significant, which means that Fe dissolution is affected by temperature, L/S and acid concentration so its value varies with changes in the value of this variables.

The statistical analysis of the interaction terms for Cu dissolution show that, at 5% significant level, there is significant interaction between [Acid] and L/S and as a result, for finding an optimum condition for [Acid], L/S is involved and vice versa. On the other hand, temperature and L/S have no significant interaction same as temperature and [Acid].

Table 4. P values for Fe dissolution.

Term	Coef	P
Constant	9.2	0.000
L/S	4.4	0.000
T (°C)	-5.0	0.000
[Acid]	4.6	0.000
L/S × T (°C)	-1.8	0.040

The statistical analysis of the interaction terms for Fe show that, at 5% significant level, L/S and temperature have significant interaction that means an optimum level of L/S depends on the temperature and vice versa. On the other hand, the interaction of [Acid] with temperature and L/S is insignificant due to a P value higher than 5%. The P-values for Cu and Fe are less than 5% and lack of fit values for Cu and Fe are more than 5%, so as a result the model is statistically significant (Table 5 and Table 6).

According to regression coefficient resulted from calculations (Table 3 and Table 4) a polynomial regression model equation for Cu and Fe were propound as follows:

$$Cu\ (g/L) = 20.4 + 5.8\ L/S + 13.2\ [Acid] - 12.1\ (L/S)^2 + 5\ [Acid]^2 + 5.5\ L/S \times [Acid] \qquad R^2 = 72.73\% \quad (1)$$

$$Fe\ (g/L) = 9.2 + 4.4\ L/S - 5\ T + 4.6\ [Acid] - 1.8\ L/S \times T \qquad R^2 = 91.07\% \quad (2)$$

Table 5. ANOVA table for Cu.

Total	17	798.885				

Based on regression coefficients (Equations 1 and 2), acid concentration has the most significant effect on the values of Cu and Fe concentrations. However, the effect of acid concentration on the Cu extraction is higher than that of Fe extraction.

The main effect plot for Cu (Figure 1) indicates that, the effect of acid concentration is more significant than L/S, and temperature has negligible effect on extraction of Cu. The main effect plot for Fe (Figure 2) demonstrates that increase in the level of L/S and acid concentration and decrease in the level of temperature have significant effect on the extraction of Fe.

Surface plots are produced to show and identify clearly interactions between significant terms.

The curvature of the surface presented in Figure 3a indicates that there is a significant interaction between L/S and acid concentration in the Cu extraction; i.e. at a constant level of acid, increasing in the level of S/L, up to ~1/6, leads to higher extraction percentage of Cu. However, when the S/L is higher than 1/6, the same increasing in the level of acid results in a decrease in the Cu extraction percentage. Thus, the optimum range for dissolution of Cu is 6< L/S <8 at an acid concentration of 45g/L.

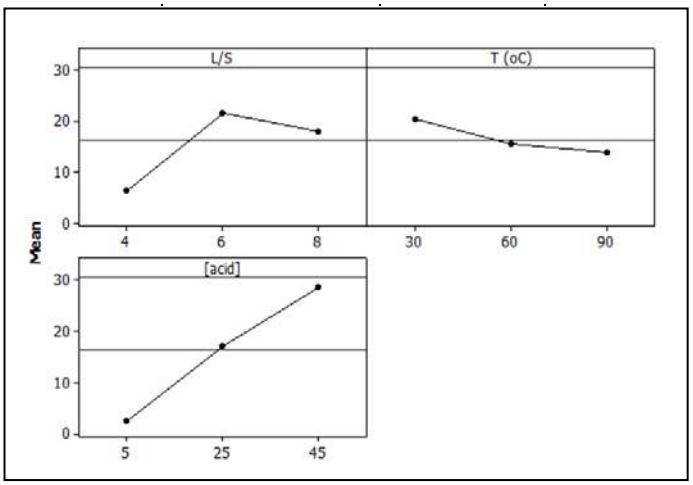

Figure 1. Effect of temperature, L/S and acid concentration on solubility of Cu.

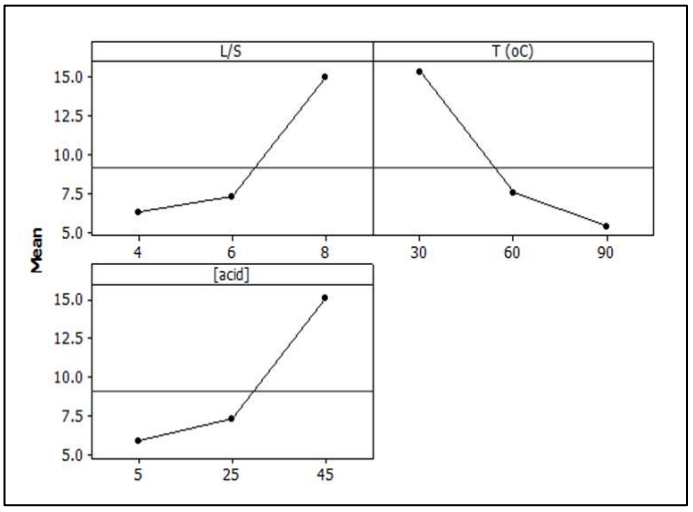

Figure 2. Effect of temperature, L/S and acid concentration on solubility of Fe.

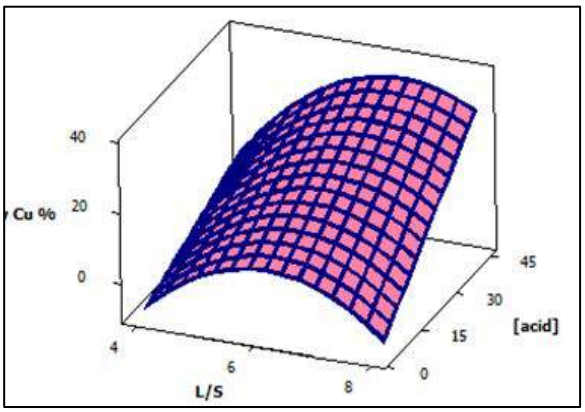
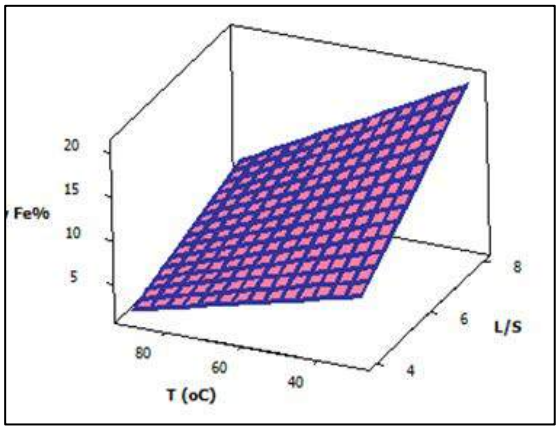


(a)



(b)

Figure 3. Surface plot for a) Cu, b) Fe.

The surface plot presented in Figure 3 shows that reducing in L/S from 8 to 4 and increasing the temperature from 30° C to 90° C adversely affect the dissolution of Fe. The counter plot presented in Figure 4. Indicates that the lowest recovery of Fe is obtained when L/S is less than 6 and temperature is higher than 60°C.

4 CONCLUSIONS

In this article, leaching parameters were studied in detail to evaluate the optimum conditions for leaching of copper slag. The most reliable approach for finding the best parameter was optimizing the leaching parameters. This study revealed that a recovery of 92.2% Cu was achieved after 45 minutes of leaching at an acid concentration of 150g/L and liquid to solid ratio of 10. Furthermore, the optimized leaching parameters in low acid concentrations was obtained at a L/S>6 and acid concentration>40g/L. As a result, the sample with liquid to solid ratio of 8, acid concentration of 45g/L and temperature of 30°C had the highest recovery of 41%.

Recovery of Nanoparticles from Flue Gas using Dielectrophoresis

A. Neculae, A. Lungu, N. Strambeanu, M. Lungu
Faculty of Physics, West University of Timisoara, Bd. V. Parvan 4, Timisoara, Romania

ABSTRACT The industrial burning processes are responsible for the emission of a significant amount of nanoparticles. As the presence in the environment of nanoparticles with size ranging from 50nm to 150 nm was proved to have a profound impact on human health, the filtration of nanoparticles suspended in flue gas became an important technological challenge. In this context, the nanoparticle manipulation using strongly non-uniform electric fields, and especially dielectrophoresis (DEP), proved to be an extremely efficient tool.

This paper presents an experimental DEP-based micro-system used for the selective retaining of nanoparticles suspended in a gaseous environment. The particles deposited on the electrodes are analyzed using a reflection metallographic microscope with CCD camera and a data analysis system. The experimental results highlight the deposition of nanoparticles on electrodes and the fact that the concentration of captured particles diminishes as one depart from the input region, in concordance with our simulation results.

Keywords: Flue gas, recovery, dielectrophoresis, nanoparticles, numerical simulation

1 INTRODUCTION

Filtration of nanoparticles suspended in flue gas is an important technological challenge, as in urban environment the burning processes including waste incinerators or diesel emissions are responsible for the emission of a significant amount of nanoparticles (Sbrizzaia et al., 2005). The presence in the environment of nanoparticles with size ranging from 50nm to 150 nm has a profound impact on human health. Once inhaled, due to their tendency to remain trapped in the inner respiratory ways, infiltrate into the blood and cannot be eliminated, because the macrophage cells cannot identify them. Inhaled nanoparticles may generate free radicals, affect the DNA and alter the genes, being responsible for mutagens and carcinogenic effects or causing a variety of lung-disease typologies (Gatti and Montenari 2014). From a public health standpoint, the size of a particle is as important as its composition, recent research showing that although raw materials may not be dangerous, they can become toxic under the form of nanoparticles (Rickerby and Morrison, 2007, Minutolo et al., 2010, Shegokar 2014). Although the nanoparticles have smaller masses than microparticles, their number is at least four orders of magnitude higher than the number of all other particles found in the flue gas. Sources of polluting emissions are generally equipped with various filters that capture the micron particles, but permit nanoparticles to escape in atmosphere (Chang and Huang, 2001, Lungu et al., 2010).

The traditional methods (retention and separation) have not been successful when were applied for nanoparticles manipulation. In a typical particle-capture device, only a small fraction of them is collected, and the method is successful only when the nanoparticles are attached to larger ones. Mechanical devices used for filtering the post combustion gases resulted in waste incinerators (cyclones, bag filters, sedimentation chambers) are less effective at this scale because of the nanoparticles' low weight, while Corona electrostatic filters have high micrometric particle retention efficiencies (93-99%), yet most nanoparticles still remain undetected

(Sbrizzaia et al., 2005, Rickerby and Morrison, 2007).

The most promising technique for nanoparticle trapping and controlled spatial separation is a method based on dielectrophoresis (DEP), phenomenon in which a spatially non-uniform AC or DC electric field induces a dipole moment in a dielectric particle. Hence, the particle undergoes a DEP motion under the resulting translational force. This force does not require electrically charged particles; the strength of the force depends on the medium and particle's electrical properties, particle's shape and size, and on the applied electric field amplitude and frequency (Pethig, 2010, Neculae et al., 2012). Due to its ability to manipulate particles based solely on their dielectric properties and size, DEP is used for a wide variety of applications such as separation of particles, simultaneous capturing of multiple groups of nanoparticles, etc. (Green et al., 2002, Barbaros and Dongquing, 2011).

This paper presents a study regarding the filtering process by the entrapment of nanoparticles dispersed in flue gas in a microfluidic device using positive dielectrophoresis. The first part of the study presents a set of results obtained by numerical simulations describing the behavior of nanoparticles with size ranging from 50 to 150 nm in a 3D DEP-based microsystem, which consists in a microchannel-working unit of a particulate trap. The concentration profile of nanoparticle suspension inside the microfluidic separation device is calculated using input parameters previously determined experimentally, and the performance of the device is analyzed in terms of a new specific quantity of separation process, called *Filtration rate*. In the second part of the study, the experimental microfluidics device for dielectrophoretic manipulation of nanoparticles from flue gas is presented, together with some preliminary but relevant experimental results highlighting the capability of the device to capture the nanoparticles. The analysis system of the images is described as well. Combining of numerical analysis with experimental investigation, lead to the improvement of the mathematical model and the determination of the optimal parameters of the experimental device.

2 THEORETICAL BACKGROUND

The time averaged DEP force acting on a spherical particle situated in an AC electric field can be written as (Green et al., 2002):

$$\left\langle \mathbf{F}_{DEP} \right\rangle = 2\pi a^3 \varepsilon_m K_R(\omega) \nabla \left(\left| \nabla V_R \right|^2 + \left| \nabla V_I \right|^2 \right) \quad (1)$$

where we denoted by a the particle radius, ω the angular field frequency, and V_R, respectively V_I the real and imaginary part of the electric potential phasor, $\tilde{V} = V_R + jV_I$, with $j = \sqrt{-1}$. For a homogeneous medium, the electric potential satisfy the Laplace equation $\nabla^2 \tilde{V} = 0$.

$K_R(\omega)$ is the real part of the complex quantity $\tilde{K}(\omega) = \left(\tilde{\varepsilon}_p - \tilde{\varepsilon}_m \right) / \left(\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m \right)$, called the Clausius–Mossotti (CM) factor, which is a measure of the effective polarizability of the particle. $\tilde{\varepsilon}_p$ and $\tilde{\varepsilon}_m$ are the complex dielectric permittivities of particle and medium. The complex permittivity is defined as $\tilde{\varepsilon} = \varepsilon - j\left(\sigma/\omega\right)$, where σ is the electrical conductivity. Consequently, the CM factor can be expressed as:

$$\tilde{K}(\omega) = \frac{\left(\varepsilon_p - \varepsilon_m \right) + j/\omega \cdot \left(\sigma_p - \sigma_m \right)}{\left(\varepsilon_p + 2\varepsilon_m \right) + j/\omega \cdot \left(\sigma_p + 2\sigma_m \right)}. \quad (2)$$

The CM factor depends on the dielectric properties of the particle and medium and on the frequency of the applied field; at low frequencies the sign is determined by the electrical conductivities of the particle and of the medium and at higher frequencies by the corresponding permittivities. The variation in this factor results in a frequency-dependent dielectrophoretic force that is unique for a particular type of particle. Therefore, DEP is an effective tool for separating particles, based solely on their

dielectric properties and size. When the sign of K_R is positive, the particle is attracted to the locations of electric field intensity maxima and repelled from the minima, phenomenon known as positive dielectrophoresis (pDEP). The opposite occurs when K_R is negative, situation referred to as negative dielectrophoresis (nDEP).

A typical DEP-based separation device has parallel interdigitated bar electrodes placed on the bottom surface, as illustrated in Figure 1.

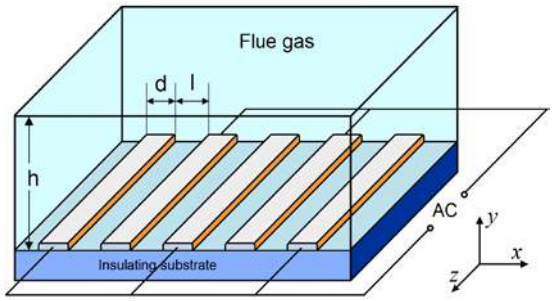

Figure 1. Schematic representation of experimental device used for DEP separation.

In most of the reported models, due to the symmetry of the geometry and considering the electrodes much longer than their width, the problem is treated in two dimensions and the electrodes' height is neglected. In our study, in order to have a more realistic description of the experimental device, a 3D geometry and a detailed description of the electrodes' shape are used. Anyway, taking into account the periodic distribution of the electrodes, the numerical calculations of the DEP force and the concentration field can be performed considering as computational domain only a so called "basic unit cell", which fully describes the entire system, except the vicinity of the device walls. The geometry of the computational domain, together with the associated boundary conditions necessary to solve the Laplace equation for electric potentials, V_R and V_I, are presented in Figure 2.

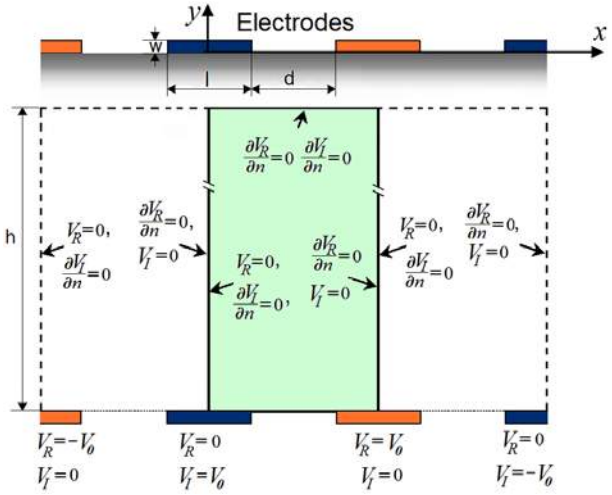

Figure 2. The geometry of the computational domain and the associated boundary conditions for the electric potentials. The solid lines indicate the basic unit cell.

The macroscopic behavior of a suspension of spherical particles of radius a in a fluid of viscosity η is modeled by considering the mechanical equilibrium between an external force **F** (DEP force in this case) and the Stokes drag force. For small particles (i.e. nanoparticles), the dynamics of the system is governed by the following system of equations (Neculae et al., 2012):

$$\mathbf{v} = \mathbf{u} + \frac{2a^2}{9\eta}\mathbf{F}, \qquad (3a)$$

$$\frac{\partial C}{\partial t} + \nabla \cdot \mathbf{j} = 0, \text{ where } \mathbf{j} = C\mathbf{v} - D\nabla C. \qquad (3b)$$

Here **u** and **v** are the fluid and particle velocities, t is the time, **j** the particle flux, D the diffusion coefficient of the particles, and C is the particle volumic concentration.

The fluid flow field inside the separation device, **u,** is calculated by solving the classical Navier-Stokes equation in the compressible case, together with the corresponding boundary conditions. For the obtained DEP-force and fluid flow field, the particle concentration is evaluated by numerically integrating equations (3a) and (3b). This calculated particle concentration field gives information at a local scale, showing how the particles are attracted on the margins of electrodes and the influence of the main parameters of the problem on this process. For the analysis of the filtration

process we define the novel quantity named *Filtration rate* (*F*), which describes the process in terms of nanoparticles entrapment at the electrodes, related to the concentration distribution:

$$F = \frac{C_{input} - C_{output}}{C_{input}} = 1 - C_{output} / C_{input} \quad [\%] \qquad (4)$$

where C_{input} and C_{output} are the mean concentrations of the suspended nanoparticles at the input and the output surfaces of the device, respectively, as schematically sketched in Figure 3.

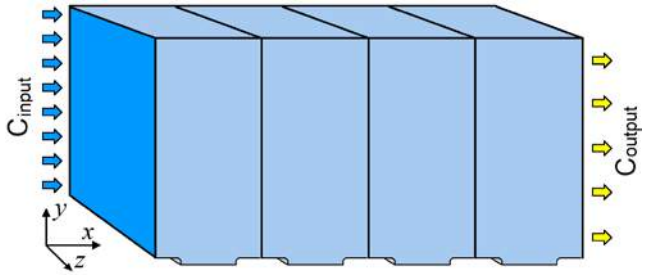

Figure 3. Schematic representation of the separation device revealing the parameters used for defining the *Filtration rate.*

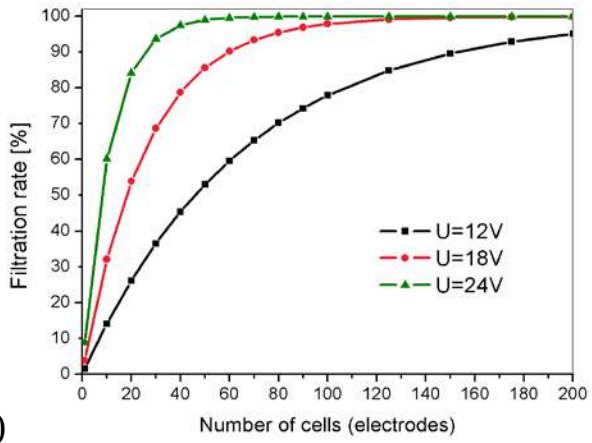
This proposed quantity gives the global information on the filtration process, and can be used in order to evaluate the efficiency of the filtration process.

3 NUMERICAL RESULTS

After we compute the pDEP force distribution inside a typical DEP device we move to the problem of determining the distribution profile of nanoparticles under the influence of dielectrophoresis. We analyze and discuss the obtained numerical results in terms of *Filtration rate*, a global quantity correlated with the concentration field, which offers a more suggestive characterization of the capabilities of the device regarding the separation process of nanoparticles from flue gas. All the numerical simulations were performed using the *COMSOL Multiphysics* program.

For the computation of the pDEP force, we first solved the Laplace equation for the real and imaginary components of the electric potential, together with the associated boundary conditions presented in Figure 2. The computational domain consists of a unit cell described by the following set of geometric parameters: $d=l=100\ \mu m$, $h=500\ \mu m$ and $w=2\ \mu m$. The simulations were performed for a suspension of particles with characteristic sizes a=50nm, a=100nm and a=200nm respectively, in air. The dielectric response of the particles is characterized by the real part of the CM factor $K_R = 1$ and we considered the amplitude of the electric potential applied on the electrodes in the range $V_0 = 12 \div 24V$.

The efficiency of the filtration process can be evaluated by calculating the *Filtration rate* given by relation (4) for different values of problem's parameters. The computation is performed using an iterative procedure: the output concentration in one unit cell is considered to be the input concentration for the next unit cell, in order to describe the cumulative effect of the filtration inside the microfluidic device. This type of analysis allows an estimation of the necessary number of cells (or electrodes) in order to obtain a certain desired filtration rate, when the other parameters of the problem are fixed. The results presented in Figure 4a show that, for example, in the case of particle having size of 100nm, a desired filtration rate of 90% can be obtained by using about 30 electrodes when applying a voltage of 24 V, about 60 electrodes for 18 V, and nearly 200 electrodes for an applied voltage of 12 V.



a)

b)

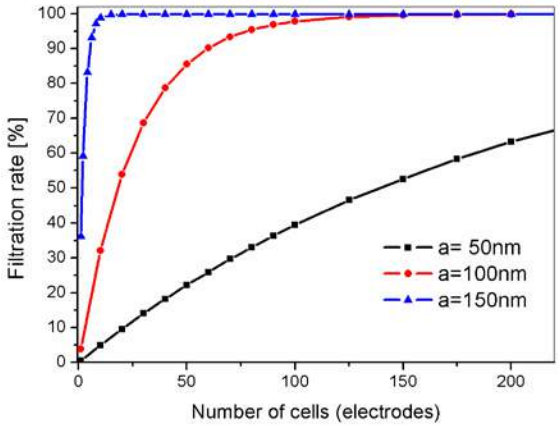


Figure 4. Calculated filtration rate versus cell numbers for a) particles with a=100nm at three different applied voltages and b) particles with three different radii at a fixed applied voltage of $V_0 = 18\text{V}$ ($d = l = 100$ μm).

When we analyze the effect of particle radii on the filtration capacity, the results presented in Figure 4b predict that, for example, when the applied voltage is 18 V, particles of 150 nm are completely captured after 10 electrodes, for particles of 100 nm we need about 150 electrodes for the complete capture, while the particles of 50 nm are captured less than 60% even if one use devices with 250 electrodes.

In conclusion, the simulations performed in the frame of the presented mathematical model allow an estimation of the performances of the filtration as a function of the geometric and physical parameters of the problem.

4 MATERIALS AND METHODS

Based on the results obtained from the mathematical model and numerical simulations, it was realized and tested a laboratory microfluidic device for retaining nanometric particles in non-uniform electric field by positive dielectrophoresis (pDEP). Practical tests were conducted on an emission source represented by a pilot plant for incineration of different waste categories. The main active parts of the device consist of the deposition plates, made by PCB (Printed Circuit Board) technique (Figure 5), with electrode width and gap between electrodes $d = l = 100$μm.

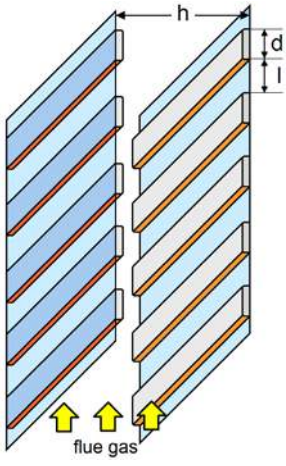
a)

b)

Figure 5. Deposition plate made by PCB technique, a), detail of intedigitated electrodes, b).

We performed experiments for nanoparticle trapping from flue gas, by fumigation at the bottom of the experimental device. The outline of the laboratory experimental device is presented in figure 6a, and a detail with experimental device under work conditions (with flue gas fumigation at the bottom), is shown in figure 6b.

a)



b)

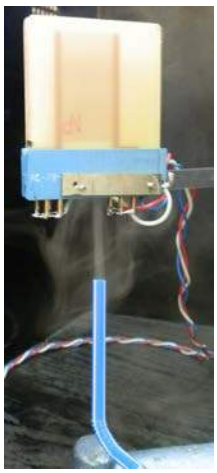


Figure 6. The outline of the laboratory experimental device, a), device at work with flue gas at the bottom, b).

Figure 7 presents the installation for the analysis of the deposition plates (consisting in a reflection metallographic microscope with CCD camera and the related computer), during analyze of a deposition plate before fumigation, in the absence of the applied voltage. On screen it appears a snapshot with a detail of the deposition plate obtained at a 100x magnitude. The vertical light stripes on the display are the electrodes, while the dark stripes are the gaps.

Figure 7. The installation for the analysis of the deposition plates, on screen appears a snapshot of a detail of the deposition plate obtained at 100x.

The tests performed with a DEP-based separation device having $l=d$=100µm and h=2mm reveal that in the absence of the applied voltage the particles are not at all attracted to the electrodes, while once applied an AC voltage, the dielectrophoretic effect appears. In the absence of applied voltage on the electrodes, the nanoparticles that exist in the flue gases are not attracted to them and, therefore, will not be deposed on the plates. By applying an AC voltage, the deposition phenomenon occurs due to positive dielectrophoresis. Figure 8 shows successive video frames (snapshots) representing the deposition of nanoparticle on the collection plates by pDEP of the smoke resulted from the incineration of wastes in the pilot plant. On the electrodes were applied AC signals. Snapshots were performed at different distances from the top of the plate, where obtained a minimum density of the collected material versus the bottom, where the density of deposited nanoparticle is the greatest. The figure shows a decreasing in the concentration of captured nanoparticles, vertically from the entrance toward the exit area. As the smoke "climbs" the device, particles in suspension are lost by their accession to the collection plate, the result being in accordance with numerical simulations.

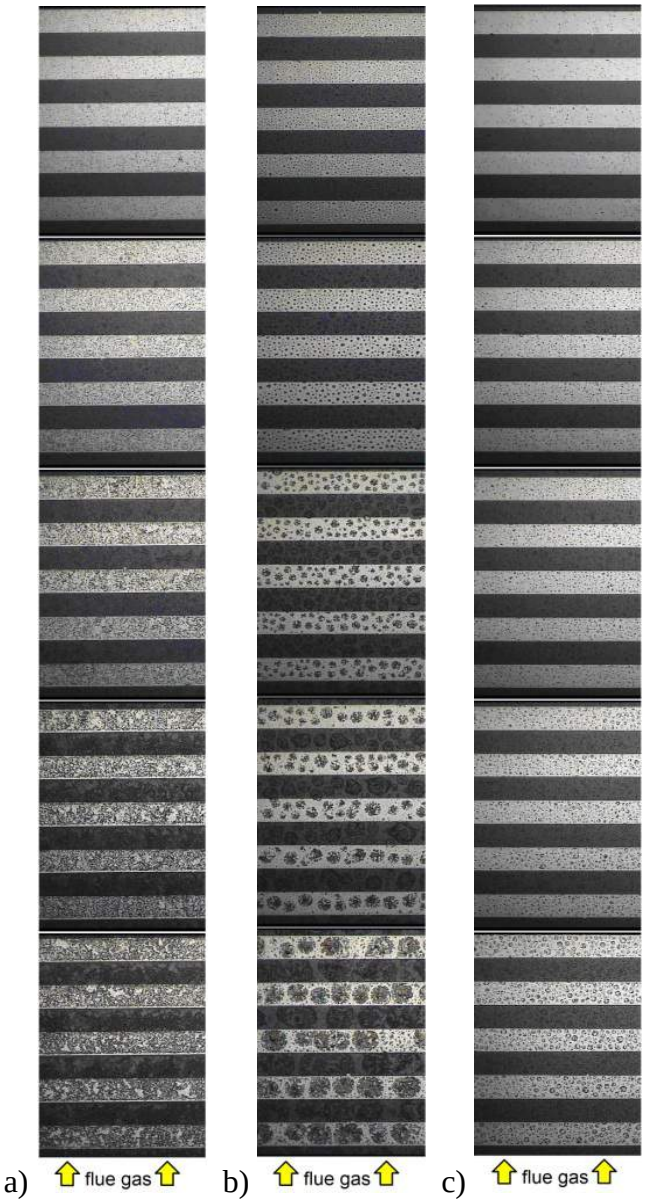

Figure 8. Successive snapshots revealing the results obtained after fumigation with the DEP-based separation device with $l=d$=100µm, h=2 mm, at: U=37V, AC sinusoidal signal, f=50Hz, time of fumigation t=30s, a); U=12V, AC rectangular signal, f=100Hz, time of fumigation t=30s, b); and U=12V, AC rectangular signal, f=100Hz, time of fumigation t=30s, c). A decreasing in the concentration of captured nanoparticles, vertically from the entrance toward the exit area is observed.

5 CONCLUSIONS

This contribution presents the study of a DEP-based microsystem for the selective manipulation of nanoparticles using dielectrophoresis. We applied a theoretical model and build-up of an experimental

device for retaining the nanoparticles from combustion gases in non-uniform electric fields based on the simulations of a physically realistic problem, and then we performed experiments on nanoparticle trapping from flue gases.

The numerical study focuses on the effectiveness of filtering nanoparticle from combustion gases in a microfluidic device designed to improve the filtering process of nanoparticle suspended in flue gas using positive dielectrophoresis. This type of analysis allowed the estimation of the number of cells (or electrodes) required to achieve a given filtration rate when other parameters of the proposed model are established.

Based on the results obtained from mathematical modeling and numerical simulations, it was designed, developed and tested a laboratory microfluidic device for retaining in nonuniform electric field by positive dielectrophoresis of nanometric particles from the emissions of a pilot plant incinerator. The experiments performed with this device highlight the deposition of nanoparticles on electrodes and the fact that the concentration of captured particles decreases as we move away from the entrance area of the smoke resulted from the combustion of different wastes, the results being in good agreement with the numerical simulations.

ABSTRACT One of the major obstacles to the implementation of an appropriate plastics recycling scheme is the inhomogeneity of many plastics waste. Accordingly, most of the existing recycling schemes require a feedstock that is reasonably pure and contains only items made from a single polymer type. This often requires sorting into different polymer fractions, a process that is both cumbersome and expensive. This work therefore investigates the reduction of two sources of iron oxide by mixed plastic waste (MPW) and its blend with sawdust (SD) through experiments conducted in a laboratory scale horizontal tube furnace. Composite pellets of EAF slag (47.1% FeO) with a blend of MPW and SD were rapidly heated at 1520 °C under high purity argon gas and the off gas was continuously analysed for CO, and CO2 using an online infrared gas analyser (IR). The extent of reduction after fifteen minutes was determined for each carbonaceous reductant. The results show that iron oxide can be effectively reduced to produce metallic iron using MPW and its blend with SD as reductant. An improvement in extent of reduction was observed over conventional metallurgical coke and the individual polymers when the blend (MPW+ SD) was used as reductant. This eliminates the need to sort out individual plastics from municipal solid waste for their effective utilisation as reductants, carburisers and desulphurisers in iron making.

Keywords: Reduction, metallurgical coke, mixed plastics waste, sawdust, extent of reduction, carburization, desulphurisation

1 INTRODUCTION

One of the major obstacles to the implementation of an appropriate plastics recycling scheme is the inhomogeneity of many plastics waste. Accordingly, most of the existing recycling schemes require a feedstock that is reasonably pure and contains only items made from a single polymer type. In the metallurgical industry, particularly in iron and steelmaking technologies, the use of postconsumer plastics is currently gaining the attention of various researchers. However, most of the existing research in this area involves the use of a single plastic [1-4] and/or its blends with metallurgical coke or graphite [5-12] or with biomass as reductants [13, 14]. In reality, most postconsumer wastes contain a mixture of plastic types, and are often contaminated

with non-plastic items. Little or no information exists in the literature on the use of MPW and blends of MPW with biomass as reductants in the metallurgical industry as reductants. The potential feasibility of utilising MPW and its blend with biomass as reductant in iron oxide reduction is thus the motivation of this research project.

2 EXPERIMENTAL

2.1 Sample Selection

The MPW used in this investigation was comprised of 40 wt % HDPE, 30 wt % PP, 10 wt % LLDPE, 10 wt% PET and 10 wt % SD. The chemical composition (wt %) of the carbonaceous samples and the ash analysis (of Met Coke and SD) are given in Tables 1and 2, respectively. No ash analysis was performed on the plastics because of the negligible amounts of ash produced An EAF slag with 47.1 % FeO and basicity (B3) of 1.66 was provided by OneSteel Sydney Steel mill, which was further analysed by XRF and its composition after removal of free metallic iron by a magnet is given in Table 3..

Table 1: Compositions of the carbonaceous materials utilised in this investigation

Component	Met Coke	HDPE	PP	LLDPE	PET	SD
Moisture	4.6	0	0.01	0	0.18	1.90
Ash	18.3	0.3	0.45	0.3	0.04	10.30
VM	3.00	99.7	98.8	99.7	88.42	80.20
Fixed Carbon	71.36	0	0.74	0	11.35	7.60
Total Carbon	78.7	85.5	83.8	85.5	62.5	50.30
Sulphur	0.32	0.30	0.092	0.20	0.00	0.04
Hydrogen	0	14.2	13.9	14.3	4.2	5.78
Oxygen	0	0	0	0	33.3	43.64

Composition (wt %)	24.1	47.1	4.9	9.6	10.2	4.8	1.66

(*-analysis conducted at Analytical Centre, UNSW-Sydney, Australia)

2.2 Sample Preperation

Samples of SD were ground and sieved to particle size in the range of -470 +450 µm while samples of granulated HDPE, PP, PET and LLDPE were crushed to smaller sizes by using a cutting mill “Pulverisette 15” (Fritsch GmbH, Idar-Oberstein, Germany), Fig. 1. By means of a sieve insert with 0.5 mm trapezoidal perforations in the cutting mill a particle size -470 +450µm, similar to that of metallurgical coke was obtained. The slag was subsequently mixed with the carbonaceous blends and compacted in a die to produce cylindrical pellets (11.6-12.0 mm thick and 14 mm diameter) (Fig. 2), by applying a load of 7.5 tonnes for 1 minute in a hydraulic press.

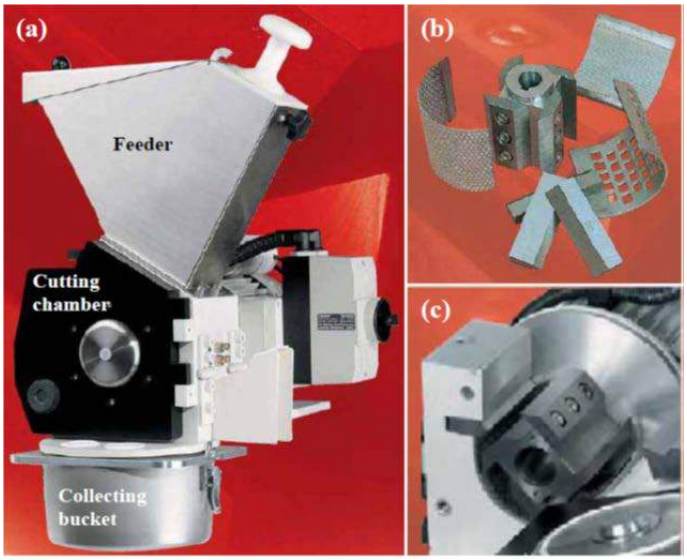

Figure 1. (a) Cutting Mill Pulverisette 15, (b) Cutting rotor and sieve inserts and (c) Grinding Chamber. [6]

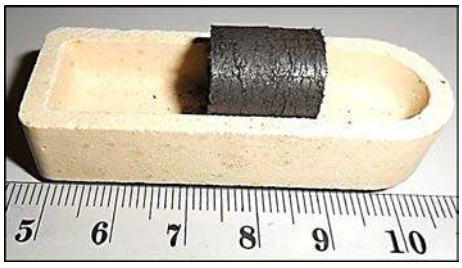

Figure. 2: Cylindrical pellet (slag + carbonaceous material) placed in the LECO crucible prior to the experiments

2.3 Experimental Procedure

The experimental procedure involved three parts: the reactions in a custom-made horizontal resistance heated furnace (Fig. 3), visual observation using a CCD camera and off-gas analysis using a gas chromatographic analyser (SRI 8610C Chromatograph Multiple Gas #3 GC configuration equipped with a thermal conductivity conductor (TCD)) and a continuous infrared gas analyser, to monitor off- gases produced by the reduction reaction.

The results (gas analyses and visual imaging) were recorded in a data-logging computer. The sample assembly was inserted in the furnace, which was purged continuously with argon (of 99.995 % purity and flowing at1L/min) to ensure inert conditions in the furnace. After the furnace had attained the desired hot zone temperature (1520 °C), the sample was pushed into the reaction hot zone and the reactions were monitored for 30 minutes.

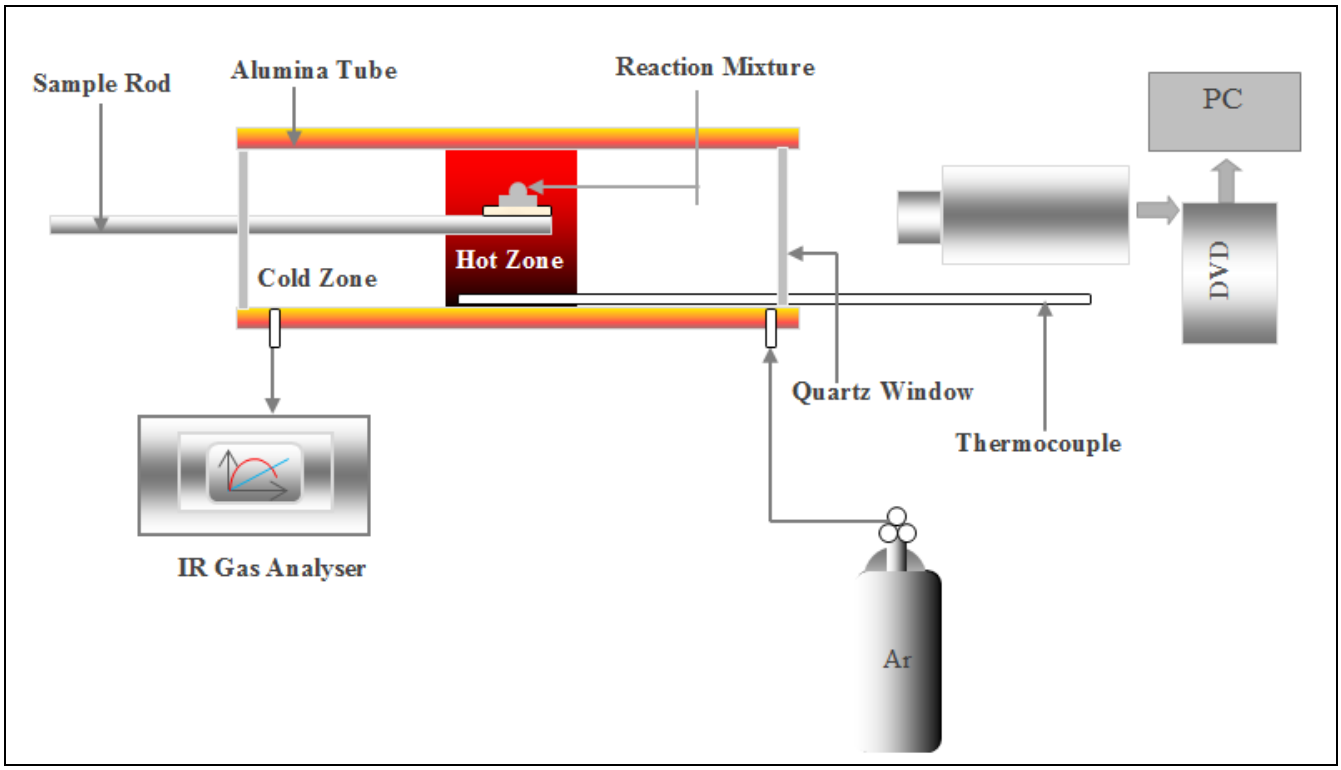

Figure 3. Schematic of the horizontal tube furnace and IR gas analyser system

This time was selected since initial trials showed that the reactions ceased and thus there were no further changes in gas composition or degree of reduction beyond this time. The reacted carbonaceous material/slag samples were quenched by rapidly withdrawing the tray from the hot reaction zone into the cold zone of the furnace.

2.4 Results and Discussions

Particles of reduced iron metal, which were clearly visible to the naked eye (Fig. 4), were removed magnetically and analysed.

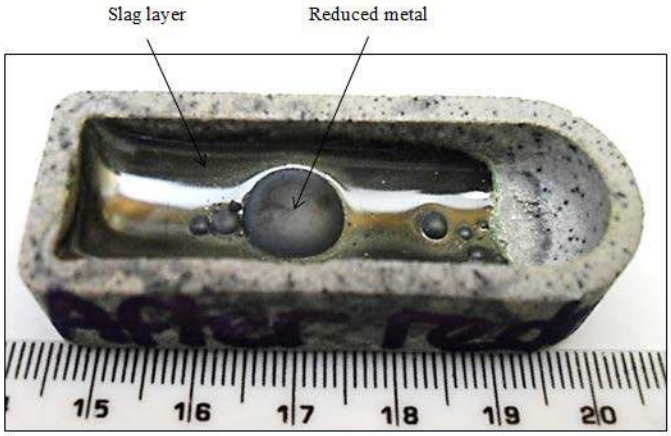

Figure 4. Nature of metal produced from reduction of slag-MPW composite at 1520 °C

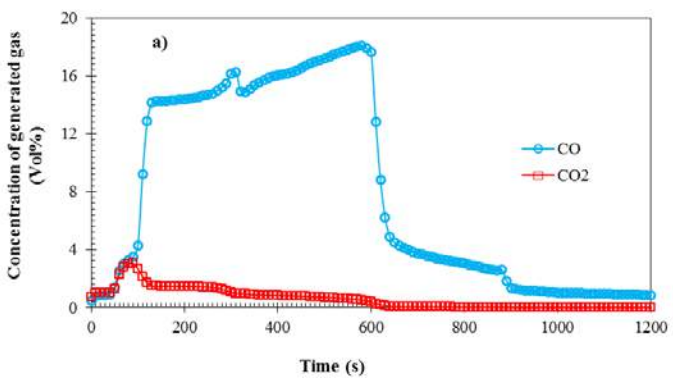
2.4.1 Gas generation rates (IR Analyser)

The contents of CO and CO2 in the off-gas were measured continuously by an infrared (IR) gas analyser and the amounts of CO and CO2 removed from the slag were calculated using the off-gas data for each blend. The results are shown in Figs. 5 and 6 for MPW-SD and coke, respectively.



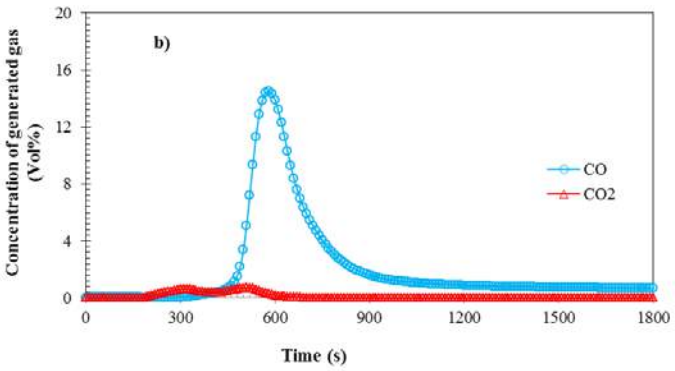


Figure 6. Concentration of generated gas as a function of time during the reduction of FeO in slag by a) MPW + SD and b) Coke 1520 °C

The relatively lower values recorded for CO_2 compared to CO may be an indication of direct reduction of FeO by C (equation 1) or a dominant Boudouard reaction (equation 2) or carbon gasification reaction (equation 3).

$$(FeO) + C = Fe + CO \quad (1)$$

$$CO_2 + C = 2CO \quad (2)$$

$$H_2O + C = CO + H_2 \quad (3)$$

Another possible reaction is the direct reduction of FeO by CH4, which was the predominant hydrocarbon detected in the off-gas above 1500 °C.

$$CH_4 + FeO = Fe + 2H_2 + CO \quad (4)$$

2.4.2 Extent of reduction

After reduction the reduced metal, was removed magnetically and weighed and the content of oxygen was determined using a LECO Nitrogen/Oxygen analyser (model TC-436 DR 602-500-600, LECO Corporation, Michigan, USA). The extent of reduction was determined from the oxygen values, bearing in mind that the initial concentration of removable oxygen from the reducible component of the slag (FeO) is about 22.27%. The result is illustrated in Fig 5.

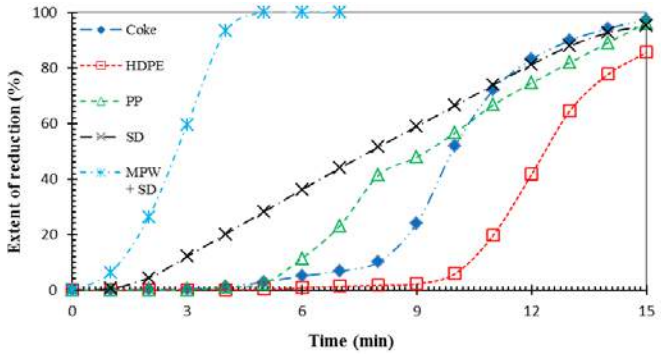

Figure 5 Observed extent of reduction for each carbonaceous reductant during the reaction of FeO in slag by various reductants

From Fig 5, each of the polymers shows a slightly lower extent of reduction than that by coke after 15 min, with the measured extent of reduction being 85.9, 95.2, 96.2 and 97.3 % for HDPE, SD, PP and coke respectively. However, blending the mixed plastics with SD the polymer (MPW + SD) resulted in a significant improvement in the extent of reduction, with the reaction essentially going to completion after about five minutes. This improvement in reduction is attributed to the extra reducing gases H2 and CH4 made available in the system through the thermal decomposition of the mixed polymers along with the fixed carbon from SD. The beneficial effect of H2 on the reduction of iron oxide by coke was elucidated in earlier investigation [5,6, 13-19].

The observed improvement in extent of reduction in the presence of a polymer is consistent with previous observations by Rahman et al. (sessile drop approach) [6], Dankwah et al. (crucible reduction approach) [5,7] and Kongkarat (sessile drop approach) [8].

3 CONCLUSIONS

The reduction of FeO from EAF slags by MPW-SD has been investigated in a horizontal tube furnace at 1520 °C. Extent of reduction of FeO from EAF slag by MPW-SD was compared with those by the individual polymers and metallurgical coke. It was observed that:

- MPW-SD is an effective reductant for iron oxide reduction.
- Significant improvements in the extent of reduction were observed for MPW-SD over the individual polymers and coke.
- Iron oxide reduction therefore offers and effective route for recycling waste plastics without the need to sort out individual plastics.

ACKNOWLEDGEMENTS

The Dissolution of Vanadium in Silica Sand with Organic and Inorganic Acids

Silis Kumundaki Vanadyumun Organik ve İnorganik Asitlerle Çözünmesi

H. Hacıfazlıoğlu, İ. Kurşun, T.D. Tombal, M. Terzi
İstanbul Üniversitesi, Maden Mühendisliği Bölümü, İstanbul

ABSTRACT Being one of the important rare elements, vanadium is mainly used for the production of certain alloys. Various methods have been adopted so far for the recovery of vanadium. New methods are also being tried together with the developing technology and such methods have been included in the literature. The sample of the silica sand used within the scope of this study was taken from the silica sand beneficiation facility of a private mining company operating in Sile, Istanbul. In such facility, raw silica sand was filtered through a scrubber first and then sized with the help of a hydrocyclone and a hydrosizer and taken to the beneficiation facility. Several characterization tests and leaching tests with organic and inorganic acids were conducted for the recovery of vanadium from the sample and the dissolution conditions of vanadium with the best grade and efficiency were investigated. Following such leaching tests, the best result for vanadium dissolution was obtained with hydrofluoric acid. As a result of 2-hours leaching process performed with 800 kg/tons hydrofluoric acid amount under 40 ^{o}C, the dissolution efficiency of vanadium was found as 76%.

Keywords: Vanadium, silica sand, dissolution

ÖZET Önemli nadir elementlerden biri olan vanadyum, ağırlıklı olarak, belirli alaşımlar üretmek için kullanılmaktadır. Vanadyumun kazanımı için geçmişten günümüze çeşitli yöntemler uygulanmıştır. Gelişen teknolojiyle birlikte de yeni yöntemler denenmekte ve literatüre alınmaktadır. Bu çalışma kapsamında kullanılan silis kumu numunesi İstanbul Şile' de faaliyet gösteren özel bir madencilik şirketine ait silis kumu zenginleştirme tesisinden alınmıştır. Söz konusu tesiste, tüvenan silis kumu önce pervaneli yıkayıcıdan (scrubber) geçirilmekte, daha sonra hidrosiklon ve hidrosizer ile boyutlandırılarak zenginleştirme tesisine girmektedir. Numuneden vanadyum kazanılması için bir dizi karakterizasyon testi ve organik asitlerle liç deneyleri yapılarak en yüksek tenör ve verimde vanadyumun çözünme koşulları incelenmiştir. Liç deneyleri sonrasında vanadyum çözünme verimi için en iyi sonuçlar hidroflorik asitle elde edilmiştir. 800 kg/ ton hidroflorik asit miktarı ile 40^{o}C' de yapılan 2 saatlik liç işlemi sonunda vanadyum çözünme verimi % 76 bulunmuştur.

Anahtar Kelimeler: Vanadyum, silis kumu, çözünme

1 INTRODUCTION

The existence of vanadium was discovered for the first time by Spanish mineralogist Manuel Del Rio in 1801 in Mexico as a result of the studies performed on lead vanadate ore (Oztürk, 2008; Lagerkvist and Oskarsson, 2007). Vanadium is a relatively abundant trace element found on the crust of the earth and constitutes in many minerals and mineral beds. It does not constitute as a natural metal in the nature; however, it always co-exists with other elements.

Vanadium minerals are classified into seven classes which are namely oxides, phosphates, silicates, sulphates, sulphurs, titanates and vanadates (Gharehbagheri et al., 2013). The minerals containing vanadium consist of carnotite, mottramite, patronite, roscoelite and vanadinite (Ozturk, 2008; Moskalyk and Alfantazi, 2003). China is the world's market leader in terms of production and reserves of vanadium with a production of 40000 tons and reserves of 5 million tons, followed by Russia and USA respectively (USGS, 2013)

Vanadium is almost sole significant by-product which is used in iron or iron free alloys thanks to its physical properties such as high tensile strength, hardness and fracture strength. Vanadium is used in a wide range of combination with iron, titanium, nickel, aluminium, chrome and other metals for various commercial applications from railroads, steel tools and catalytic to aviation. Global supply of vanadium includes such primary resources as feedstock, concentrates, metallurgic slag and petroleum wastes. Furthermore, some mining wastes and waste ashes have a significant economical potential as they contain high amounts of vanadium and nickel (Moskalyk and Alfantazi, 2003; Yang et al., 2013).

Various methods are made use of for the recovery of vanadium which are namely hydrometallurgic and pyro + hydrometallurgic. The most applied methods among these are direct acid leach, direct alkali leach, post-roasting acid leach, post-roasting alkali leach and post-roasting water leach. Generally the alkali leach method is benefited from for the selective recovery of vanadium in comparison with iron. However, this method causes the dissolution of some amount of silica as well together with vanadium. Moreover, it is known as a costly and expensive method due to the used reagents. The dissolution of silica in sulphuric acid leach is relatively limited; but selective recovery is not possible for the co-recovery of nickel and vanadium. This method, on the other hand, is known to be a cost-effective and efficient method (Ozturk, 2008).

Li et al., (2010) performed some tests for vanadium production out of black shale through acid leach. Within the scope of this study, feasibility of the vanadium recovery was investigated with the use of sulphuric acid and hydrochloric acid solutions. According to the E-pH diagram for V-H_2O under 25 ° C, it was observed that the dissolved vanadium in an aqueous solution was in the form of VO^{2+} and VO_2^{+} at high potential and low pH value. The obtained optimum parameters are 87.5 g/L sulphuric acid concentration within 6-hours reaction time, 15 g/L hydrofluoric acid concentration, 1 g/L sodium hypochloride concentration (added after a reaction time of 3 hours), 95 °C leach temperature and 4 mL/g solid/liquid rate. Under these conditions, 86% vanadium was recovered to the utmost. Li et al., (2011) performed some tests for vanadium production through oxidization process out of a low grade vanadium slag in the existence of Na_2CO_3. In this study, the oxidization conditions of a low grade vanadium slag were investigated with the techniques of XRD, SEM / EDS and TG-DSC. The results obtained showed that vanadium slag was oxidized in the temperature range of 273 °C and 700 °C. Aarabi-Karasgani et al., (2010) also conducted some tests for vanadium production through the sulphuric acid leach method from Linz–Donawitz (LD) converter slag. In this study, an alkali roasting-acid leach study was performed for the sake of vanadium recovery out of LD converter slag in a steel production facility and the effect of different parameters on vanadium dissolution kinetics was determined. Optimum leach conditions were reached under 70 °C, 3 M acid concentration and 150 minutes leaching period and approximately 95% maximum vanadium recovery was obtained. Fan et al., (2013) performed both bulk and column tests for the purpose of vanadium decomposition from chrome with the use of D314 which is a mild base resin for the sake of vanadium recovery from the chromate solutions containing vanadium.

In China, various other studies were conducted for the recovery of vanadium out of hard coal (Min-Zhang et al., 2011). Wang et al., (2013) performed some studies as well for vanadium recovery from the hard coal through floatation. Final vanadium concentrate slime-floatation process was obtained with 1.88% V_2O_5 and 76.58% recovery rate and 72.51% of the raw ore was discarded as a waste.

2 EXPERIMENTAL STUDIES

2.1 Materials

The sample of the silica sand used in the experimental studies was taken from the silica sand beneficiation facility of a private mining company operating in Sile, Istanbul. In such facility, raw silica sand was filtered through the scrubber first and then sized with the help of a hydrocyclone and a hydrosizer and transferred to the beneficiation facility. The sample of the silica sand which subjected to the experimental studies was taken from the slime removal exit and brought to the Mineral Processing Laboratory of the Mining Engineering Department of the Engineering Faculty of Istanbul University in sealed containers. Within the scope of experimental studies, chemical content, particle size distribution and mineralogical analyses were performed first for the performance of sample characterization in terms of leach tests. The chemical analyses results of the sample which were conducted with the methods of XRF and ICP are given in Table 1; the particle size distribution graph obtained as a result of the particle size distribution analysis conducted with the wet sieving method is given in Figure 1 and the optical and scanning electron microscope photos are respectively given in Figure 2 and Figure 3.

Table 1. Chemical analysis results of the sample

Content	Assay Value
SiO_2 (%)	81,63
Al_2O_3 (%)	15,66
TiO_2 (%)	1,15
Fe_2O_3 (%)	0,54
K_2O (%)	0,37
ZrO_2 (%)	0,17
CaO(%)	0,12
MgO(%)	0,07
Cr_2O_3 (%)	0,07
P_2O_5 (%)	0,07
SO_3 (%)	0,05
BaO(%)	0,05
Na_2O (%)	0,04
V (ppm)	50,00
Other (%)	0,01
Total	100,00

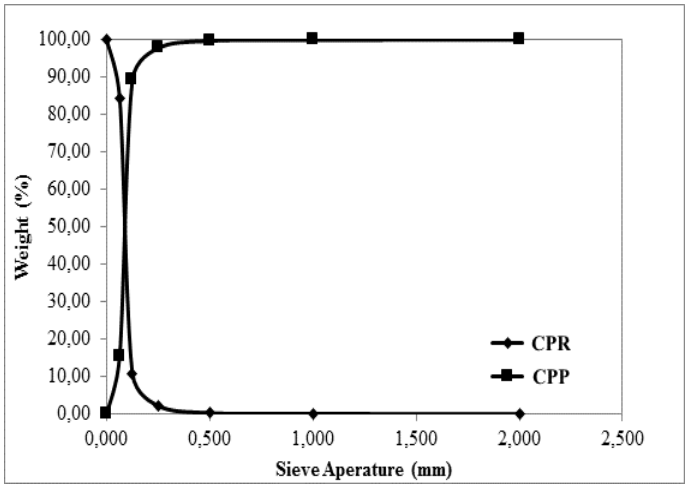

Figure 1. Particle size distribution graph of the sample

It was understood from the particle size distribution graph that the d_{50} and d_{80} sizes of the sample were respectively 0.08 mm and 0.12 mm. Following the optic and scanning electron microscope examinations performed within the scope of mineralogical analyses, on the other hand, it was identified that the sample contained hematite, ilmenite, magnetite and rutile minerals in addition to quartz. It is thought that vanadium likely exists depending on the magnetite content in the sample.

2.2 Methodology

Leaching tests were conducted with the use of different organic and inorganic acids for the purpose of dissolution of the vanadium in the silica sand within the scope of this study. The organic acids used were citric, tartaric and oxalic acids whereas the inorganic acids were sulphuric (H_2SO_4), hydrochloric (HCl) and hydrofluoric (HF) acids. The vanadium dissolution efficiencies obtained as a result of the leaching tests performed with each of the abovementioned acids were calculated and the obtained results were interpreted. The silica sand was subjected to the leaching process for 2 hours under an average leaching temperature (40 ^{o}C) at different acid amounts (100, 200, 400, 600, 800 and 1000 kg/t) with the separate use of the abovementioned organic and inorganic acids. The leaching tests in question were performed in 250 cc of conical flasks in shaking water bath. The shaking rate of the shaking water bath was selected to be 250 rpm. Solid-liquid separation was also performed through a filtration process following the leaching procedure. The filter cake obtained as a result of solid-liquid separation process was dried in a drying stove and the vanadium content was analyzed through the ICP method. The vanadium dissolution efficiency was calculated through the following formula:

$$\text{V dissolution efficiency (\%)} = \frac{\left[\underset{\text{(ppm)}}{\text{V in the feed}} - \underset{\text{(ppm)}}{\text{V in the filter cake}}\right]}{\text{V in the feed(ppm)}} * 100 \quad (1)$$

3 RESULTS

The effects of different organic and inorganic acids on vanadium dissolution efficiency were respectively displayed in Figure 4 and Figure 5 in a graphical manner.

A regular increase was observed up to the acid quantity of 800 kg/tons in the vanadium dissolution efficiency within the scope of the tests performed with citric acid. The vanadium dissolution efficiency was found to be 36% in 800 kg/ton citric acid quantity and 4% decrease took place in terms of the efficiency in 1000 kg/ton acid quantity tried after this point. In the leaching tests performed with the use of tartaric acid, on the other hand, despite the fact that an efficiency increase of 200 kg/ton acid quantity, no significant change took place after this value. Consequently, the best results for vanadium dissolution efficiency in the leach tests performed with the use of organic acids were obtained with oxalic acid. The vanadium dissolution efficiency was found to be 50% as a result of the 2-hours leaching process performed under 40^{o}C with 200 kg/ton oxalic acid quantity.

No significant change was observed in terms of vanadium dissolution efficiency up to the acid quantity of 600 kg/ton within the scope of the leaching tests performed with the use of sulphuric acid. Vanadium dissolution efficiency showed an increase after this point up to the point of 800 kg/ton and it reduced to 46% with a decrease of 14% in the acid quantity of 1000 kg/ton. An efficiency increase was observed up to 400 kg/ton acid amount where 62% vanadium dissolution efficiency was obtained in the tests performed with hydrofluoric acid. After this point, on the other hand, vanadium dissolution efficiency showed a decrease tendency. In the leach tests performed with the use of inorganic acids, the best results for vanadium dissolution efficiency were obtained with hydrofluoric acid. A dramatic efficiency increase of 20% took place in 200 kg/ton acid quantity in comparison with 100 kg/ton acid quantity in the tests performed with hydrofluoric acid. The efficiency increase tendency sustained up to the point of 800 kg/ton depending on the acid quantity but it was less than the increase between the first two quantities tried. 76% vanadium dissolution efficiency was obtained in 800 kg/ton hydrofluoric acid quantity where the best result was obtained. Figure 6 shows the concentrate and the impurities in it that was obtained as a result of the leaching process performed with hydrofluoric and oxalic acids. As can be seen from the microscopic images, hydrofluoric acid was more efficient than oxalic acid, which is an organic acid, in terms of the dissolution of V bearing impurities.

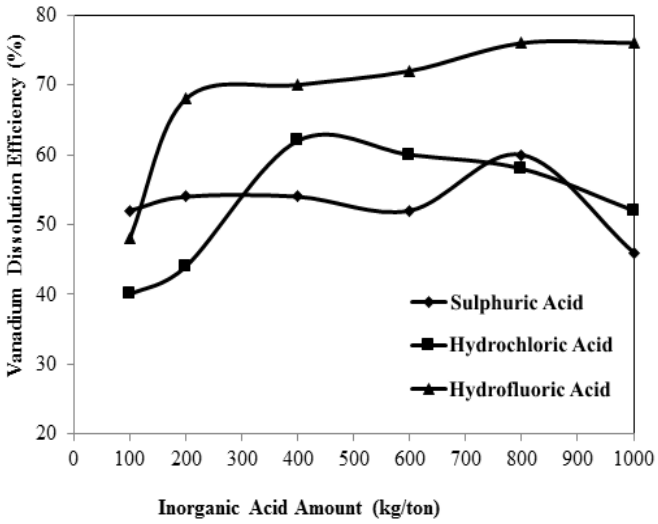

Figure 5. The effect of different inorganic acids on vanadium dissolution efficiency

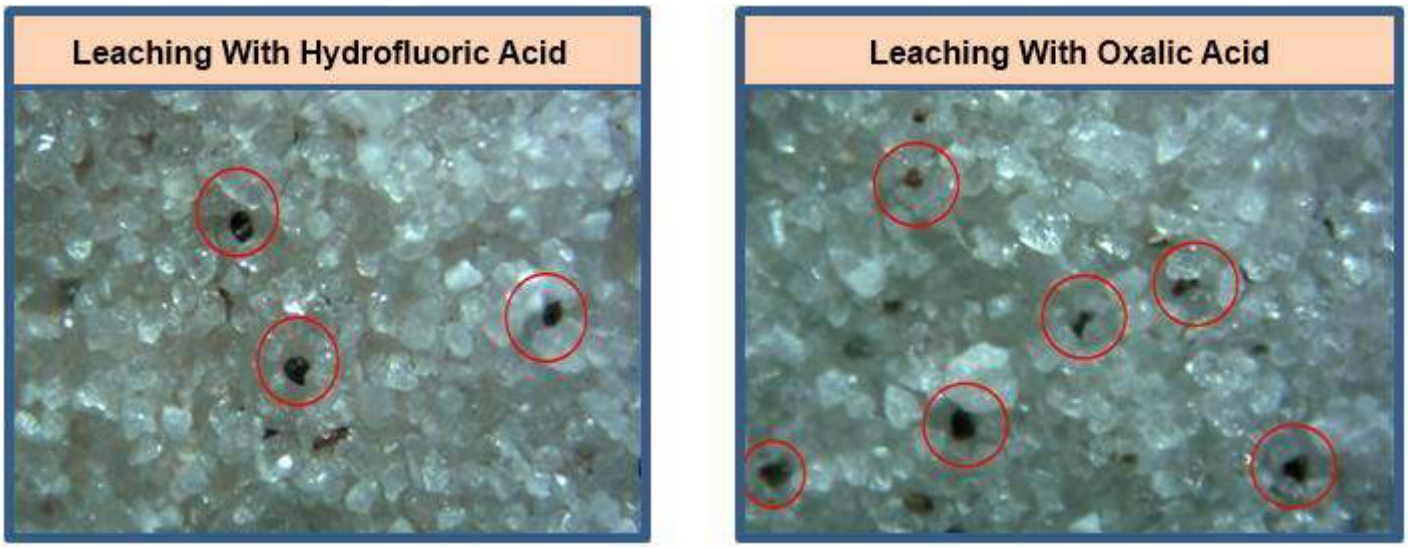

Figure 6. Images of concentrates obtained as a result of the leaching tests

4 DISCUSSION AND CONCLUSION

The best results for vanadium dissolution efficiency were obtained with oxalic acid in leaching tests conducted with the use of organic acids. Vanadium dissolution efficiency was found to be 50% as a result of the 2-hours of leach test conductedwith 200 kg/ton oxalic acid under 40 ^{o}C.

The best results for vanadium dissolution efficiency were obtained with hydrofluoric acid in leaching tests conducted with the use of inorganic acids. Vanadium dissolution efficiency was found to be 76% as a result of the 2-hours of leaching test performed with 800 kg/ton hydrofluoric acid under 40 ^{o}C.

Mining and Environment

Forestry Biological Reclamation of Damaged Mining Terrains

I. Grigorova, I. Nishkov
University of Mining and Geology "St. Ivan Rislki", Department of Mineral Processing and Recycling, 1700 Sofia, Bulgaria

ABSTRACT Subject to reclamation are all damaged terrains as well as the adjacent land lots which have partly or completely lost their productivity as a result of the negative impact upon them from the mining activities and the damaged terrains. A similar problem exists in Kaolin AD, Bulgaria. The main raw material mined in the company's open pits is quartz-kaolin sands. The overburden dumps are formed as a result of the accumulation earth material extracted with open pit mining. These earth formations have no purposeful economic use and damaged mining terrains is need of reclamation. Chemical modified zeolite, organo-zeolite compost and bio-zeolitic ameliorants for forestry biological reclamation were studied. The basic mineral ameliorant is Bulgarian natural zeolites. The pot experiments were performed. Different tree types were shown in the studied substrate mixtures and the plant growth is investigated.

Keywords: Biological reclamation, damaged terrains, the pot experiment

1 INTRODUCTION

The technology for creating forest cultivars on the damaged by the mining industry terrains differs considerably from the ones applied in the creation of plantings upon non damaged terrains and depends mainly on the forestry growing conditions which at the damaged terrains (dumping grounds and quarries) are quite specific and extremely unfavorable. The ameliorative activities should follow the objectives of an accelerated forestry biological effect through decreasing the acidity of the substrata, increasing the fertility of the dumps, creating appropriate conditions for growth of the vegetation characteristic for the natural for the region ecosystems. Tree types used for reclamation should be appropriate for the geographical climatic and forestry area, to be non exigent towards the edaphic conditions and more specially to be resistant to acidity and with high anti erosion potential.

The patterns for reforestation should be specific and should ensure a good anti erosion effect as well as to be able to quickly establish a sustainable forestry ecosystem.

Subject to reclamation are all damaged terrains as well as the adjacent land lots which have partly or completely lost their productivity as a result of the negative impact upon them from the mining activities and the damaged terrains. A similar problem exists in Kaolin AD, Bulgaria. The main raw material mined in the company's open pits is quartz-kaolin sands. The overburden dumps are formed as a result of the accumulation earth material extracted with open pit mining. These earth formations have no purposeful economic use and damaged mining terrains is need of reclamation. Numerous soil samples were taken from overburden dump and agrophysical and agrochemical properties of anthropogenic soil are determined (Prokopiev et al 2012; Ming et al 1993; Chapman 1965).

Research and development program is started to develop new ameliorants for amending the agrochemical and physicochemical properties of anthropogenic soil. The program has undertaken restoring the function of damaged lands and the creation of balanced ecological systems.

This paper describes some results on an experimental work in the frame of the research program for forestry biological reclamation of damaged mining terrains.

2 EXPERIMENTAL

2.1. Methods and Materials

For amending of agrochemical and physicochemical properties of anthropogenic soil new ameliorants for forestry biological reclamation are developed. The basic mineral ameliorant is Bulgarian natural zeolites. Three different mineral ameliorants were studied:

- Chemical modified zeolite (CMZ). This product is a slow-acting mineral ameliorant enriched of nitrogen, phosphorus, potassium and microelements.
- Organo-zeolitic fertilizer (OZF). This ameliorant is a mechanical mixture of organo-matter and chemical modified zeolite which is enriched additionally with humus (Filcheva et al 1988; Chakalov et al 2002).
- Biozeolite ameliorant (BZM). This product is chemical modified zeolite enriched of biological enzymes.

Agro-chemical parameters of new ameliorants were determined. The phosphorus and potassium in aqueous extract of ameliorants were determined by method of Egner-Riim (Chakalov et al 2002). The exchange nitrogen is determined using 1 % solution of KCl and the digestible forms and microelements - using Morgan extract solution at pH = 4.8.

One year pot experiments were performed. The substrates including studied overburden dump soil and different mineral ameliorants were produced. The ameliorant contents in the substrate mi*xt*ures are 5 and 10 vol. %, respectively. Six different substrates were studied:

- K-1 (Control): Anthropogenic soil;
- K-2 (Control): Mechanical mixture of anthropogenic soil with Nitrogen – phosphorus - potassium (NPK) fertilizer (40 g/100 kg substrate);
- B-1: Mechanical mixture of anthropogenic soil with 5 % chemical modified zeolite;
- B-2: Mechanical mixture of anthropogenic soil with 10 % chemical modified zeolite;
- B-3: Mechanical mixture of anthropogenic soil with 5 % chemical modified zeolite and 5 % organo-zeolitic fertilizer;
- B-4: Mechanical mixture of anthropogenic soil with 5 % organo-zeolitic fertilizer and 5 % biozeolite ameliorant.

Numerous pot experiments were conducted. Different plants were sown in the substrate mixtures and the process of annual growth was investigated. The following forest cultivars were studied: *Paulownia tomentosa; Paulownia elongate; Lycium barbarum; Robinia pseudoacacia L.*

The biometric measurements of annual plants were performed. The diameter of the tree trunk, tree height, number of leaves, leaf surface, number of fruits, fruit weight, average fruit weight and number of offshoots are determined. After annual plants growth the chemico-biological measurements of substrate mixtures were performed. Additionally the leaf diagnosis of annual trees was performed.

3 RESULTS AND DISCUSSION

The agro-chemical parameters of chemical modified zeolite, organo-zeolic fertilizer and biozeolite ameliorant are presented in Table 1.

The data show that all three ameliorants have slightly acidic pH and high electrical conductivity. This will be beneficial in preparation of substrate mixtures including overburden dump soil and ameliorant in relevant ratio.

Table 1. Agro-chemical parameters of new ameliorants.

Agro-chemical parameters	Chemical modified zeolite	Organo-zeolitic fertilizer	Biozeolite ameliorant
Aqueous extract			
pH	4.44	4.65	5.71

Mo, (mg/1000 g)	-	5	5
B, (mg/1000 g)	-	5	5

The data presented on Table 2 show the annual growth of *Paulownia tomentosa* in condition of pot experiments for biological reclamation of anthropogenic soil.

The anthropogenic soils fertilized with Nitrogen – phosphorus – potassium (NPK) fertilizer (40 g/100 kg substrate) providing nutrients to the middle of the second month after planting. Subsequent to initial good plants development growth retardation occurs. Similar treatment effects of the substrates with biozelite ameliorant since the initial growth stimulation are depleted nutrients and the plants cease growth.

Upon soil improvement with 5 и 10 % chemical modified zeolite and organo-zeolitic fertilizer very strong growth was established. The diameter of the tree trunk exceeds over two times that seen in the control. Tree heights are over three times greater than that of the control. The leaf surface is much larger - up to 15 times greater than the control.

The results of annual growth of *Paulownia elongate* in condition of pot experiments are presented on Table 3.

In this plant sorts the differences in the annual growth are crisper. The treatment with 10% chemical modified zeolite increased the tree trunk diameter two and a half times and the tree height up to twice. The number of the leaves increased from six to seven times compared with the control with NPK fertilizer.

The statistical analysis indicates that both two types *Paulownia* reared and treated with 5 and 10 % chemical modified zeolite and organo-zeolitic fertilizer have well-proven differences compared with control tests К-1 и К-2. These alternative solutions have no proven significant differences in plant development and can be concluded that the variant with chemical modified zeolite 5 % chemical modified zeolite probably will be economically preferred.

The biometric measurements of *Lycium barbarum* are presented on Table 4.

The treatment of anthropogenic soil with mineral ameliorants stimulates rapid growth and development of this plant sort. Once again confirms that the treatment with biozeolite does not provide prolonged normally mineral nutrition of plants.

The plants reared with 5 и 10 % chemical modified zeolite and organo-zeolitic fertilizer has doubled the height of the shrub. All mineral ameliorants supporting the first growing season to plants fruitage. In both controls fruitfulness plants do not realize. The substrate comfortable mineral nutrition treating with 10 % chemical modified zeolite providing larger fruits and nearly three times higher yield compared with those in 5% of treatment with chemical modified zeolite.

The data presented on Table 5 show the annual growth of *Robinia pseudoacacia L.* in condition of pot experiments for biological reclamation of anthropogenic soil.

Proven difference has not been established at none of biometric measurements in condition of pot experiments with *Robinia pseudoacacia L.* By visual observation was found that the best plants grow reared in anthropogenic soil with biozeolite ameliorant. Probably due to the root system initial stimulation and the organic nitrogen subsequent accumulation in the rhizosphere of these plants.

The data presented on Table 6 show the influence of mineral ameliorants on the mobile forms of macro-elements in pot experiment conditions.

The results obtained from pot experiments with *Paulownia tomentosa* indicate that N-NH_4 content increases from 22 to 102%, the N-NO_3 content - from 58 to 91%. The mobile forms of P_2O_5 increases from three to four times and a K_2O average twice times. At pot experiments with *Paulownia elongata* due to a rapid growth of the species significantly faster depletion of accessible nitrogen was found. Obviously this sort is less demanding to phosphorus and treatment with 5 and 10% chemical modified zeolite in the substrate has a good availability of phosphorous and potassium. There is enhanced nitrification activity and in some variants the nitrate nitrogen is up to 15 times higher than the control. The mobile forms of P_2O_5 are increased 6 to 14 times and potassium - from 37 to 87%.

The ameliorants have slight influence on the medium active reaction. A slight tendency to decrease the medium alkaline reaction was established. Positive effects on agrochemical characteristics are found. The positive effects on the agrochemical characteristics of the treated substrates affect plants mineral nutrition.

The macro-elements content in *Paulownia tomentosa* leaves is presented on Table 7.

The results show that *Paulownia tomentosa* grown in treated with zeolite substrates, the plants absorbed to three times much nitrogen. The phosphorus is comparable to control content and potassium is up to twice over in the plants leaves reared under ameliorated with zeolite products anthropogenic soils. The plants assimilate in large amounts of magnesium.

The leaf diagnosis of *Paulownia elongate* is shown on Table 8.

The results shows that *Paulownia elongate* grown by treated with zeolite substrates, the plants contain from 21% up to twice nitrogen in the control. This means that powerful vegetative growth which was established saplings accumulate several times over nitrogen than control plants. The phosphorus content is comparable to the control, but the content of potassium is 32 to 85% more than the control. Zeolite soil conditioners control the absorption of calcium and magnesium and significantly reduce their content in leaves.

The data presented on Table 9 show the influence of mineral ameliorants on the mobile forms of macro-elements in pot experiment conditions with *Lycium barbarum.*

The results obtained from pot experiments with *Lycium barbarum* confirm the trends that were established in experiments with *Paulownia*. The active medium reaction slightly influenced by meliorants. Using 10% zeolite ameliorant salt concentration of the aqueous extract and the total nitrogen increases. Ammonia nitrogen content reduce due to its absorption by plants and nitrification activity of represented the rising microflora. The content of available nitrogen and phosphorous in the middle of the vegetation of *Lycium barbarum* is sufficient for plant growth at a dose of 10% in this pot experiment. All substrates are well stocked with absorbable potassium.

4 CONCLUSIONS

The experimental results show that anthropogenic substrates from Vetovo region improving with zeolite meliorants increase their productivity 2.5 times in terms of pot experiments. This is due of the improved mobility of macronutrients and their enhanced absorption by the plants.

Effect of Crack Width, Length, and Depth on Surface Disposal of Sulphidic Paste Tailings

E. Yilmaz
University of Quebec in Abitibi-Témiscamingue (UQAT), Department of Applied Sciences, 445 Boul. de l'Université, Rouyn-Noranda (Québec) J9X 5E4 Canada

ABSTRACT A field study was initiated to assess the effect of crack with, length and depth on the performance and quality of sulphide-rich paste tailings. This investigation included the construction of two experimental cells covered by special disposal configurations (categorized as cemented cell CC and uncemented cell UC). Each cover was instrumented by a number of sensors to monitor its geotechnical behavior. Results show that the width and depth of cracks in the UC is bigger than those of the CC. The formation of cracks occurred in layers is reliant on the time interval and configuration of deposition. The longer the deposition process, the deeper and wider the formation of crack causes. The drainage of upper layer is accelerated after the deposition of tailings on a dry surface layer. This is due to the suction which creates a fast movement of water towards the bottom and may lead to a fast crack occurrence.

Keywords: Surface tailing disposal, Crack width, Crack length, Crack depth

1 INTRODUCTION

Mine tailings require careful management to certify the storage stability, and to avoid land contamination. The unsuitable management of mine tailings creates the unwanted events, such as acid rock drainage (Verburg, 2002; Bussière et al., 2004; Aubertin et al., 2006; Blight, 2010; Fourie, 2012). Technological advances have resulted in significant changes in the tailings management practices over the last decade. As a result of alternative tailings deposition methods, mine tailings are now better managed than they have been in the past (Slotte, 2004; Dixon-Hardy and Engels, 2007; Hudson-Edwards et al., 2011; Yilmaz, 2011; Lotermoser, 2011; Edraki et al., 2014). One of these ways is surface paste disposal (SPD), where each layer of paste tailings is deposited and allowed to dry before the next layer is put in place. Paste (70-85% solids) is made in the specialised paste thickeners or high-density thickeners and transported with the pumps into underground stopes.

Paste disposal has been effectively used as underground backfill for many years (Fall et al., 2009; Benzaazoua et al., 2008; Potvin et al., 2005; Kesimal et al., 2006; Cihangir et al., 2012; Belem et al, 2013; Ercikdi et al., 2014). Evolved from the technology used for backfilling of underground voids, SPD is new and its application is relatively limited (Robinsky, 2000; Landriault et al., 2001; Bussière, 2007; Deschamps et al., 2008; Yilmaz, 2010). Transporting and producing paste is costly due to the high capital and operating cost of thickeners and pumps. Compared to other methods, SPD becomes an attractive option since it allows for a smaller footprint area, an improved water recovery capability and lower environmental impacts (Sofra and Boger, 2002; Grabinsky et al., 2002; Crowder et al., 2002; Cadden et al., 2003; Benzazoua et al,, 2004; Deschamps et al., 2007, 2011; Bryan et al., 2010; Tariq and Yanful, 2013; Yilmaz et al., 2014). A lot of investigations have been done on quality and behaviour of SPD at laboratory and field environments. These consist of rheological behaviour for an advanced tailings delivery system, disposal behaviour for minimizing the environmental impact, and environmental behaviour for the improved geotechnical properties of tailings (Theron et al., 2005; Verburg et al., 2006; Simms et al., 2007; Martin et al., 2010; Mizani et al., 2013).

The Bulyanhulu mine (Tanzania) was the first gold mine to adopt the technology of SPD for tailings management (Shuttleworth et al., 2005). Paste tailings do not contain any binder when they are used for surface disposal. Tailings have a slump consistency of 250 mm (Theriault et al., 2003). One of the most challenging tasks to be considered for SPD is to eliminate the tailings' potential reactivity. It is well known that sulphide-rich paste tailings may oxidize in the presence of water and oxygen, and generate sulphuric acid (Benzaazoua et al., 2004). The SPD's behaviour has also been examined using lab-scale physical models, which could replicate the in situ conditions of surface disposal in terms of climatic conditions, consolidation, volume change, evaporation, surface cracks, and geometry (Landriault et al., 2001; Kwak et al., 2005; Oxenford and Lord, 2006; Henriquez and Simms, 2009; Deschamps et al., 2011; Yilmaz et al., 2011, 2013). These studies have well confirmed that field testing is vital to realize the SPD's behaviour.

Consequently, a complete understanding of these aspects is needed to evaluate in situ depositional behaviour of tailings at Laronde Mine (Canada). This paper deals the two field cells undertaken to study the effect of crack width, length, and depth on surface disposal of tailings. The goals of this work are; *i)* to assess the effect of two different disposal conditions (cemented cell – CC and uncemented cell – UC) on surface paste disposal; and *ii)* to characterize the behaviour of sulphidic paste tailings. The key interest of the present paper stems in part from the fact that this is one of the very first attempts, to the authors' knowledge, to investigate in situ behaviour of tailings under accurately simulated surface disposal conditions. The key contribution of this paper is related to the assessment of SPD's crack behaviour.

2 LARONDE MINE

LaRonde is Agnico-Eagle's flagship mine, located in the Abitibi region of northwestern Quebec, 45 km from the town of Rouyn-Noranda and 650 km in the direction North West of the city of Montreal. Since 1988, LaRonde has produced more than 4.3 million ounces of gold. With proven and probable gold reserves of 4.7 million ounces (33 million tons grading 4.4 g/t gold), LaRonde has one of the largest gold reserves of any mine operating in Canada. In 2006, LaRonde began to construct a deep extension of the mine to access higher-grade ore to a depth of about 3.1 km and extend the life of the operating mine. The 7,200-ton-per-day mine and plant are expected to average about 320,000 ounces of gold production annually, over a mine life lasting through to 2023.

2.1 Tailings Management

Mine tailings not recycled underground in paste backfill, are stored in tailings ponds covering an area of approximately 119 hectares and waste rock is stored in two waste rock piles with a combined volume of approximately 1.43 million cubic meters. The Company holds mining claims to the north-east, to the east and to the south-east of the mine tailings ponds that would allow expansion of the tailings ponds and the establishment of additional waste disposal areas. Figure 1 shows an aerial view of the tailings pond sites.

Figure 1. Laronde's tailings impoundments sites, including mine tailings discharged by spigotting off dykes

2.2 Paste Backfill Plant

The mine uses paste backfill as a means of supporting underground excavations and to return a large percentage (30-50%) of mill tailings. Paste backfill is made up of total tailings, mine recycled water for mixing and a binding agent (a blend of ordinary Portland

cement and high sulphate resistant hydraulic cement with a ratio of 50:50) at a binder content of 5 wt% (by the solid mass of dry tailings). Figure 2 shows a typical flow chart of the LaRonde paste backfill plant.

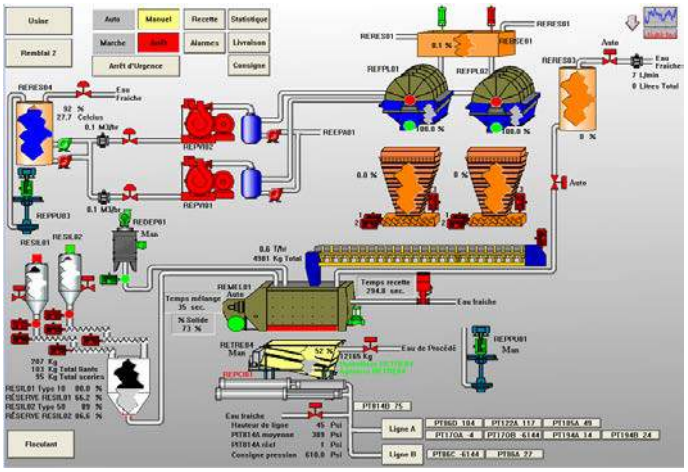

Figure 2. Laronde's paste plant flowsheet

Tailings are first fed into a high capacity conventional thickener of 20 m diameter to increase the solid concentration to 60 wt%. The thickened tailings are then pumped from the thickener to a high capacity holding tank (900 tonnes). From the high-density storage tank, the thickened paste tailings are fed to two disc filters operating in parallel to make filter cake with a solid concentration of 70-85 wt%. The filter cake is then discharged onto a reversible belt conveyor and fed to a feeder for weighing. Finally, the filter cake batches are mixed in a high intensity mixer (5 m^3) with binder and water added for about 45 sec to make a paste with a consistency of approximately 267 mm. The paste material prepared is transported underground through a piping system using pump and gravity. The underground stopes to be filled by tailings with cement are characterized by a fractured rock which allows a well drainage conditions during the gravity-driven consolidation.

3 MATERIALS AND METHODS

3.1 Materials

Tailings were sampled as representative of the tailings streams from the paste plant of the LaRonde mine. Portions of the samples were air dried to conduct a set of lab tests needed for the material characterization. The following tests were conducted according to ASTM standards testing procedures. Further details on material properties can be found Yilmaz (2010), and Yilmaz et al. (2011).

3.1.1 Paste tailings characteristics

The representative paste tailings were sized using a Malvern Mastersizer® laser particle size analyser under wet conditions. Based on unified soil classification system (McCarthy, 2007), the tailings tested can be classified as low plastic silt. The fine content (minus 20 μm) within paste tailings was 41 wt%. Table 1 lists a summary of the tailings' physical properties. The effective grain diameter D_{10} in the tailings was 5.04 μm.

Table 1. Physical properties of tailings

Parameter	Value
Gravimetric water content w (%)	24.3
Solids specific gravity G_s	3.37
Clay-sized particles (< 2 μm, %)	3.5
Silt-sized particles (2-50 μm, %)	67.0
Sand-sized particles (50-2000 μm, %)	29.5
Coefficient of uniformity C_u	6.90
Coefficient of curvature C_c	1.03

3.1.2 Hydraulic cement characteristics

For the cemented cell CC, the first layer was cemented paste tailings. The binder used for the mixture preparation is Portland cement or type (PCI). Only 2wt% of binder was chosen to evaluate the influence of barrier cover as cemented material on surface paste disposal. Proportion was calculated on basis of weight, relative to total dry tailings. The chemical analyses and physical property tests show that PCI has a specific gravity of 3.15, a specific surface area of 1.58 m^2/g, a Al_2O_3 content of 4.86 wt%, a CaO content of 65.76 wt%, a Fe_2O_3 content of 2.44, and a SiO_2 content of 19.51 wt%.

3.1.3 Pore water characteristics

ICP-AES (Perkin Elmer Optima 3100RL) system was used to analyze the chemistry of initial tailings pore water. Results show that sulphate content was high at 3295 ppm due to cyanide destruction by SO_2/Air method.

The calcium content was high at 505 mg/L, due to the addition of lime for pH control during milling. Given that the acidification potential AP of 897.2 kg $CaCO_3/t$ (AP = $31.3 \times S_{sulphide}$), tailings are acid generating.

3.1.4 Paste tailings mineralogy

The mineralogy of tailings was evaluated by X-ray diffraction tests. The diffractograms used to assess the detectable mineral phases of paste tailings were evaluated by Rietveld fitting method using the TOPAS software. Results revealed that tailings were dominated by quartz (53%) and pyrite (29%). Minor quantities of alumino-silicate minerals which mainly include paragonite (6.7%), muscovite (4.9%), chlorite (4.7%), and gypsum (2.1%) were detected.

3.1.5 In-situ porosity determination

The porosity measurement of in-place paste tailings is made by using a volume-known and end open cup ($D \times H$ =6.7 cm × 3.2 cm), based on a specific gravity and dry mass of the tailings (Fig. 3). Results exhibit that for all the layers, cemented cell CC provides a porosity of 48% while uncemented cell UC provides a porosity of 49%.

Figure 3. In-situ porosity determination

3.2 Methods

3.2.1 Field experimental cells

The testing site selected for construction of two field cells is near the existing tailings pond at LaRonde mine. A significant amount of tailings is currently discharged as slurry from mill to this pond via pumping. The cells are installed at old tailings pond. This area was chosen together with mine operators, taking consideration several factors, such as capacity, topography, and accessibility. Due to the fact that site elevation is about 3 m below the tailings pond, tailings are pumped easily to the cells. The site is roughly 100 m long by 25 m wide, ensuring the enough space so as to handle cells and construction equipment. A space of at least 5 m is also left between the cells for machinery.

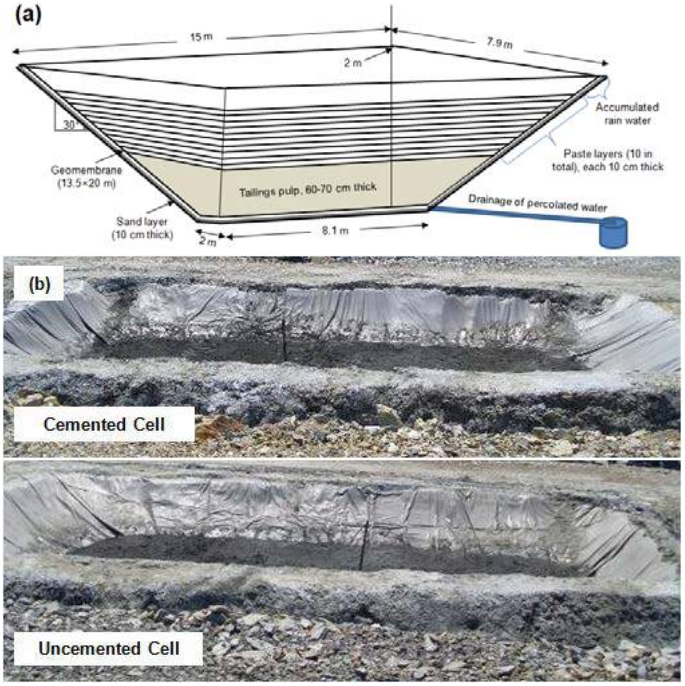

Figure 4. A schematic view (a) and photos (b) of field experimental cells

The two mini field experimental cells were designed at the surface depositional area of the LaRonde mine (Fig. 4). The first cell is designed by filling partially with the tailings containing a low cement content of 2 wt% and termed as Cemented Cell – CC while the second cell is designed by filling completely with tailings without cement and termed as Uncemented Cell – UC. This latter is also regarded as control cell.

3.2.2 Different disposal configurations

Disposal configurations refer to the layering patterns of the different layers of paste with our without cement addition. The deposition frequency was set at about one layer every

one week or three weeks, depending on paste plant and tailings availability. Underground mine operations required more paste to back-fill the mined-out openings. Figure 5 shows the photos of two field experimental cells designed in two configurations.

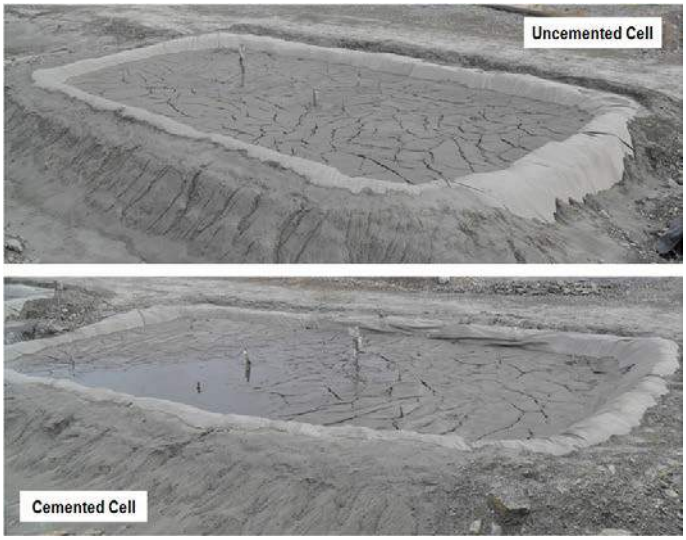

Figure 5. Photos of a successfully-completed layer of paste tailings into field cells

Each disposal configuration was made of 10 paste layers, each about 10 cm. The main reason behind this thin layer deposition is to let the paste material attain faster strength gains through desiccation since thick layers do not permit adequate desiccation to stop flows as the stack rises in height. To get a flat layer of the tailings, a Topcon® RL-H3C Rotating Laser is used across the cell. Only first layer is kept cemented in order to show the cementation effect as a barrier layer on mitigation or prevention of acid rock/mine drainage or tailings oxidation. The binder content used was only 2% by dry weight of tailings. The selected binder was ordinary Portland cement. Following the deposition of each layer, the deposited angle of layer is monitored and adjusted to 5° to ensure good drainage water. Between each layer disposal, some photos are taken to better characterize the phenomenon of desiccation.

3.2.3 Surface crack measurements

At the end of the drying period that followed the deposition of each layer, a number of crack measurements were taken using 5 m plastic tape meter rule (Fig. 6). Please note that the measurements taken will help better understanding the effect of cementation layer on overall surface disposal of paste tailings. In normal conditions, it is expected that the width, length, and depth of surface cracks in the uncemented cell is relatively larger than the ones in the cemented cell.

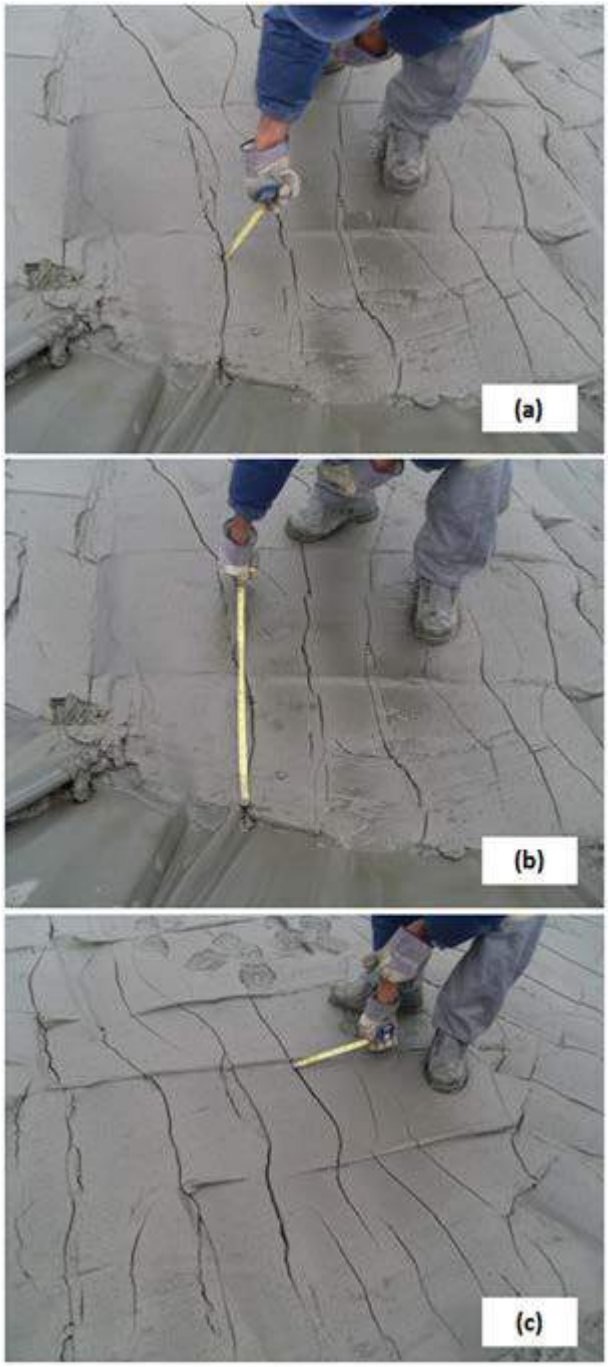

Figure 6. Photos of top surface crack depth (a), length (b) and width (c) of paste tailings in the field experimental cells

4 RESULTS AND DISCUSSION

Figures7-8 presents the raw and processed images of the top surface cracks (Layers 1 to 10) of deposited paste tailings in the CC and

UC configurations. The processing of the selected top images was performed using the Adobe Photoshop version 7.0 software. Once the cracked top surface of paste tailings layer is photographed, the cracks appear darker than the intact zones in the matrix; this clear different in contrast makes possible a good analysis. To give a consistency, the images taken are processed at similar configurations: balance = 1; black = 1; and white = 5.

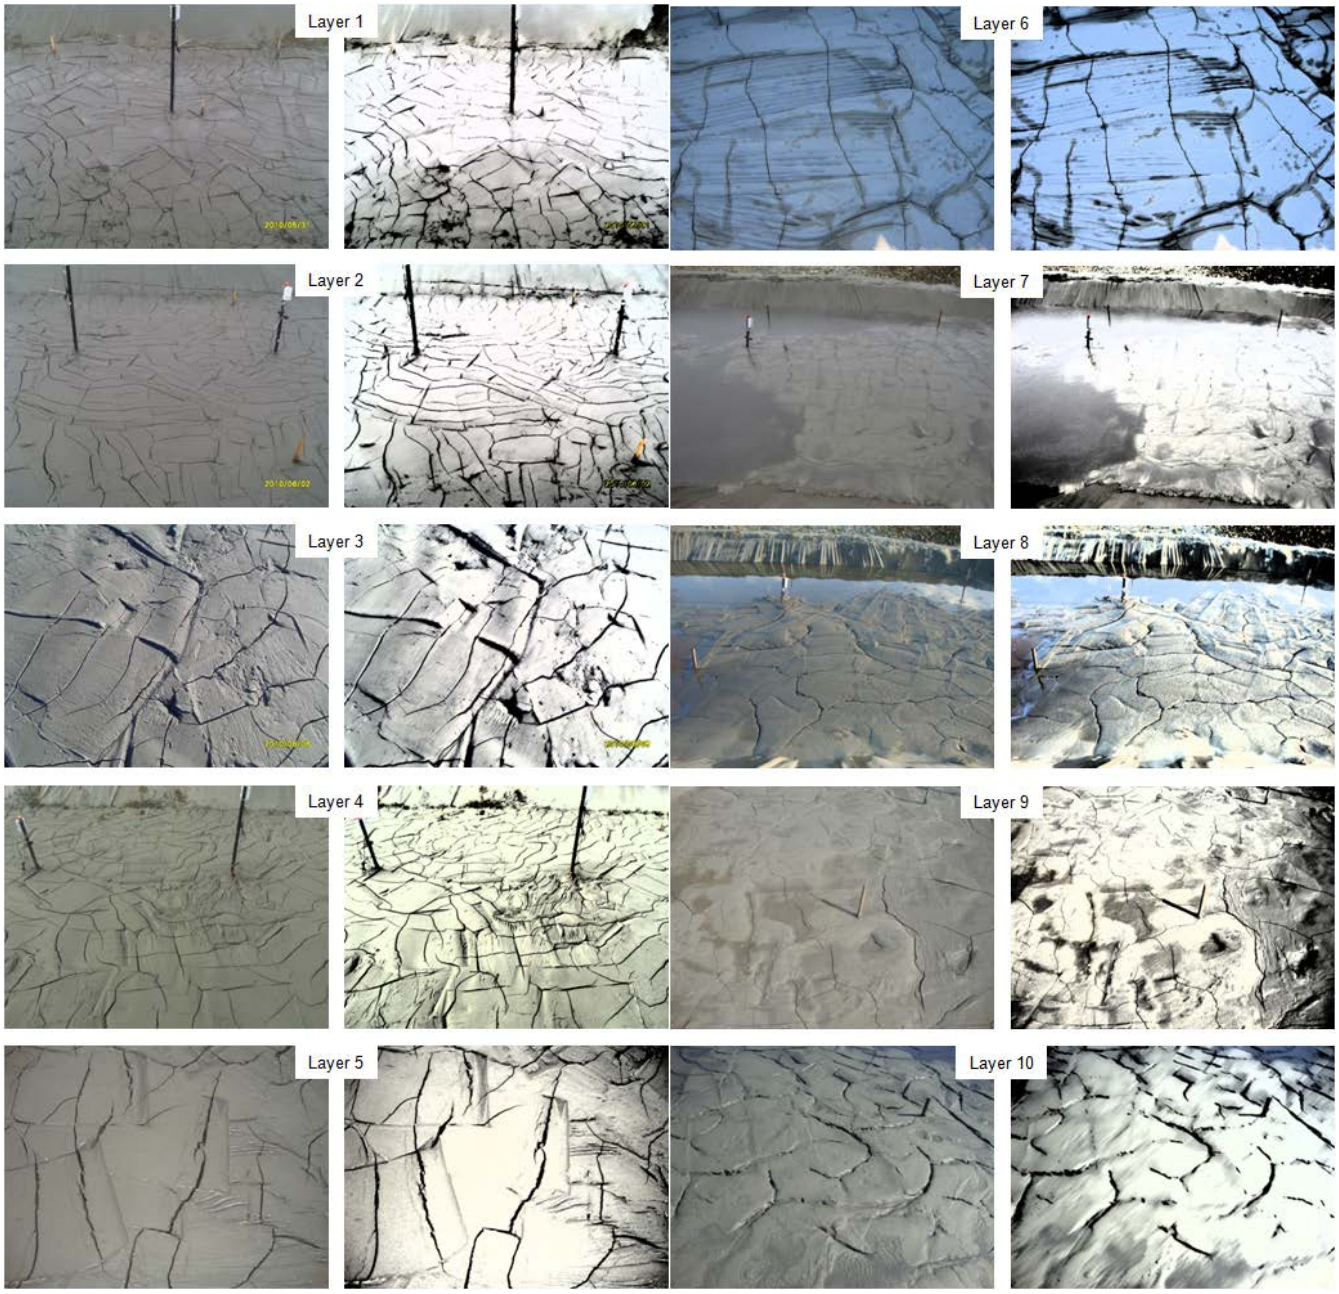

Figure 7. The raw (left) and processed (right) images of the top surface cracks (Layers 1-10) of paste tailings within the cemented cell (CC) disposal configuration

One can observe clearly that, irrespective of the layer, the first five layers shows more cracks than the remaining five layers due to the climate condition where evaporation is higher than precipitation, and the deposition time. Overall, the width, length and depth of cracks occurred in the UC is relatively bigger than the ones gained by the CC. This may be explained by continuous water consumption or retention (reflects increased saturation) of the cemented layer by the fresh-placed paste addition and self-desiccation processes.

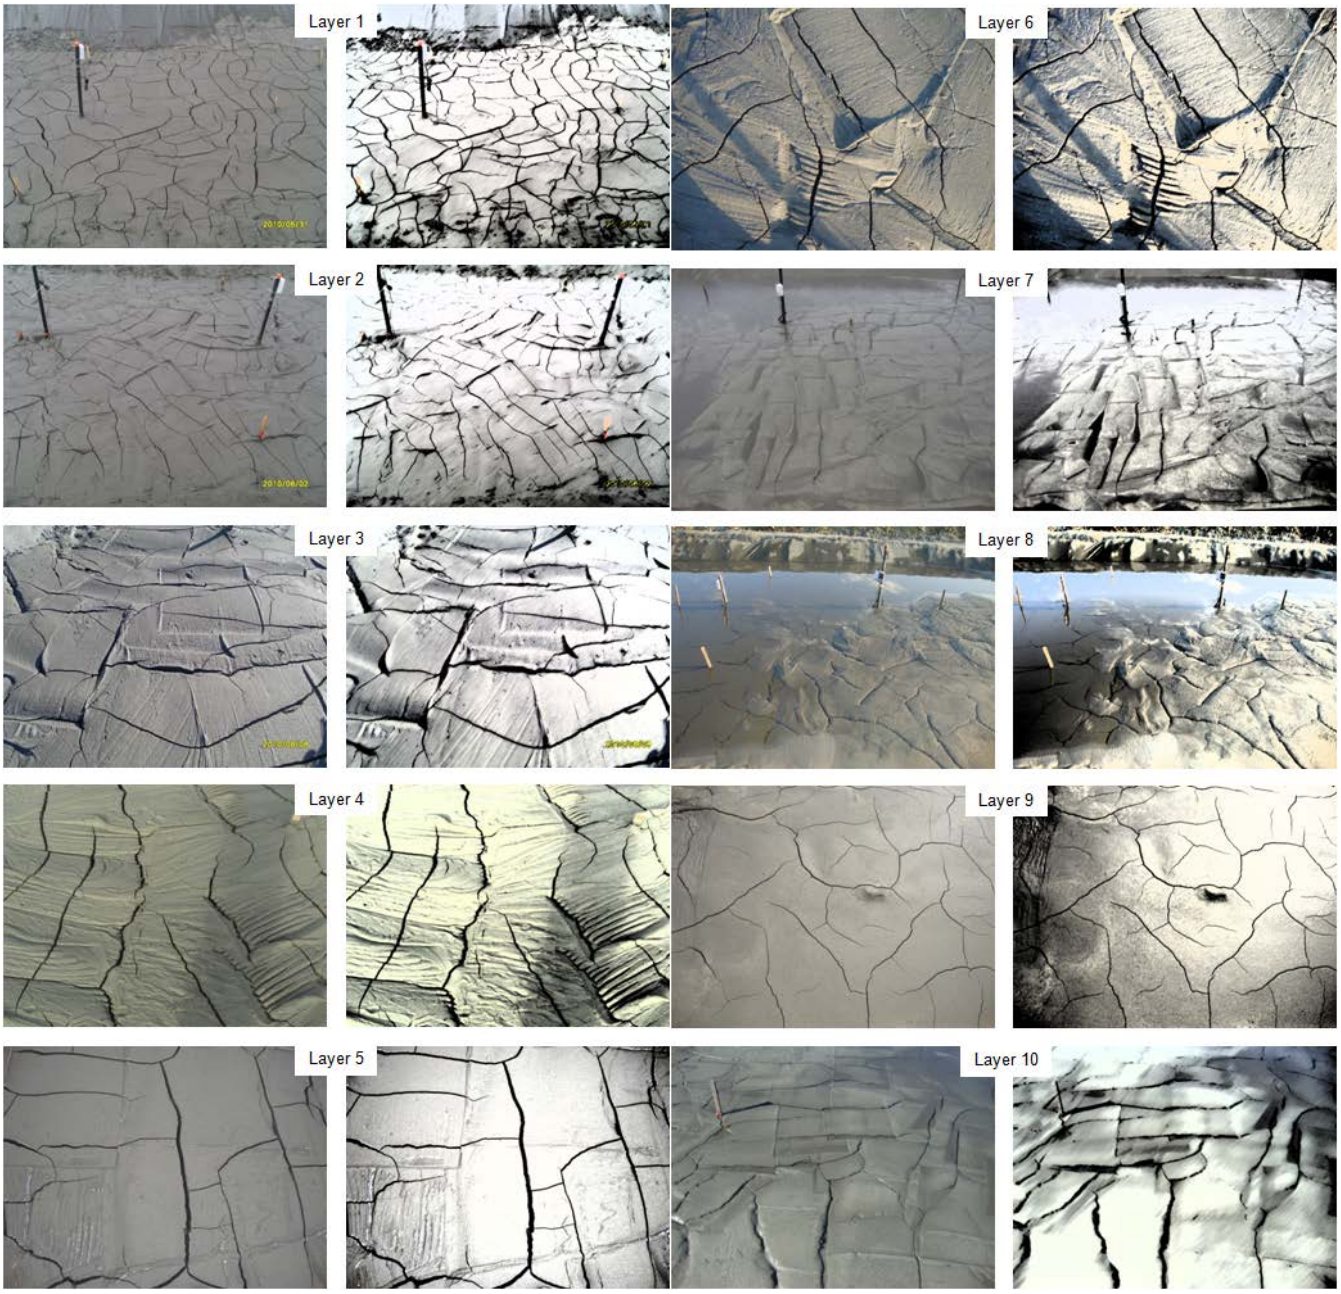

Figure 8. The raw (left) and processed (right) images of the top surface cracks (Layers 1-10) of paste tailings within the uncemented cell (UC) disposal configuration

It may also be interpreted that the total number of cracks decreases notably with the increasing number of deposited paste layers, but the width and depth of these cracks are getting fatter and bigger since they seem to reopen within previously-occurred cracks at similar locations in the cells. Figure 9 shows the plots of top surface crack measurements in terms of width, length and depth for paste tailings in the CC and UC configurations. One can speak that the crack width reduces or the surface crack depth increases when the number of the layers is increased. The range of crack width is reduced from 18.5 mm to 15 mm for the CC, and reduced from 21.5 mm to 20 mm for the UC while the crack depth is increased from 57 mm to 68.5 mm, and from 65 mm to 80 mm for the CC and UC, respectively. It must be noted that the formation of cracks occurred in the surface layers is dependent on the time interval and disposal configuration. The longer the paste storage process, the deeper and wider the formation of crack causes. The drainage of upper paste layer is accelerated right after the deposition of fresh tailings on a dry surface layer. This is due to the suction developed by layer below. This suction creates a fast

movement of water towards the bottom and might lead to a fast crack occurrence. This phenomenon is observed in the first layers where the crack occurred within three to four hours after the placement of paste.

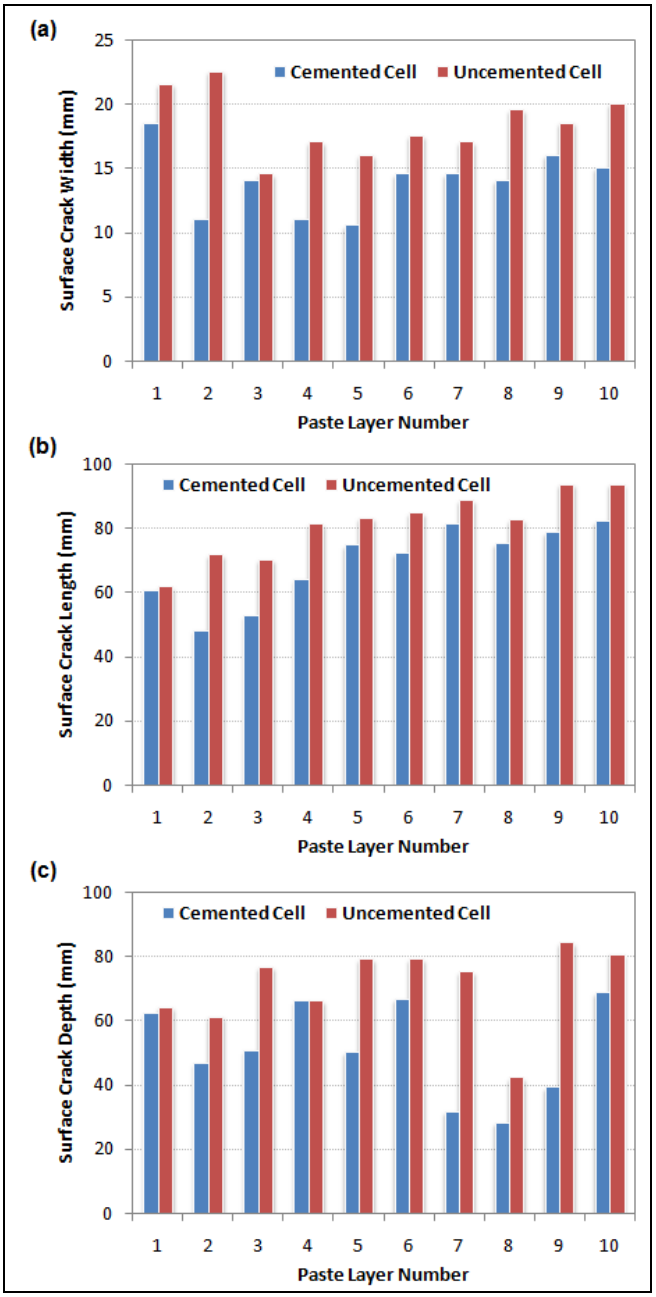

Figure 9. The plots of surface crack width (a), length (b), and depth (c) measurements of paste tailings in the CC and UC conditions

Please note that thinly-deposited tailings layers up to 30 cm are affected by the daily circle of the sun and may let excess water drain and therefore strength gains up to 20 kPa which allow for foot access within 1-2 days. The deposited paste layer in the UC was found to be more resistant than the ones deposited in the CC. This may be a part due to formation of cracks occurred depending on cemented layer and evaporation.

5 CONCLUSIONS

A field experimental study was carried out at the LaRonde Mine (Quebec, Canada) to investigate a possible application for surface disposal of paste tailings in the cemented cell CC and uncemented cell UC configurations. Paste tailings are prepared in the paste plant, transported by a read-mix truck to the mine site, and then deposited in the experimental cells layer by layer. A slump consistency of at least 10 inches (250 cm) for all the paste tailings is used prior to their placement. All the paste layers were made up of uncemented paste tailings, except layer 1 in the CC where 2 wt% of cement is added to paste tailings. This cement addition was chosen to assess the leachate reduction/ removal potential by the release of the contaminated metals and to prevent tailings oxidation by making layers saturated. Thus, this eliminates the diffusion of oxygen between layers. The top surface crack measurements show that the width, length and depth of cracks increase with the increasing number of the accumulated layers. This is due to the reappearance of already-occurred cracks in prior layers by the effects of evaporation and settlement. As a result, it is strongly believed that the results of these field works will bring a new light to tailings planners and operators and modern mines will shift their current tailings management systems to paste technology.

ACKNOWLEDGEMENTS

The author wishes to state his sincere gratitude to Mostafa Benzaazoua and Bruno Bussière for their financial support during this investigation. Special thanks are extended to Denis Bois, the principal of the UQAT-URSTM Laboratory, for experimental facilities, and to the professional people of URSTM Laboratory for their technical assistance. The Agnico-Eagle's LaRonde Mine and the Industrial NSERC-Polytechnic-UQAT Chair in Environment and Waste Management and the Canada Research Chair in the Integrated Management of Sulphidic Tailings are gratefully acknowledged for funding this project. A special

thank also goes out to Sandra Pouliot and Martin Bernard of the LaRonde Mine for their technical assistance during the project.

N. Poushkarov Institute of Soil Science, Agrotechnologies and Plant Protection, Sofia, Bulgaria

ABSTRACT Present paper discusses the problems related to accumulation of waste (pyrite cinder) on the territory of chemical plant "Neochim" Joint Stock Company, Dimitrovgrad, Bulgaria. Based on detailed study of affected areas is recommended technology for restoration of disturbed areas. The technology includes: neutralization of adverse pH activity; construction of surface layer of appropriate materials for technical and biological reclamation (fly ash from thermal power plants, soil and geological materials); selection of suitable plant species; organic-mineral fertilization with appropriate rates.

Keywords: pyrite cinder, reclamation, waste dumps

1 INTRODUCTION

Most of the production processes in different sectors of industry are connected with parallel creation of waste products. Some of these secondary materials have characteristics that allow their use for improving of properties and quality of soils, influenced somewhat by natural or anthropogenic degradation as well as for reclamation of technogenically constructed areas (Banov et al., 2009 a, b).

In other cases, composition and properties of industrial waste products pose a risk of ecological damage on the pedosphere. Often such wastes are associated with the chemical industry, which provides materials and reagents for subsequent use in various industries and mining activities. As an example can be mentioned, applied to 1994 geotechnological method for extraction of uranium using sulfuric acid solutions (Banov et al., 2010).

In present paper, based on preliminary studies, we present detailed characteristics of the area of chemical plant "Neochim" JSC, Dimitrovgrad and adjacent waste dumps for reclamation purposes.

2 MATERIAL AND METHODS

The "Neochim" JSC plant for production of sulfuric acid has operated until 1993. So far, the process of production of sulfur dioxide – SO_2 (semi product for production of sulfuric acid) was connected with accumulation of so-called pyrite cinder (waste from combustion of the pyrite concentrate). Deposition of waste products was carried out at two sites bordering the ash pond of thermoelectric power plant "Maritsa 3".

Preliminary studies were carried out in the area of pyrite cinder waste dumps, in order to identify the specific characteristics of the region and to prepare climate, geomorphological, geological, hydrological, and soil characteristics of the surrounding area. The soil types were correlated with the World Reference Base for Soil Resources (IUSS Working Group WRB, 2006).

Different materials from the area were studied to establish their suitability for possible use in technical and biological reclamation of waste dumps. The studies include geological materials from the area of mine "Marbas", fly ash from ash pond of thermoelectric power plant "Maritsa 3" and soil materials stored along the Maritsa River.

For complete characterization of appropriate geological materials, additional sampling was performed. The collected samples from all types of materials were analyzed for the following parameters:

- Mechanical composition – Kachynski (1958);
- Carbonates content – by the method of Sheibler (Vilenskiy, 1945; Nikolaev, 1962);
- Content of organic carbon – by the modified method of Tyurin (Kononova, 1963);
- pH (H2O) – potentiometric (Arinushkina, 1962);
- Content of available nitrogen (mg/kg) (Bremner, 1965);
- Content of available phosphorous (mg/100g) (Ivanov, 1984);
- Content of available potassium (mg/100g) (Ivanov, 1984;
- Content of heavy metals – ISO 114 66: 1995;

3 RESULTS AND DISCUSSION

Field study was carried out in the area for establishment of soil types. In addition with published data (Koynov et al., 1968; Dimitrov et al., 1992), it was found that soil groups in the area are the following:

- Vertisols (Pellic);
- Rendzic Leptosols;
- Fluvisols;

Impact of chemical plant on the soils in the area has been described by many authors. Dimitrov et al., (1992) found changes in soil pH values in surface horizons with up to 1 unit compared with the values found during the mapping carried out by the Institute of Soil Science "N. Poushkarov". Studies of other authors (Chuldzhiyan et al., 1995) indicate that emissions from the plant affect soils in two ways:

1. There is a fertilizer effect of nitrogen deposition;
2. Soil acidification due to nitrification;

On one hand, fertilizer effect is beneficial within certain limits, but on the other hand, acidification reduces buffer capacity of soils and lead to disturbance of their agronomic properties.

The studies show that there is soil contamination with heavy metals (lead and zinc) and sulfur in the periphery of the plant at a distance of 1,5 – 2,5 km. At a distance of 2,8 – 3,0 km east and south of the plant pollution is weak, but there are soil profiles where the content of cadmium, lead and zinc in depth is over limited permissible concentrations (BSECEEP and POVVIK-CAB Ltd., 2000; BSECEEP, 2000). That can be explained by the influence of airflows – established less contamination on the southeastern area around the plant corresponds to the prevailing west winds.

Studies of geological materials from the area for establishment of their suitability for technical and biological reclamation show that materials from "New mines" are suitable for technical reclamation of pyrite cinder waste dumps (Tables 1, 2).

As a result of studies on mechanical composition (Table 1) and average values of particles, the waste (fly ash), soil and geological materials have sandy loam texture. This creates prerequisites for creation of favorable water-air status and nutrient enrichment.

Table 1 Mechanical fractions in waste, soil and geological materials from studied region (%)

Sample	Particle size (mm)							
	>1	1,00 0,25	0,25 0,05	0,05 0,01	0,01 0,005	0,005 0,001	sum <0,001	sum < 0,01
1. fly ash	0,0	7,2	52,1	30,1	5,5	4,0	1,1	10,6
2. fly ash	0,0	8,2	37,8	38,9	10,2	2,4	2,7	15,3
3. fly ash	0,0	6,8	49,5	31,2	7,5	3,2	1,8	12,5
4. fly ash	0,0	8.5	41.3	35.5	8.2	4.3	2.2	14.7
5. soil materials	0,0	1,6	43,7	31,4	12,3	4,7	6,3	23,3
6. soil materials	0,0	3,2	61,3	19,4	9,2	2,1	4,8	16,1

Table 1. (cont'd) Mechanical fractions in waste, soil and geological materials from studied region (%)

7. soil materials	0,0	2,8	57,6	12,0	14,4	6,3	6,9	27,6
8. soil materials	0.0	2,5	49,3	25,3	13,7	4,1	5,1	22,9
9. geological materials	sandy loam							
10. geological materials	sandy loam							
11. geological materials	sandy loam							
12. geological materials	sandy loam							

Agrochemical studies show that soil and waste materials are alkaline. The geologic materials are characterized by neutral values of pH (Table 2).

Availability of phosphorus and potassium in fly ash and soil materials is good, while the content of these elements in geological materials is low. All studied materials have low nitrogen content (Table 2).

Carbon content, which is the basis for determination of humus content, defines low preservation of soil materials. In fly ash, the carbon quantities are result of presence of coal admixtures and do not give us a reason for interpretation of data in terms of humus content. Similarly is explained the high carbon content in geological materials from "New mines". In fact, in this case the values are also a result of presence of coal admixtures in collected samples (Table 2).

Table 2. Agrochemical characteristics of waste, soil and geological materials from studied region

Sample	pH		P_2O_5	K_2O	NH_4	NO_3	C
	H_2O	KCl	mg/100 g		mg/kg		%
1. fly ash	9,0	8,8	18,1	35,0	2,00	2,31	2,33
2. fly ash	8,9	8,7	16,8	29,7	2,40	4,06	2,78
3. fly ash	8,8	8,7	17,4	32,6	2,30	3,82	2,54
4. fly ash	9,0	8,8	18,5	30,5	2,40	4,26	2,18
5. soil materials	8,5	7,8	14,0	67,7	9,08	11,10	1,05
6. soil materials	8,5	7,9	8,3	42,6	6,20	9,08	1,73
7. soil materials	8,4	7,8	10,5	59,6	10,30	12,45	1,28
8. soil materials	8,5	7,9	11,6	70,23	8,70	9,94	1,53
9. geological materials	7,1	6,1	7,2	-	5,94	7,34	4,72
10. geological materials	7,3	6,5	8,3	-	6,12	8,52	6,55
11. geological materials	7,5	6,2	6,5	-	7,45	8,76	4,35
12. geological materials	7,5	7,2	7,6	-	6,57	7,84	3,17

The heavy metals content in studied materials (Table 3) was evaluated according to the requirements of Ordinance 3 on the admissible content of harmful substances in soils and Ordinance on supplementing Ordinance 3. According to the pH values (Table 2), which is limiting factor in terms of maximum admissible concentrations (MAC) of heavy metals, it is established that the fly ash, soil and geological materials do not contain heavy metals above the MAC.

Table 3. Heavy metals content in waste, soil and geological materials from studied region (mg/kg)

Sample №	Pb	Cu	Ni	Mn	Fe	Zn
1. fly ash	33,3	73,0	53,0	760	38000	93,5
2. fly ash	28,8	74,0	55,0	636	34200	105,0
3. fly ash	30,1	72,0	51,0	810	31000	87,5
4. fly ash	27,6	69,0	49,0	685	37500	108,0
5. soil materials	40,5	66,0	38,0	725	26250	99,0
6. soil materials	36,0	36,0	26,5	520	23060	75,0

10. geological materials	55,4	45,7	34,2	720	26400	160,5
11. geological materials	65,6	61,3	37,3	650	31500	157,0
12. geological materials	60,7	57,2	44,6	810	29450	162,5

4 CONCLUSION

As a result of the studies and additional research it can be concluded that the waste (fly ash), soil and geological materials are suitable for technical and biological reclamation of waste dumps for pyrite cinder. Essential for the success of reclamation is proper planning of: activities in different stages; the quantitative ratios between different groups of materials; the choice of appropriate plant species. First of all, it is necessary to be carried out neutralization of the adverse pH value in the terrains. The sandy loam texture of the studied soil and geological substrates will facilitate development of plant species, especially in the initial post reclamation period. Neutral and alkaline pH value of studied materials will have an additional positive effect on unfavorable acidity. The low content of available nitrogen may be offset by fertilization with appropriate rates. The lack of heavy metals in fly ash, soil and geological materials in quantities above the MAC exclude the possible negative impact on the environment.

ABSTRACT The present paper deals with possibilities for technical and biological reclamation of damaged areas in the region of Chiprovtci, Chiprovtci Municipality.

The physical and chemical characteristics of soil varieties from the territory of Chiprovtci region, disturbed during ore excavation were determined. The soil differences in the area and the climatic characteristics are described. Traditional scientific and analytical methods for soil analyses are used.

Different materials from the area were studied in order to establish their suitability for possible use in technical and biological reclamation of waste dumps.

A technological scheme for the implementation of technical and biological reclamation of damaged areas is proposed. Technology includes: filling of soil materials, fertilization, grassing and reforestation.

Keywords: Soil differences, Geological materials, Reclamation, Grassing, afforestation.

1 INTRODUCTION

The extraction of ore minerals is accompanied by extreme violations of the environmental components – mainly soil. The violations result from excavation and mining operations, the accumulation and distribution of the sterile geological materials, the construction of industrial zones of the mine, the building of subsidiary roads and others. Additionally, soils in neighboring area are subject to contamination with heavy metals and anthropogenic acidification. In conclusion, soils are mostly completely destroyed, as in most cases the changes even affect the landscape of the site.

According to the requirements of the European regulations (Directive 2004/35/ of the European Parliament and the Council on environmental liability regarding the prevention and remedying of environmental damage; the Thematic Strategy for Soil Protection; the Proposal for a Directive of the European Parliament and of the Council; the Establishing Framework for the Protection of Soil and amending Directive 2004/35/EC/) and the Bulgarian legislation (Ordinance 26 for Land Restoration, Improvement of Low Fertility Lands, Removal and Utilization of the Humus Layer) damaged and contaminated sites are subject to restoration and fertilization – reclamation.

This process is linked to the execution of a number of events that are directly dependent on the specific terms /condition of the terrain, the weather conditions, the presence of vegetation, etc. / on-site and in the adjacent areas.

2 MATERIAL AND METHODS

The subject of this study are the damaged and contaminated sites due to the activities of mine "Martinovo", where ferrous ore is extracted.

Mine “Martinovo” is located about 8 km west of the town of Chiprovtzi. The production activity of the mine was suspended in 1999.

As a result of the mining and processing activities in the area of mine "Martinovo" a technogenic (industrial) landscape has formed.

The established damaging of the natural landscape and the effect of the negative impact on the environment components can be prevented through the application of appropriate reclamation measures.

Preliminary studies were carried out in the investigated area in order to identify the specific characteristics of the region and to prepare climate, geological, hydrological, vegetation and soil characteristics of the surrounding area.

Different materials from the area were studied to establish their suitability for possible use in technical and biological reclamation of waste dumps. For complete characterization of appropriate geological materials, additional sampling was performed. The collected samples from all types of materials were analyzed for the following parameters:

- Mechanical composition – Kachynski (1958);
- Carbonates content – using the method of Sheibler, 1945; Nikolaev, 1962);
- Content of organic carbon – using the modified method of Tyurin (Kononova, 1963);
- pH (H_2O) – potentiometric (Arinushkina, 1962);
- Content of available nitrogen (mg/kg) (Bremner, 1965);
- Content of available phosphorous (mg/100g) (Ivanov, 1984);
- Content of available potassium (mg/100g) (Ivanov, 1984).

3 RESULTS AND DISCUSSION

3.1 Climatic Characteristics on Site

The climate of the studied area is temperate continental, with significantly greater precipitation during the spring and summer seasons.

Warm weather starts in April and lasts until the end of October - 210 days. The highest monthly temperatures are in July and August.

In winter, the average monthly temperature ranges from 0,4 ^{o}C to –1,8 ^{o}C. The coldest winter months are January and February, during which the average monthly temperature is below 0 °C /Table 1/. If there is insufficiently thick snow cover in winter, it is possible for the winter crops to freeze.

In the spring and summer winds blow strongly and continuously from northwest, they prevail during this period and act by restraining the rapid development of agricultural crops.

Where crops with a long growing period are concerned, the negative climatic factors should be taken into account - frost, long northwesterly winds and cold weather in winter, in order to reduce their negative impact to a minimum.

Table 1 Average monthly and yearly air temperature

Stations Berkovitza and Belogradchik

Months												Average Year Temperature (^{0}C)
I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII	
-1,8	-0,5	4,7	11,0	15,6	19,0	21,6	17,5	11,3	7,2	5,4	0,4	10,5
-1,4	-0,5	4,6	10,8	15,4	19,0	21,6	17,7	11,0	6,9	4,9	-0,1	10,4

The distribution of rainfall during the year has a decisive influence on the development and yield of crops /Table 2/.

The average annual rainfall for Chiprovtzi station is 776 mm, and for station Berkovitza - 953 mm. The first rainy maximum covers the period from April to August, and the second - the months of October and November. The lowest rainfalls in winter are from December to February. There is low monthly rainfall in September too.

The data for rainfalls presented in Table 2 show that their yearly movement is characterized by a marked spring-summer maximum. A second maximum could be established in the months of May and June.

Table 2 Average monthly and yearly precipitation in mm

Stations Chiprovtzi, Berkovitza, Montana, G.Genovo

Months												Average yearly sum
I	II	III	IV	V	VI	VII	VIII	IX	X	XI	XII

46	53	62	93	116	132	94	80	71	83	75	61	953
42	25	34	48	80	82	55	61	41	52	46	38	586
36	30	37	57	76	77	54	42	40	59	50	41	599

3.2 Geological and hydrological characteristics of the region

The studied region occupies part of Western Stara Planina and Predbalkana, due to which the relief is varied. Predbalkan here is hilly and significantly truncated with ravines and gullies. Bedrocks show quite a wide variety of non-carbonate eruptive, metamorphic and sedimentary rocks. Weathering material from these rocks has formed different thickness weathering crust that has leaked soil forming processes.

The area of the site has a rich hydrographic network. The main river artery is river Chiprovska Ogosta. It collects the waters of river Martinovska and river Androvitsa in the town of Chiprovtzi.

3.3 Vegetation

The area of mine "Martinovo" falls in the lower and middle forest vegetation belt of Trakia area, also called the Beech Belt.

Forest vegetation is mainly deciduous and is represented by oak, beech, hornbeam, willow, hawthorn, drain, rosehip and others. There are plantations of pine, acacia and others. Due to the mountainous nature of the terrain, the terrain is occupied mainly by forests and pastures.

The effect of the forests as a soil making factor is huge, but a large portion of them have been cut. Deforestation in sloping terrain has contributed to increasing the erosion in the area.

3.4 Soil characteristics

A study was conducted in order to establish the soil diversity in the area of the site. On the basis of the conducted study and the used literature data it was found that the prevailing common soil types in the area of the site are as follows:

- Brown forest soils, shallow, heavily eroded, slightly sandy clay;
- Shallow, undeveloped soils and rocks.

The identified soil types are characterized by the following physical, physico-chemical, chemical and other indicators and properties:

3.4.1 Brown forest soils, shallow, heavily eroded, slightly sandy clay

They are formed on sandy clay non-carbonate materials with the participation of erosion. Their profile is represented mainly by the humus layer with a capacity of 18 to 20 cm, compact, with a small grain structure. The surface horizon of these soils is formed at the expense of lower iluvial horizon and part of base rock. Due to strong erosion and adjacent base rock the soils have deteriorated water and physical properties.

Mechanical composition: soils are slightly sandy clay. The content of physical clay in the surface horizon is 28,6%, and the content of fraction under 0,001 mm is 10,5%. The predominant fraction in the mechanical composition are particles from 0,05 to 0,01 mm, as their content in the surface horizon is 25% (Table 3).

The content of organic matter (humus), characterizes studied soils as poor humus. The content of humus in the surface horizon is 1,90% (Table 2).

The availability of total nitrogen is low – 0,098%, and the availability of total phosphorus is average - from 0,122% to 0,096 (Table 4).

Carbonates have not been established. The soil reaction is moderately acid (Table 4).

Table 3 Mechanical Composition

Horizon and depth of the sample	Particles size in mm							
/cm/	sum >1	1 - 0,25	0,25 - 0,05	0,05 - 0,01	0,01 - 0,005	0,005 - 0,001	<0,001	sum <0,01

3.4.2 Shallow, underdeveloped soils and rocks

Underdeveloped shallow soils and rocks are found mostly on the steepest terrain. They are very shallow - from 0,0 to 15 cm and are located directly on the solid rock.

Conducted field and analytical studies have shown that the soil in the area of the site and adjacent lands are destroyed, damaged and very dirty. Since the humus and soil materials have not been previously collected and disposed they are practically lost. Underlying soil analyses show high levels of arsenic and cyanide, which makes impossible the direct cultivation of energy crops without amelioration of damaged and contaminated areas.

Figure 1. Disturbed Area From Martinovo Mine

The established violation of the natural landscape, its transformation into an industrial and the effects of the negative impact on the environmental components can be prevented through the application of appropriate reclamation measures.

The purpose of reclamation is not rapid economic effect, which leads to immediate and rapid recovery of the investment. In this case, the aim is environmental performance that is of greater public importance, because in the long run, its economic impact is greater than the rapid payback of the cost of reclamation.

The effect of timely and quality reclamation is expressed in several ways:

1. Ecological effect.

a) Suspension and removal of heavy metal contamination on site.

b) Improving the adjacent areas due to eliminating the adverse effects of reclaimed areas.

c) Protection of reclaimed territory from erosion or swamping

d) Complete Landscape restoration of damaged areas.

2. Social impact.

a) Elimination of the risk of harmful effects on the population and the related health problems.

b) Increase in the number of jobs and increased employment during the execution of the reclamation activities.

Remediation of contaminated and violated sites takes place in two stages – technical reclamation and biological reclamation. During the technical stage a preparation of the land is made by preparation for restoration of damaged areas and improvement of the landscape of the area.

In the next stage (biological), on the technically prepared areas specific crops are grown under specific technological schemes.

For a full and qualitative implementation of the reclamation activities and optimal recovery of damaged areas and natural landscape a number of events are needed, the most important of which are the following:

1. Cleaning the field from the construction and other waste and its leveling.
2. Filling of soil and geological materials with suitable physicochemical characteristics for full alignment and enhancing the landscape of anthropogenic areas.
3. Submission of sludge from waste water treatment plant in order to improve the quality of reclamation substrate and provide medium for plants
4. Plant species - Grass and tree.

Figure 2. Filling Of Soil And Geological Materials

Figure 4. Sowing and planting certain plant species

Figure 3. Submission of sludge from waste water treatment plant

Figure 5. Sowing and planting certain plant species

Sludge from wastewater treatment plants is a biomass rich in macro- and micronutrients and organic reserve that can be used to maintain the fertility of the reclamation substrates. Mechanical composition sediments are sandy clay. Dominant is the fraction of fine sand which has high hygroscopic humidity. In sediments, there are high microbial densities of soil microorganisms, lower respiratory capacity, large amount of microbial carbon, high potential nitrogen-fixing activity and immobilization of nitrogen. C/N ratio shows great heterogeneity of the studied sediments and evidence of smoldering process of transformation and the initial phase of humifitsirane. Research conducted by the Institute of Soil Science, Agrotechnologies and Plant Protection "Nikola Poushkarov" in the area of Chiprovtzi - Martinovo mine show that sediments improve the physical properties of soils and can be used with success for reclamation of disturbed lands, without the risk of environmental pollution.

The use of sludge will optimize the diet of plants and reduce the utmost application of organo-mineral fertilization.

In this case, a suitable source of sediments, corresponding to the soil and climatic conditions and physico-chemical composition of geological materials used in the process of reclamation in the area of mine "Martinovo" is the wastewater treatment plant - Sofia.

4. CONCLUSION

As a result of the studies a technological scheme for the implementation of technical and biological reclamation of damaged areas is proposed. The technology includes:

1. Cleaning the field from construction and other waste and its leveling.
2. Filling of soil and geological materials with suitable physicochemical characteristics for full alignment and enhancing the landscape of anthropogenic areas.
3. Submission of sludge from waste water treatment plant in order to improve the quality of reclamation substrate and provide medium for plants.

A Review of Acid Mine Drainage in Turkey
Türkiye'deki Asit Maden Drenajının İncelenmesi

S. Yerel Kandemir

ABSTRACT Natural transformations and environmental changes are very complex in the world. Mineral, water and soil interactions are important topic influencing environmental changes. The interaction generates a large quantity of mine waste. Acid mine drainage is a key concern of mining industry due to its impact of water and soils.

Turkey is one of the developed countries in the world. Mining activities have been going on in several parts of Turkey and acid mine drainage are affected issue in Turkey. In this study, acid mining drainage and mine wastes in Turkey are reviewed.

Keywords: Acid mine drainage, mine waste

ÖZET Dünyamızdaki doğal dönüşümler ve çevresel değişiklikler çok karmaşık bir yapı sunmaktadır. Maden, su ve toprak etkileşimleri çevresel değişiklikleri etkileyen önemli bir konudur. Bu etkileşimler büyük miktarda maden atıkları üretmektedir. Bu atıklar nedeniyle asit maden drenajının meydana gelmesi ve su ve toprakların etkilenmesi madencilik sektörünün önemli bir husustur.

Türkiye, dünyanın gelişmiş ülkelerinden biridir. Madencilik faaliyetleri Türkiye'de artarak devam etmekte ve madenlerin bulunduğu çeşitli yerlerde asit maden drenajı görülmektedir. Bu çalışmada, Türkiye'deki maden atıkları ve asit maden drenajı meydana gelen sahalar incelenmiştir.

Anahtar Kelimeler: Asit maden drenajı, maden atıkları

1 INTRODUCTION

The mining of certain minerals, including gold, copper, and nickel, is associated with acid drainage problems that can cause long-term impairment to waterways and biodiversity. Furthermore, some effluents generated by the metals mining industry contain large quantities of toxic substances, such as cyanides and heavy metals, which have serious human health and ecological implications (Azapagic, 2004; Akcil and Koldas, 2006). Of all chemical pollutants of the environment, heavy elements are considered to be of a special ecological significance because excessive concentrations of them may be toxic to living organisms and affect the quality of surface water and groundwater (Kabata-Pendias et al., 1992; Loredo et al., 2005).

Mining activity compose a large quantity of mine waste. Acid mine drainage causes environmental pollution that affects many countries having historic or current mining industries (Johnson and Hallberg, 2005).

The potential hazard of mine waste depends on the host mineral. The tendency of mine waste to produce acid mine drainage containing potentially toxic metals depends on the amounts of sulfide, carbonate minerals, and trace-element concentrations found in ore deposits (Yucel and Baba, 2013).

For example, massive sulfide deposits and resultant mine wastes can affect the environment through several pathways. Oxidative weathering of pyrite can generate highly acidic conditions, which in turn enhances the solubility of metals from other sulfide minerals and from gangue silicate and carbonate minerals. The acid and metals collectively affect surface and groundwater quality and the associated aquatic ecosystems and drinking water supply (Gunduz et al. 2007; Gunduz and Baba 2008; Seal et al. 2008; Baba and Gunduz 2010).

Acid mine drainage has been widely recognized as one of the major environmental problems caused by mining worldwide, as evidenced by numerous studies (Pozo-Antonio et al., 2014). In this paper, firstly overviewed of acid mine drainage. After, provides a case studies of acid mine drainage in Turkey.

2 OVERVIEW OF ACID MINE DRAINAGE

Acid mine drainage is produced when sulfide-bearing material is exposed to oxygen and water (Akcil and Koldas 2006). Rivers affected by this kind of contamination are characterized by their acidity and also by the high sulfate and heavy metal content in their waters and metal content in their sediments (Nebel and Wright 1999). The pollutant effluent from acid mines is complex and is characterized by elevated concentrations of iron and sulfate, low pH, and elevated concentrations of a wide variety of metals (Gray 1998 in Achterberg et al. 2003; Grande et al., 2010).

Both sulfate and conductivity are useful indicators of acid mine drainage contamination. Unlike pH, they are both extremely sensitive to acid mine drainage even where large dilutions have occurred. The advantage of using sulfate to trace acid mine drainage is that conductivity is especially sensitive to sulfate ions (Gray 1996).

Acid mine drainage sources is showed in Table 1.

Table 1. Acid Mine Drainage Sources (Akcil and Koldas, 2006)

Primary sources
- Mine rock dumps
- Tailings impoundment
- Underground and open pit mine workings
- Pumped/nature discharged underground water
- Diffuse seeps from replaced overburden in rehabilitated areas
- Construction rock used in roads, dams, etc.
Secondary sources
- Treatment sludge pounds
- Rock cuts
- Concentrated load-out
- Stockpiles
- Concentrate spills along roads
- Emergency ponds

3 PREVENTIVE AND CORRECTIVE TECHNIQUES OF ACID MINE DRAINAGE

Acid mine drainage is a well-known international environmental problem related with both working and abandoned mining operations (Candeias et al., 2014). Preventive techniques and corrective techniques about acid mine drainage is given below.

3.1 Preventive Techniques

Acid mine drainage preventive techniques are classified of five class. This techniques are given below.

- Control of water migration
- Separation and blending

- Dry covers, soil covers and liners
- Water cover "sub-aqueous disposal"
- In-pit disposal (Kuyucak, 2012)

3.2 Corrective Techniques

Acid mine drainage corrective techniques are classified of five class. This techniques are given below.
- Chemical neutralization plants
- “In-line system” plants
- Treatment plants by ion exchange
- Neutralization plants by reverse osmosis
- Natural neutralization with river waters. "Synergistic" solutions (Pozo-Antonio et al., 2014).

4 ACID MINE DRAINAGE IN TURKEY

4.1 Acid Mine Drainage in Can Region, Canakkale

Can region (Canakkale) is very important in coal reserve and contains numerous mines that were operated by private companies and later abandoned without any remediation. Abandoned open pit mines typically fill with water from runoff and groundwater discharge, producing artificial lakes. Acid drainage waters have resulted in the degradation of surface water quality in Can region.

The results show that the concentration of most elements, such as Fe and Al, exceed national and international water quality standards (Yucel and Baba, 2013).

4.2 Mercury Mine, Alasehir

Mine waters are dominantly acidic with pH values and are sulfate rich. Acidity is caused mainly by the oxidation of sulfide minerals. Pyrite is the main acid producing mineral in the Alasehir.

Mine waters have showed As, Fe, Mn, Ni, and Al with concentrations higher than drinking water standards. The stream sediments derived from the mining area with the surface waters are potentially hazardous to the abandoned Hg mine and the mine is needed of remediation (Gemici, 2007).

4.3 Simav Plain, Kutahya

Simav Plain (Kutahya), were conducted to determine the source of high arsenic levels in the surficial aquifer. Rock and sediment samples supported the fact that local metamorphic rocks contained important ratios of sulfur minerals where arsenic-containing lenses are present inside. Another potential arsenic source in the study area was the geothermal fluid. Thus, the natural sources and anthropogenic influences of arsenic were found to create high concentrations in local water reserves of the area and influence human health (Gunduz et al., 2010).

4.4 Mining Activity of Koyulhisar, Sivas

The study area has active Pb–Zn–Cu mining. It is thought that the sulfide minerals in the region generally contribute to the acidification of groundwater. Mining wastes have affected concentrations of trace elements in the water. These values exceed the Turkish drinking water standard (Keskin and Toptas, 2012).

4.5 Emet Stream Basin, Kutahya

Emet Stream (Kutahya) is one of the most important branches of Uluabat Lake and also one of Turkey’s most important river systems. According to data obtained, statistically significance differences were identified between Kinik and Emet Streams according to Cr and Ni accumulations in water and sediment. Chromium levels of Kinik Stream were extremely higher an average of 153 times for water and 10 times for sediment than uncontaminated stations (Tokatli et al., 2014).

4.6. Halikoy Mercury Mine, Western Turkey

The acid drainage and the mine wastes create environmental problems around the mine. Surface and ground water samples were collected and analyzed to evaluated Hg and other heavy metals. Finally, this paper show

that the main sources of pollutants are derived from calcines and adit discharge (Gemici, 2004).

5 CONCULUSION

The present study reviewed the mine waste and acid mine drainage such as Can region (Canakkale), mercury mine (Alasehir), Simav Plain (Kutahya), Koyulhisar (Sivas), Emet Stream (Kutahya) and Halikoy Mercury Mine (Western Turkey) in Turkey. This study illustrated that mine wastes and mine acid drainage is affected surface and underground water. Thus, preventive and corrections techniques are urgently performed and developed in new techniques about to reduce acid mine drainage.

Gas Monitoring in the Environment, Following a Fire in an Underground Touristic Facility

M. Kovacs, G. A. Găman, A. Calamar, L. Toth, S. Simion
INCD INSEMEX, str. G-ral. Vasile Milea nr. 32-34, jud. Hunedoara, Petroşani, România,

ABSTRACT: The therapeutic effect of salt mines, in medical terms, were found only in the last decades of the twentieth century. In course of time, Speleotherapy's beneficial effects have been proven, namely: high degree of air purity (sterility, relatively high air humidity (vapor content), vapor condensation favorite content, constant air temperature, low air flow rate, high content of carbon dioxide in the air, high negative ionization (high number of micro ions).

For some events, INCD-INSEMEX Petrosani as specialized institute and national authority is empowered to carry out technical valuations under GD. 1461 / 18.10.2006, Annex no. 1 "development of methods for technical valuation of events caused by explosive atmospheres and / or toxic and / or explosive materials."

The current paper presents the monitoring of environmental factors parameters preceding a fire that took place the fresh air inlet circuit of a treatment saline, as well as measures taken for reopening the tourist area of the underground salt mine.

Keywords: Gas monitoring, INCD-INSEMEX Petrosani, treatment saline, fresh air inlet circuit

1 GENERAL MEDICAL ASPECTS REGARDING SPELEO THERAPEUTICAL TREATMENT

The therapeutic effect of caves and underground excavations (galleries and abandoned operating rooms), has been known for centuries. In scientific and medical terms, the effects on the respiratory system were determined only in the last decades of the twentieth century. In the cave "Klutert" of Westphalia (near the town of Ennepetal) during the Second World War, a bombproof shelter was set up. Among the refugees there were some that were ill, suffering from asthmatic disorders. After a certain period of staying in the cave, the patients showed some signs of improvement in respiratory disease.

The salt mines of Ukraine, at "Solotvino" ("Aknaszlatina"), the practice of speleotherapy treatment for respiratory diseases is ongoing since 1968. Patients are placed in abandoned operating rooms, corresponding to hospital rooms with 2-3 beds at a depth of 206 m, attending four-week treatment cycles.

According to doctors who looked into speleotherapy is not about particular medical factors, but about a set of manifesting physical, chemical and biological conditions, causing complex effects on the human body. Based on research conducted the following factors, which contribute to the specific of speleotherapy, may be numerated:

a. The high degree of air purity (sterility). The characteristic specificity of caves and abandoned mine rooms microclimate is the lack allergenic and irritant effects on the airways. In the polluted air of large cities, floating particles (number of germs) exceeds 1000 particles / cm^3, and in the air of caves and cavities, the number is less than 100 particles / cm^3.

b. The relatively high air humidity (vapor content). Under these conditions, microscopic particles (aerosols) dust, germs, pollen and fungal spores (Mycromicetes) are precipitated on the walls of the rooms, and under the action of moist air, an aqueous film is formed that increases the diameter of particles. Therefore, the inhaled air, rich in

these particles, is deposited on the airway mucosa (nasal mucosa, pharynx and trachea). With inspiration, the air is warmed, the relative humidity decreases, and again it can be again saturated with water vapor and by exhaling the vapor-saturated air eliminated from the lungs, causes the dilution of adherent tracheal secretion.

c. Favorable vapor condensation content. After research conducted in the air of mines and caves, the vapor condensation seems to have a relatively high presence of calcium ions, which has an anti-inflammatory effect, when inhaled. Inhaling air with high content of NaCl, draws tissue secretions from the walls of the bronchia system, through the osmotic effect. In addition to the osmotic effect, the stimulating action of the hypertonic mucous secretion on the bronchia mucous enhances secretion development and contributes to its elimination. In addition to Ca^{2+} ions, dominant in the saline air there can also be found other aerosols rich in sulphates, nitrates, ammonium, Mg, K, Na, I and Br, floating through microscopic droplets of water, thus completing the therapeutic effect of Ca and Na particles.

d. Constant air temperature. Usually, in underground cavities (natural or artificial) at a larger distance from the entrance, air temperature is stable with a few tenths of a degree difference.

e. Secondary effect of relatively low temperature. Relatively cool air from the saline galleries and chambers, similar to cold aerosols, has a stimulating effect on the "cough receptors" in the human body.

f. Low speed air currents. Operating room section varies between 240-250 m^2 so, because these dimensions, humans do not perceive air currents, not feeling the cold.

g. High content of carbon dioxide in the air. The active mines and caves, the highest CO_2 values recorded vary between 0, 1-0, 3 %, which stimulates the breathing center, thus increases lung aeration.

h. High negative ionization (high number of micro ions). After the results of recent measurements in some underground cavities negative air ionization is very high (compared to surface measurements). In the saline the main component of radioactivity is isotope Ra 222. The decomposition of the isotope forms beta and gamma radiations and air ionization increases. The increased share of natural negative ions decreases the intensity and number of asthma attacks also increases the rate of bacteria and allergens elimination from the airways.

i. Reduced quantity of ozone in the air. From the medical point of view, the lack of ozone (O^{3+}) in the saline air means a high purity and reduces smooth muscle convulsions. The low concentration of the reducing material is in inverse proportion with the degree of air purity.

j. Air pH is low (acidic character). The low pH of the saline air contributes to the air disinfection and reduces bacterial flora.

k. High oxygen partial pressure. Usually, in underground cavities air pressure is higher (about 12-15 m / m Hg), and because of this oxygen partial pressure is 2.07% higher than at the surface. It is understood that when inhaling saline air, body supplying with oxygen is increased by 2%.

2 SHORT HYSTORY OF THE ANALYSED TOURISTIC AND SPELEO THERAPEUTICAL TREATMENT FACILITY

Based on the positive therapeutic results obtained in the salt mines abroad, at the analyzed mine, speleo therapeutic treatment began in 1960, in one of the chambers of the old exploitation. Salt extracting was performed at the same level with the treatment rooms, at an appropriate distance.

Many events and exhibitions ensured the influx of visitors, especially the influx of patients. In these abandoned operating rooms painting and sculpture competitions and camps were organized, who's works even these days, adorn as drawings and bass relief the saline's walls.

Based on data collected from the patients treated, began to develop the scientific basis for speleo therapy and climatic treatments.

Subsequent the treatment base moved from the underground to a higher mine level, located at 120 m depth from the surface in a drier chamber system, where it functions even today.

Currently, treatment rooms and annexes are electrically illuminated and have continuous general ventilation. They are also equipped with playgrounds, chairs and sun loungers, pool tables, ping-pong tables, internet club, historical museum, coffee terrace and souvenir shop, an ecumenical chapel and bathroom facility, all to make the mandatory minimum 4 hours of underground treatment daily more bearable and more varied.

For the future they intend to expand this base on a new level (at the bottom of the current one), thus creating an underground complex for tourism and treatment.

We mention that currently they are still exploiting the salt deposits on four lower levels, using the "method of operation with small chambers and rectangular pillars (Canadian method)". Operating room size is 20-275x20x12 m and pillar size is 95-100x20x12 m. The thickness of the plateau between levels is 8 m.

3 CHARACTERISTICS OF THE ANALYSED TOURISTIC FACILITY'S AMBIENT AIR

The physical, chemical and biological characteristics of the tourist attraction ambient air are:

- low concentration of allergens and pathogens, the number of germs varies between 180-270 germs / cm^3, thus observing the condition of fresh air. There are present certain fungal strains (Mycromicetes) some of which may have the same effects as antibiotics (eg. type Penicillium),
- relative vapor content is 45-50%, which is maintained in all seasons, ensuring a constant hidric environment, regardless of outside conditions,
- 50% of microscopic particles of salt (NaCl) in ambient air are under 5 microns in size,
- During the cold season air temperature is 16.4 - 17.40C and 20.80C during summer,
- Salt rock temperature covers the range between 15.4 to 16.4° C,
- Air velocity is 0.1-0.2 m / sec, independent of outside weather conditions,
- CO_2 content varies between 387-775 mg / m^3,
- Ionization level varies between 413-580 ion / m^3, the share of negative ions being higher during summer,
- Natural radioactivity in air expressed as Ra 222 varies between 1.5-1.9 x 10-13 Curie / liter, 2-3 times less than that of the outside atmosphere,
- The low value of air pH varies between 6.5 ÷ 6.9,
- Atmospheric pressure varies between 734 mm Hg in October, and 726 mm Hg in June, directly related to the variation of atmospheric pressure on the surface.

From the statistics stated, resulted that in recent years in the case of the patients present for treatment 3-4 times / year, the number and intensity of asthma attacks decreased, convulsion cough was improved, quantity of eliminated secretion and it's viscosity decreased and the body's respiratory capacity increased. Results show that underground speleo treatment and climatic therapy are simple and effective natural methods that contribute to rapid improvement of the condition of patients suffering from respiratory diseases, maintaining and restoring mental balance and neurovegetative system's tonus.

3.1 The Results of Monitoring Gases from Underground Treatment Tourism Objective's Air after a Fire

On 07.30.2013 at the mining unit from which belongs the tourist and treatment objective, in an abandoned gallery located at 190 m surface (two floors down to that objective) a fire broke out. Through this gallery, was ensured the fresh air supply to the mine, including the treatment area.

The unit immediately triggered a general alarm, following which hundreds of people, tourists, patients and workers were evacuated after gases and odors were infiltrated in the objective area. Fire outbreak manifested in an area of 30 square meters of wood and beams abandoned gallery.

To extinguish the fire the area was flooded by rescue teams However, the management of the mine ordered intensive ventilation in tourism objective and the control of air quality so that they can be reopened only after the gas will be below the limits permitted by the rules of protection of public health.

INCD INSEMEX – Petroşani made a technical expertise to this fire, setting the occurrence of the event (fire) due to a short circuit produced at the power cord from the underground ventilation system, from which were lit wooden beams.

In order to check the air quality INCD INSEMEX Petrosani was asked for monitoring residual gas remaining after the fire till their placing below the permissible standards.

Since the fire occurred on 07/30/2013 and fire-rescuers intervention and ventilation of the objective lasted several days, measurements were performed in two stages during 02 ÷ 04.08.2013 and 19 ÷ 20/08/2013.

The results carried out in two steps close to fire are given in Table 1.

The analysis results show the following:

- CO concentrations (190 mg / m^3) determined on 08.02.2013 in the fire and at 100 m from the fire scene (180 mg / m3) exceeded the limit of 10 mg / m3 established by Law 104/2011 on air quality ambient 18-19 times,
- CO concentration determined on 20.08.2013 in the fire was reduced to 31 times on 02.08.2013, thereby falling into admissible concentration of 10 mg / m^3,
- SO_2 concentration determined on 08/02/2013 at fire exceeded the maximum permissible concentration (MPC) of 350 mg / m^3 established by Law 104/2011, 1.1 times. At the determination made on 8/20/2013 the concentration decreased to 320 mg / m3, falling within the permissible limit,
- for NO_2 and CH4 were identified only traces,
- O_2 and CO_2 were enrolled in normal atmospheric air.

From Fig. 1 can see how the CO concentration decreases over time below the maximum permissible limit specified in Law 104/2011 (on 08.19.2014). During 07 ÷ 19/08/2013 determinations were not made because the ventilation was increased

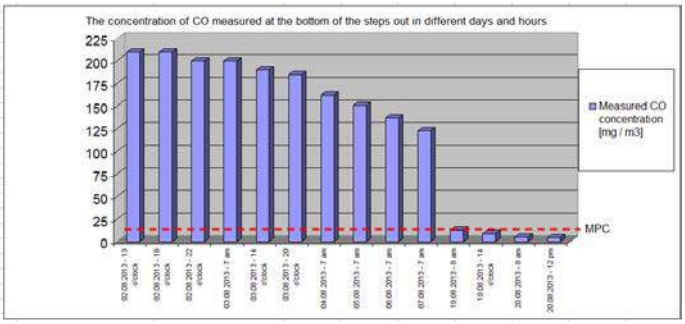

Figure 1. Concentration of CO due to the different time intervals and the at different tours.

The determination results are shown in Table no.2.

Table 1.

W_r - relative humidity, [%]

We chose four target locations analyzed as follows:

- Pt. M1. Waiting room,
- Pt. M2 the playground before passage,
- Pt. M3- Flatbed Gymnastics,
- Pt. M4- At the bottom of the stairs out.

From Table 2 shows the following:

- CO concentrations determined on 08/02/2013 at 1 PM in four locations M1, M2, M3, M4 were 140, 190, 160 and 210 mg/m^3, exceeding the limit of 10 mg / m^3 14, 19, 21, or 16, times
- CO concentrations determined on 04/08/2013 at 7.00 AM in four locations M1, M2, M3, M4 were 120, 175, 145, 180 mg/m^3, exceeding the limit of 10 mg / m^3, 12; 17.5; 14.5 and 18 times,
- CO concentrations determined on 20.08.2013 in four locations had values of 4; 4.5; 3.5; 4,5, reducing 35; 42.2; 45.7 respectively 46.6 times the concentrations determined on 02.08.2013 at 1 PM
- SO_2 concentrations determined in 02 and 08.04.2013 in four locations M1, M2, M3, M4, did not exceed the limit of 350 mg / m^3 established by Law 104/2011,
- for NO_2 and CH_4 were only traces identified in the four locations M1, M2, M3, M4,
- O_2 and CO_2 were scored within the normal range of air in four locations M1, M2, M3, M4,
- Temperature (T) in four locations M1, M2, M3, M4 had values between 17.2 and 19.9 ° C,
- Relative humidity (Wr) ranged between 39.1 and 47% specific of dry air.

4 CONCLUSIONS

• Research by doctors who were occupied with speleotherapy have demonstrated the beneficial effect of physical factors, chemical and biological from underground

excavations on human respiratory tract.
In Romania there are several underground facilities, where due to the air quality were designed to treat patients with respiratory diseases.

• On 07.30.2013 at the mining unit from which belongs the tourist and treatment objective, in an abandoned gallery located at 190 m surface (two floors down to that objective) a fire broke out. Through this gallery, was ensured the fresh air supply to the mine, including the treatment area.

Because of fire hundreds of people, tourists, patients and workers were evacuated after gases and odors were infiltrated in the objective area.
To extinguish the fire the area was flooded by rescue teams However, the management of the mine ordered intensive ventilation in tourism objective and the control of air quality so that they can be reopened only after the gas will be below the limits permitted by the rules of protection of public health.

• In order to check the air quality INCD INSEMEX Petrosani was called for monitoring residual gas remaining after the fire till their placing below the permissible standards.

Since the fire occurred on 07/30/2013 and fire-rescuers intervention and ventilation of the objective lasted several days, measurements were performed in two stages during 02÷04.08.2013 and 19 ÷ 20/08/2013.

• Measurements of SO_2, NO_2, CO, O_2, CH_4, CO_2 conducted between 08.20.2014 and 02÷04.08.2013 close to fire showed that only CO exceeded the limit. Thus CO concentrations determined on 08.02.2013 in the fire and at 100 m from the place of fire exceeded the limit of 10 mg / m^3 established by Law 104/2011 on ambient air quality, 19 and 18 times.

Determinations dated 08.20.2013 in the fire area showed that CO was reduced by 31 times from the date 02.08.2013 and at 100 m from its the area of 36 times, falling under admissible concentration of 10 mg / m^3 .

For NO_2 and CH_4 were only traces identified and O_2 and CO_2 were enrolled in normal atmospheric air.

• Measurements of SO_2, NO_2, CO, O_2, CH_4, CO_2 conducted between 08.20.2014 02-04.08.2013 in four locations M1, M2, M3, M4 showed that only CO exceeded the limit upheld.

Thus the concentration of CO due on 08/02/2013 exceeded limit of 10 mg / m^3 determined by the Law 104/2011 14, 19, or 16, respectively, 21 times

CO concentrations determined on 20.08.2013 in the four locations M1, M2, M3, M4 decreased to values of 4; 4.5; 3.5; 4,5, reducing 35; 42.2; 45.7 respectively 46.6 times from the concentrations determined on 08/02/2013 at 1 PM falling below the limit of 10 mg/m^3.

For NO_2 and CH_4 were only traces identified and O_2 and CO_2 were enrolled in normal atmospheric air.

Temperatures in four locations M1, M2, M3, M4 had values between 17.9 and 19.9° C and relative humidity between 39.1 and 47% specific of dry air.

• Based on the report of mine air parameters monitoring conducted by INCD INSEMEX - Petrosani, by reducing the concentration of CO under the the limit of 10 mg/m^3, the management ordered the reopening of the treatment area.

Impacts of Mechanical Preparation and Agglomeration of Iron Ore on Environment. Case: Arcelormittal Annaba (Algeria)

Z. Mekti, A. Boutemdjet, M. Bounouala, M. Boukeloul, and A. Idres
Laboratory Natural Resources and Management, Mining Department, Faculty Earth Science, Badji Mokhtar University of Annaba, Algeria

ABSTRACT Among the industries involving exposure to silicogenic risk, the metallurgy occupies, unfortunately, a significant part, this present article highlights the extent of the dust issues in ArcelorMittal stell manufacturer in Annaba, thus a reality of pollution of the region. For this purpose, a methodology for dusts characterization was developed to aim:

- The assessment of the impact of metallic dusts collected at the steel complex,
- Avoid, prevent or reduce harmful effects of these substances on human health, animals, fauna & flora and materials.

The present article, which the main purpose is the identification of dust risk in the sector of Preparation of Raw materials and Addition "PMA" of ArcelorMittal, was conducted during the period of September and November 2012. It is based on the measurement of concentrations of dust, and the determination of levels of their main chemical constituents. These measurements, conducted within acceptable technical conditions, allowed realizing the importance of this nuisance.

Keywords: Iron ore, mechanical preparation, agglomeration, environmental impact

1 INTRODUCTION

Although unavoidable in many materials processing operations, the particle emission of dust into the atmosphere is undesirable; the chemical composition of the solid particles identified two dangerous factors, iron and silicon dioxide in the form of quartz.

These two elements are present in average rates for iron 34.27%, and low for silicon dioxide 6.16%. On the other hand, the quantities of dust are very high and exceed the allowable threshold values; this is particularly alarming because the greater proportion of the particles (62%) have a size less than 5µm and can penetrate inside the human alveoli.

2 RESEARCH METHODOLOGY

Guided by this work, a current medical study try to establish the causal relationship between the air pollution by dust in the workplace and the incidence of respiratory disease. Confrontation and interpretation of these results will allow the development of a specific prevention program for dust related risks.

Since the allowable limit for the human body of neutral dust in a workshop is 10 mg/m^3, it will be necessary to:

- If the dust contains 10% of silica, the maximum permissible concentration must be lowered to 4 mg/m^3.
- If the dust contains 10 to 70% of silica, the maximum allowable concentration should be reduced to 2 mg/m^3.
- If the dust contains more than 70% of silica, it should be reduced to 1 mg/m^3.

3 CASE STUDY

The steel complex of El Hajar ArcelorMitall, is located in the North East side of the country, in the industrial zone of Annaba, 15 km south of the city. It occupies an area of 800 hectares including:

- 300 hectares occupied by the production workshops.
- 300 ha for storage.

- 200 ha for utilities.

Inside, there are more than 60km of rails used for the circulation of raw materials and nearly 100 km of roads for the movement of vehicles (buses, trucks, light vehicle).

4 EXPERIMENTAL PART

4.1 Introduction

The present article is based on the measurement of dust concentrations and the determination of levels attained in an acceptable technical conditions. This allowed us to realize the importance of this nuisance. Thus we can make the following observations:

- The dust concentrations measured were far exceeding the health limits; 1.2 to 7 times the international standards.
- The least polluted area is the coke preparation workshop “PMC”.
- The most polluted area is the ore preparation workshop “PM2”.
- In the mixer building (agglomeration) the situation is critical, because the values found are 10 times the USSR standards and 40 times the US standards. This building looks like a metric source that pollutes the surrounding environment,
- The contents of silicon dioxide in the dust are 5.53% to 7.30%.

The causes of this increase in air pollution are summarized in Table No. 1.

Table 1. Dust concentration in the air of workplace.

Sector	Workshop	Machines	Concentration			Limit values	Observations

		DOS-6	24.2	14.5				

4.2 Particle Diameter

The particles with size higher than 5 µm are stopped in the air see above (Table 2). Those having diameters of less than 4µm penetrate to the alveoli and are retained by the lungs. The percentage of lung penetration depending on the particle size is as follows.

Table 2. Diameters of particles

Particle size (µm)	Percent penetration (%)
2	90
2.5	75
3.5	50
5	25

4.3 Chemical Nature of Dust

It is the silicon dioxide (SiO_2) or free silica which is implicated in the occurrence of silicosis. Free silica may exist under : An amorphous, non-pathogenic; and another crystallized pathogen which is in the form of compounds:

- Quartz = Hexagonal Crystal.
- Cristobalite = cubic Crystal.
- Tridymite = hexagonal crystal.
- Coesite = hexagonal crystal.

4.4 Limit Values of Dust

A formula proposed by American hygienists, sets a limit value valid for dust particles smaller than 5 µm;

$$\frac{10}{Quartz + 2} \ (\mathrm{mg/m^3})$$

This maximum allowable concentration reflects the SiO_2 content. When it comes to tridymite or cristobalite, the value of this crystallization is divided by two. Therefore, our work method was as follows:

- Determining the average dust concentration from 6 samples of 15 minutes each. The device used is the type Gravicon Sariorius;
- Determination of the chemical composition of the dust. The analysis was focused on the research of four basic elements such as iron, silicon dioxide SiO_2, CaO Calcium oxide, aluminum oxide Al_2O_3.
- Determination of the particle size characteristics using the optical microscope.
- Establishment of the map of studied dust.

4.5 Description of the Industrial Process

The PMA field is a part of the First raw materials and cast iron. The raw materials; coke, ore, adding: limestone, sand, dolomite, quartzite are handled, prepared (screening, grinding, homogenization) before being sent to towns and blast furnaces for the production of chipboard and then cast iron.

The main workshops are:

- The ore iron circuit, ore iron processing.
- Coke circuit, coke processing and additions.
- Agglomeration areas 1 and 2 provide agglomerate for blast furnaces.

The product consists of agglomerated ore (-10mm) fine coke, thin back and additions in the proportions according to Figures 1.

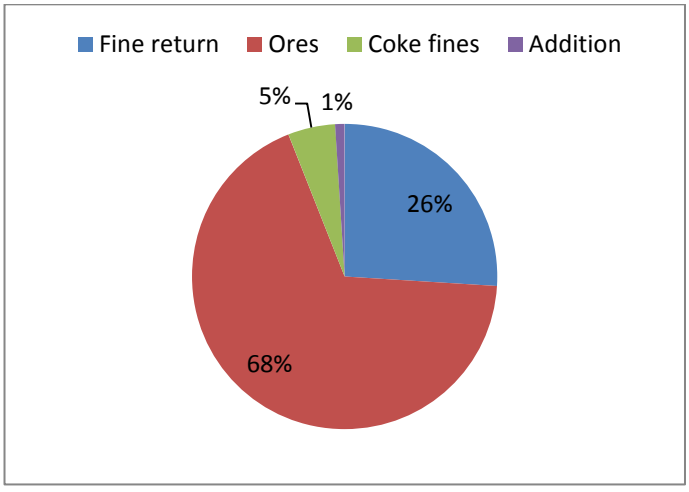

Figure 1. Component of agglomerate

Table 3. Chemical analysis of contents

Substances %	Matières premières						agglomère

X_4 = 5 - 10	R_4 = 21,5	Particle superior than 5µm 25 %
X_5 > 10	R_5 = 3,5	

Case the dust of the workshop mechanical preparation of ores (AG2)

The chemical analysis of the substances is; Fe: 49.14%, CaO: 6.87%, SiO_2 7.30% and MnO_3:3.30%, with a density of 5.33 g / cm^3.

The measurement results are recapitulated in Figure 6 and Table 7.

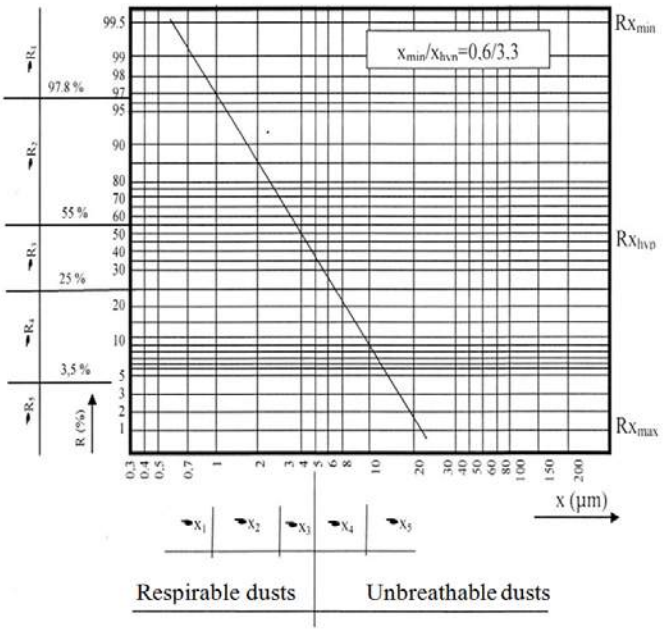

Figure 5. Granulometric characterization dust of PM2

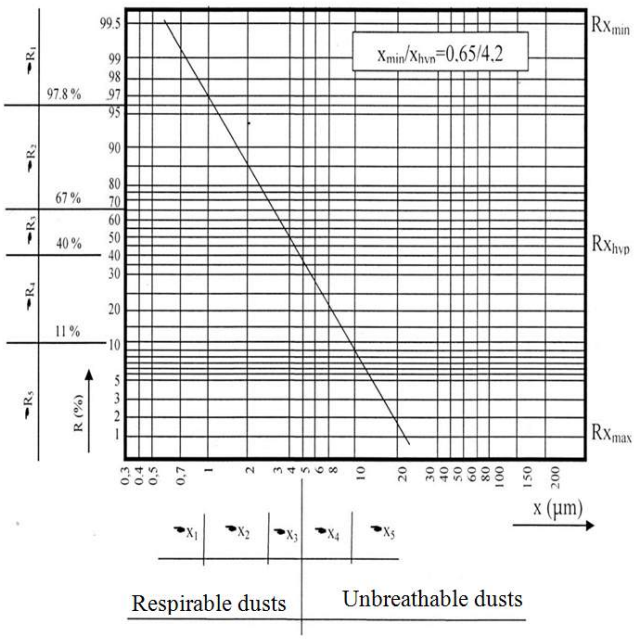

Figure 6. Granulometric characterization dust of AG2

Table 7. Dust particle size analysis (AG2)

Particle size X (Fm)	frequencies R (%)	Observation
$X_1 < 1$	R_1=2,2	Particle inferior than 5µm 60 %
$X_2 = 3 – 1$	$R_2 = 30,8$	
$X_3 = 3 – 5$	$R_3 = 27,0$	
$X_4 = 5 - 10$	$R_4 = 29,0$	Particle superior than 5µm 40 %
$X_5 > 10$	$R_5 = 11,0$	

5 GENERAL CONCLUSION AND RECOMMENDATIONS

A general study of pollution by dust in the air was carried out at the PMA. After comparing these measures with international standards advocated for coal, mineral dust and respirable quartz, it appears that the dust levels well beyond tolerable limits in the three areas of preparation materials and Surroundings (PMC, PM2, AG2). These rates vary from 4.6 to 46.5 mg / m3.

The proportion of dust respirables fluctuates between 51% and 75%; these dusts are less than 5 µm and can attack the respiratory tract.

Chemical analysis of the dust reveals the following average composition:

- Fe 42-50%.
- CaO 4-8%.
- SiO_2 5-8%.

One particular point should be stressed: the website of the mixture of raw materials or dust concentrations reached alarming values, or 10 to 40 times higher than the permissible level. The presence of a considerable amount of dust in the air can also cause danger to the facilities (wear parts, disruption of machinery ...). We will not dwell on the discomfort produced in workers operating the equipment periodically. This site is similar to a transmitting source that pollutes the environment unnecessarily.

All the conditions exist to promote bronchopulmonary aggression characteristic of the dustiness plus the emanation standards of toxic gases and vapors and microclimate conditions of the workshops. The daily inhalation of charged particles of iron and silica involves Sidero-silicosis risk. While taking account of this dust for the effect of high temperatures. In this case, the activated silica is extremely dangerous because it may precipitate the occurrence of silicosis, this formidable assignment characterized by the destruction of the normal structure of the lung parenchyma and its inexorable move towards the aggravation. An important dustiness can cause material damage, yield loss of equipment or a disruption in production.

Investigation of Environmental Pollution Caused by Waste Dump of Takab Gold Mine in West-Azarbaijan of Iran

E. Moosavi, A. Vameghi
Department of Mining Engineering, Islamic Azad University, South Tehran Branch, Tehran, Iran

R. Javani
Department of Basic Sciences, Faculty of Plant Physiology, Arak University, Arak, Iran

ABSTRACT Waste rocks aggregated by grinding, gritting and grading up of ores extracted from North West of Takab gold mine, naturally contains significant amounts of arsenic and sulfide compounds, leading to extended pollution of soil and ground water. Additionally, wet waste rocks removed from flotation and leaching processes in mineral processing are discarded in the same place as dry waste dump of the mine. Waste dump contains a great percentage of chemical materials and increase the pollution of ground water in the area. Various factors including atmospheric rainfall causes chemical compounds to permeate to depth along with water, broadening and accelerating the contamination. Rocks samples taken from different areas of waste dump indicate that pollution is chemical type and consist of sulfate, carbonate and nitrate compounds. Altogether have basic of acidic effect compounds; the amount of which is higher in the western part of waste dump. Chemical dissolving by original cations and anions of water samples showed the intensity and location of pollution of ground water; so that polluted areas were separated from unpolluted ones.

Keywords: Environmental pollution, gold mine, waste dump

1 INTRODUCTION

Mining is one of the earliest activities of human, which has been necessary for developing and continuing civilization. Dependency of human on minerals has been constantly increasing and modern civilization is unable to continue without products of mining. However, the best miner is the one who is also responsive to environmental issues, as to be able to change the mined areas into its original state as much as possible or take some measures to impose minimum damage to physical environment of the mined areas. The effect of extraction of minerals on an environment depends on some factors such as mining methods, materials and types of the rocks, hydrologic and climatic conditions of an area, size of mining operation, topography and many related factors [2]. As Iran is a developing country and it needs to develop mines for its development, environmental aspects of mines and mineral industries should be identified and studied for sustainable development of country's mine industry with respect to its different climatic zones.

As far as local divisions are concerned, the area under study is located extreme southeastern of West Azarbaijan province. The area includes north, northwest, and west regions of Takab city. It is about 700 km2 between longitudes of 46 º, 55' and 47º, 15' E and latitudes of 36º, 25' and 36º, 45' N. North region of Takab is a mountainous and relatively impassable area. It has cold and dry winters covered with snow and temperate summers. The highest point in extreme northwestern region is called Garadagh mount, which is 2955 m above sea level. The lowest height is located southwest of Yahrlī village in extreme southwest of the area under study. It is 1785 m above sea level. It has a mountainous climate.

Farmlands are in foothills region usually with steep slopes. the slopes are steeper at the elevations higher than 1900 meters, but the slopes gradually become less steep, as they reach about 2-3 percent.

As the region is mountainous with high mountains, most rainfalls are as snow and its surface currents flow into the rivers around and finally the Saruq main river through the primary and secondary branches. Saruq river flows into the Zarriné-Rūd river, 58 km southeast of the area under study. Permanent rivers (armlets) of the area include the Zarshoran, Ahamd Abad, Agh Darreh, Ghizghapan, Nabi Kandi, and Gogerdchi rivers. With respect to the mines and mineral potentials in the upstream sections of the rivers, the Zarshoran and Agh Darreh rivers are environmentally more important. Means of rainfall in Takab were measured by Alasghol station and Takab Synoptic Station as 400.3 and 399.10 ml, respectively. The approximate total distance between Takab and Agh Darreh mine is 38 km. Figure 1 shows the access road to the area under study.

2 CONTAMINATION OF AGH DARREH MINERAL AREA

The area under study consists of watershed of the Agh Darreh river and downstream environment of confluence of the Agh Darreh river and the Saruq river in northwest of Takab in West Azarbaijan province. The Agh Darreh river at upstream sections is made up of a primary and a secondary branches. Water and bed sediments of the primary branch are clean and without specific contamination, whereas water and sediments of the secondary branch of the Agh Darreh river has a very high contamination of potentially toxic elements of mercury, antimony and arsenic. This way, after flowing water of the secondary branch into the primary branch in the downstream area, water of Agh Darreh river is contaminated. In the downstream, contamination rate increases by flowing runoff into the mined sections of Agh Darreh gold mine to the Agh Darreh river. As per the results, positions of the primary and secondary branches of the Agh Darreh river, geographical position and topography of the mined sections, and the place of waste dumps of Agh Darreh gold mine, it is necessary to conduct some studies on layout and improvement of substructure of waste dump.

Generally, in order to study the contamination formed in mining waste dumps, it is necessary to recognize source(s) of contamination, types, areas or contamination extents, contamination control geologic and hydrologic factors, and the way contamination is spread. Agh Darreh gold mine in Takab region is detached at different stages and dumped in a place. It contaminates soil and rock layers above groundwater table and finally groundwater table of the region. This article discusses underground contamination due to these waste dumps in Takab region. Figure 1 shows access road of the area under study. The second paragraph is written 5 mm inside the left.

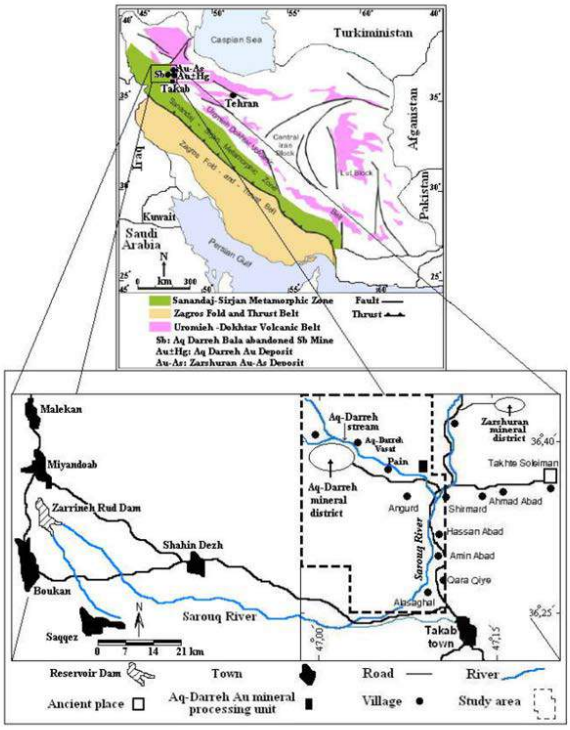

Figure 1. Access road of the area under study.

3 METHODS TO EXAMINE CONTAMINATION IN AGH DARREH WASTE DUMP

Collection of samples from mining waste dump aims at finding a small portion for examining and conducting research. Before any sampling, a sampling project should be designed for supervising research objectives or plan. The sampling project includes specific information concerning sampling place and positions, methods and techniques, number of samples, types of samples, sampling times, samples storage duration, types of preservatives, and numbers and types of standard samples for quality control and quality assurance. Sampling operation may be time-consuming and costly. Factors that should be considered in selection and sampling methods are:

1) *Accuracy of sampling*
2) *Cost of sampling methods*

Sampling of different rock units within the area was made of dry and wet waste dumps of Agh Darreh mine in a specific period. Surface water resources (rivers) and ground water resources (springs) of the area were contaminated by arsenic and antimony. Riverbed sediment, runoff sediment, surface and arable soils, and the vegetation of some parts of the area were contaminated by arsenic, antimony, and mercury. Therefore, only the main phase and environmentally significant minerals of the three elements in the area were studied.

4 SAMPLING AND STUDYING SAMPLES IN WET AND DRY WASTE DUMP

In the first stage, sampling of different parts of the accumulated wastes was performed to study contamination of the region. Generally, many waste samples were collected, but necessary studies and experiments were conducted on a few of them. Among numerous samples taken from different northern and southern parts of the waste dumps (with respect to area slope and its rivers), only five samples were analyzed chemically. Figures 2 and 3 show some images of the northern and southern waste dumps, respectively.

Figure 2. View of the waste dump from the Agh Dareeh mine- Northern region [2].

Figure 3. View of the waste dump from the Agh Dareeh mine- Southern region [2].

The results of chemical analyses indicate that some samples of the area are also contaminated; they contain high concentrations of potentially toxic elements of mercury, antimony, and arsenic. The sampling positions show that most of the contaminated samples include fixed samples formed by source rocks (gold mineralization host rocks and their elements) with a high concentration of these elements or they are carried surface rocks formed in the downstream of source rocks. The chemical analyses indicate that most samples are contaminated by arsenic and antimony. In contrast, samples of the area are less

contaminated by mercury. Tables 1 and 2 show chemical analysis results of the wet and dry waste samples taken from Agh Darreh region, respectively.

Table 1. Chemical analysis results of the dry waste samples.

Percentage	Element	Environment
73.18	As	Waste dump Southern region
81.18	Sb	
36.42	Hg	
79.45	As	Waste dump Northern region
63.06	Sb	
49.86	Hg	

Table 2. Chemical analysis results of the wet waste samples.

Percentage	Element	Environment
89.04	As	Waste dump Southern region
93.53	Sb	
45.37	Hg	
84.67	As	Waste dump Northern region
77.75	Sb	
57.19	Hg	

5 CONCLUSION

The wastes extracted from the ores of Agh Darreh mine in Takab region in northwest of Iran are separated during different mining stages and dumped in the region. Naturally, they contain considerable amount of mercury, arsenic, and antimony compositions; they caused widespread contamination of soil and groundwater. Moreover, wet wastes of a processing and acid treating factory are discarded where dry wastes are dumped. They contain considerable amount of toxic elements and increase contamination intensity in the region. Different factors - such as rainfalls - lead to further influence of chemical substances with water into the underground levels. They intensify, accelerate, and spread contamination of neighboring rivers. Interpretation and chemical analysis of the samples of the mineral wastes dump, which were selected with respect to the region slope and adjacency of streams, represent toxic elements of arsenic, antimony, and mercury. Therefore, severe rainfalls in the region during rain seasons and active streams in the region have environmentally potential threats.

To prevent any consequences caused by mining activities in the region, it seems necessary to use waste dams with geosynthetic infrastructure. Concrete barriers can be used to control sewage of different mined sections of Agh Darreh mine. It seems necessary to conduct several environmental studies on groundwater, agriculture and fertile soil of the region in order to complete its environmental process.

Studies on Gravity Backfilling Method for Blind Backfilling of Abandoned Coal Mines

S. K Pal, S. Panda
IIT Kharagpur, Kharagpur, INDIA

A. K Tripathi
NIT Surathkal, Mangaluru, INDIA

ABSTRACT In this paper a new, simple and low cost gravity backfilling method for stabilization of ground above abandoned underground mines is proposed. Laboratory investigations carried out on this simple gravity hydraulic blind backfilling method to fill up a fully transparent model of a section of a bord and pillar mine, have indicated that deposition of the filling material surrounding the inlet hole occurs in a regular shape with full packing up to the roof. Some empirical relationships on maximum volume of sand throughput and spread of sand around the inlet hole have been developed with a view to help the practicing engineers. In the field trial the spread of sand in different directions has been witnessed using an ROV camera fitted with a sonar imaging system. The shape and nature of deposited sand bed surrounding the feeder hole in field and laboratory studies are alike. The empirical relationships developed under field conditions have also been found to be similar to those of laboratory model.

Keywords: Gravity backfilling, blind backfilling, coal mines

1 INTRODUCTION

In earlier days many coal mines in India have been worked under shallow cover and were practically extracted using Bord and Pillar system of working. Depillaring with regular stowing provides adequate support of the voids and reduces the risk of accidents arising out of pillar spalling and premature collapse of large areas. But depillaring with stowing could not be always followed due to various constraints. Therefore, the coal mines which have been worked without stowing of void spaces became either fully or partially waterlogged and are now unapproachable. Blind hydraulic backfilling is a commonly used technique for subsidence control of the strata over unapproachable waterlogged underground excavations.

2 BLIND BACKFILLING METHODS

There exists number of differences between backfilling methods in active mines and those used in blind backfilling of abandoned mines. The main difference is the lack of access to the abandoned mine voids. The backfilling operation in active mines can be directly observed. The backfilling operation in abandoned mines can only be monitored by special techniques. In abandoned mines due to lack of access, all the work must be done from the surface in remotely controlled manner.

According to placement mechanism, the blind backfilling can be classified into:
(a) Pneumatic method, and
(b) Hydraulic method.

2.1 Pneumatic Blind Backfilling Method

The pneumatic backfilling refers to a special form of pneumatic conveying in which the backfill material is transported through a blind borehole into the mine and thrown all around the inlet zone with the help of compressed air. This method can only be used in dry mines. With suitable design good packing of fill material may be achieved

around one small inlet hole (Sand et al, 1990).

2.2 Hydraulic Blind Backfilling Method

In hydraulic blind backfilling method filling material is mixed with water to form slurry and the mixture is injected from surface into the mine through a feeder borehole. This technique is used to fill up a relatively larger area from the inlet feeder borehole. Walker (1993) had described the state-of-the-art techniques for backfilling the abandoned mine voids by hydraulic flushing from single or multiple boreholes. Thill et al. (1983) described the process of backfilling the flooded mines using sand or crushed mine refuse. The following section describes two important variants of this method that are practiced widely.

2.2.1 Air assisted hydraulic backfilling

This method which is also known as hydro-pneumatic backfilling technique is developed and practiced in India. In this system, solid-water mixture is sent to fill underground voids through a larger diameter hole and compressed air is sent through a smaller diameter pipe placed inside the larger diameter hole. The solids used for filling may be sand, fly ash, small size gravel, crushed stone or washery rejects. Detailed research work in this area in the form of model studies had been conducted at CMRI and at I.I.T. Kharagpur, India (Saxena, 1984, Pal et al, 2001 and 2011). Saxena et al. (1989) presented a field trial carried out at 'Jogta Fire Project' for stabilizing ground over unapproachable workings, which were underneath a jore. Ghosh et al. (1988) described the hydropneumatic method on a field trial in Ramjivanpur colliery.

2.2.2 Pumped slurry injection

In pumped slurry injection method sand-water slurry is pumped down a well under pressure. With this approach, increased spread of the fill material within the mine can be achieved due to the increased velocity at which the slurry is injected. Solid particles settle out near the borehole when the slurry is first delivered and the velocity of the injected slurry drops as it enters in the mine workings. As more material is injected, the fluid velocity increases in the mine workings and the solid materials are transported further away from the borehole (Colaizzi et al. 1981).

Various types of material, such as, crushed stones, mine refuse, and fly ash, can be used for pumping them into the mine with water. The fill material is transported into the mine as slurry and deposited in the void until the void is completely filled. But most of the time filling has to be abandoned due to choking or jamming of flow path inside the mine. The slurry pumping technique includes two methods:

A) High-volume Pumping
B) Low-volume pumping

In high-volume and low-volume pumping methods the granular material is blended with water in a large mixing tank at a processing plant and is then pumped to a series of injection bore holes through pipe lines. The energy provided from the pump and the static head of water in the borehole gives the back fill material the required velocity to keep them in suspension and governs the size of the packing area surrounding the injection borehole.

2.2.2.1 High volume pumping

The high-volume pumping is normally used on very large mine areas that are known to be open and have few obstructions. The high volume of water and its velocity at the injection point ensure wider spread of material than in any of the other methods since the energy of the slurry is much greater. The advantages of high-volume pumping are that a large amount of material can be placed in a short period of time, at low cost, and locally available backfill material can be used. The disadvantages of the system are the costs of establishing central slurry mixing plant, setting pipeline network, and a high volume water supply.

2.2.2.2 Low volume pumping

In low volume pumping water requirements are about 10 times lower than that of high volume pumping. The advantages of the system are that the small, portable, construction-type pumping equipment causes little or no congestion within the working area. The disadvantages of the system are longer material placement time and need for additional boreholes because the material spreads over a limited distance from the injection point.

2.3 Drawbacks of Existing Methods

In air-assisted gravity backfilling process the injected air, if not released completely from the rise side holes, may cause troubles by way of creating cracks and potholes on the surface. The pumped-slurry technique has exhibited filling up of relatively larger areas at a faster rate, especially when high-volume, low-pressure method was selected. This method requires high initial investment on pumps and mixing arrangements. This also requires frequent maintenance and replacement of components on account of excessive wear and tear. Thus, development of a low cost and safer method to stabilize areas over old and abandoned mines has become extremely important under the present context because some regions in Raniganj coalfield have experienced sudden collapse due to subsidence without any prior warning thereby causing loss of property and lives.

In the present study a simple gravity blind backfilling method is proposed where backfill material and water mixed in the form of low concentration slurry, is fed into the mine through a borehole without the assistance of compressed air or pump pressure, till the time the inlet hole will not accept any additional backfill material. The effectiveness of the proposed simple gravity blind backfilling depends on several parameters like slurry flow rate and sand concentration, inclination of the seam and depth of water table from surface.

3 LABORATORY EXPERIMENTS

In this study, laboratory investigation on simple gravity hydraulic blind backfilling has been carried out in a fully transparent scaled model of underground coal mine worked by bord and pillar method. It has 72 pillars of two different sizes representing 45% and 75% extractions. Figure 1 shows a schematic diagram of the experimental set up. A variable-speed bucket elevator is used to transport sand from the storage bunker to the mixing funnel. The sand flow rate from the conveyor is calibrated with the rpm of the conveyor. The volumetric sand flow rate, Q_S in litres per minute, is related to rpm of bucket elevator as

$$Q_S = 0.1389 * (\text{rpm}) \quad (1)$$

The recirculating water feeding arrangement has a small capacity centrifugal pump which delivers water through a turbine type flow meter into the mixing funnel. A manually operated throttle valve is used to vary the volumetric flow rate of water.

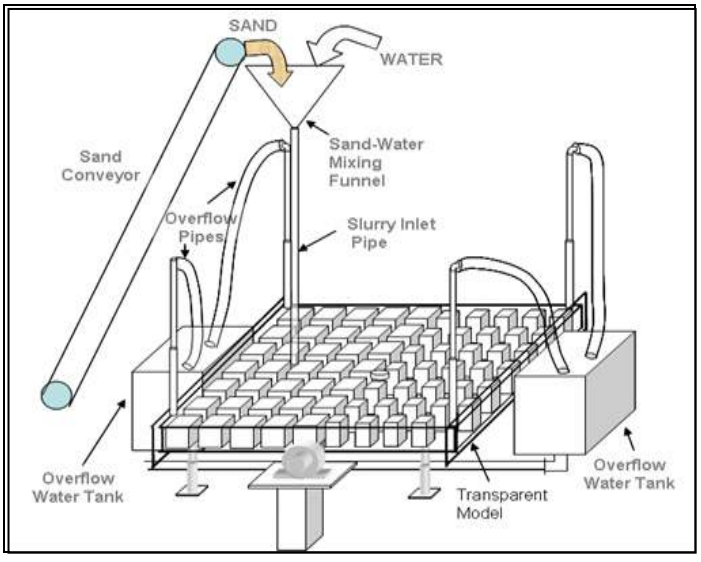

Figure 1. Experimental arrangement in laboratory.

The sand water slurry of given concentration from the mixing funnel gravitates down and enters the model through a transparent inlet pipe. The volumetric flow rates of sand and water as well as the inlet pressure of slurry are recorded in the computer using a continuous data acquisition system. The experiments are continued till flow jamming

occurs, and no further amount sand could be injected. From the stored data the cumulative volume of sand injected may be calculated.

3.1 The Filling Process

When the slurry first gravitates down to the open void of the model through the inlet tube, its velocity decreases rapidly and solid particles drop down from the slurry towards the bottom of the model and form a conical-shaped heap on the floor (Fig. 2). As the height of the heap approaches the roof, the narrowing of the gap between the roof and the fill material causes an increase in the velocity of the slurry. The impact of the input slurry forms a crater at the top of the conical heap just under the bottom of inlet hole. The turbulence created by the water helps the sand particles to be in suspension and transports them through the narrowed gap between the top of the truncated conical heap and the underside of the top cover of the model and finally the particles get deposited along the slope of the conical heap. In this way, the slanted surface of the conical heap advances almost equally in all the directions from the inlet pipe.

The channel flow configuration started after the deposited sand mound grows further in the form of a top-truncated conical heap with a central crater. It was observed that at the beginning four to eight small channels existed, but ultimately after some time, only one, two or at most three channels continued. When sand-transport along the routed channels continued for some time, the pressure within the channel increases sufficiently to cause a puncture a new flow route to deposit sand in a new area of the model. As the new channel starts the old channel gets plugged with sand. This meandering nature of the channels continued through a sequence of depositions and breakthroughs. Finally, a diamond-shaped sand deposit is built up extending almost equally along both left and right strike directions and slightly more in the rise direction. This phenomenon of transport of sand is more similar to the sediment transport phenomenon in open channels or rivers.

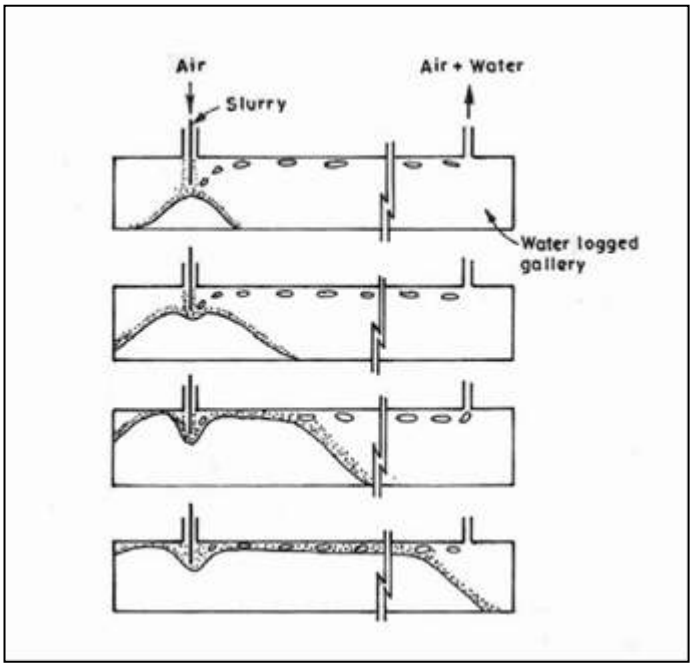

Figure 2. The filling process.

3.2 Effect of Slurry Flow Rate and Sand Concentration on Volume Throughput

Different experiments, with varying slurry flow rates were conducted when the inlet pipe located towards the bottom-end of the model. Figure 3 depicts the maximum volume throughput from a single inlet pipe for a given flow rate at varying concentrations. It may be seen that with increase in sand concentration in the slurry, the maximum sand throughput V_S decreases exponentially for all flow rates of slurry following a general relationship as

$$V_S = K * e^{-n*C} \quad (2)$$

where K ranges from 228 to 604 and n from 0.0822 to 0.1232

Again, for a fixed sand concentration, the maximum sand throughput V_S increases nearly linearly with increase in slurry flow rates.

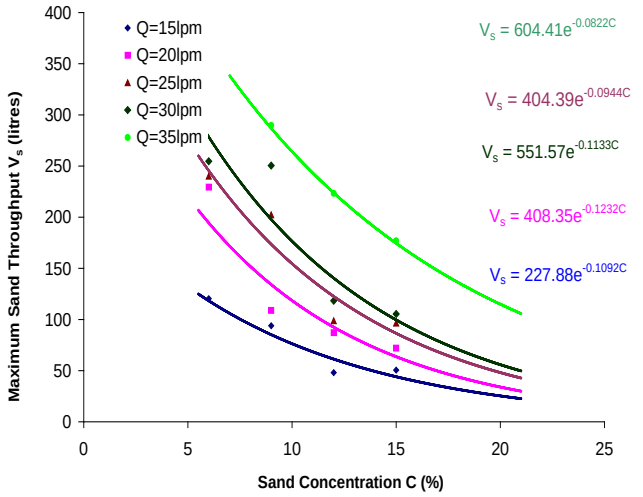

Figure 3. Variation of V_S with C in laboratory experiments at fixed flow

The maximum volume of solid throughput V_S may also be related to both slurry flow rate Q and sand concentration C by using multiple regression as

$$V_S = 0.224 * h * Q^{1.294} * C^{-0.8}, \quad (3)$$

where h is the height of fill.

3.3 Shape of the Filled-up Area

The filled-up area by the sand may be approximated as pentagonal shape in the initial stages of filling, as shown in the Figure 4, and the size of pentagon grows along the strike directions as well as towards the rise direction till the side walls of the model in the strike direction is touched.

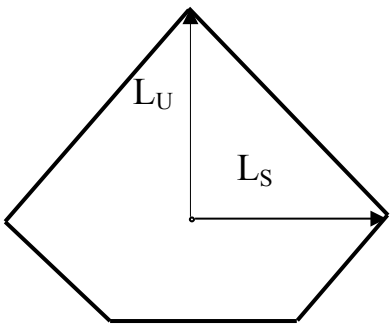

Figure 4. An approximation of the shape of sand-filled area.

Until this stage of filling, the spread along strike and rise directions, L_S and L_U, are measured from the inlet pipe. The volume of the deposited sand, V_S, is then correlated with L_U and L_S through multiple regression technique. The general relationship obtained is

$$V_S = 1.062 * k * h * L_U^{0.378} * L_S^{1.149} \ldots \quad (4)$$

where, k is extraction coefficient and h is height of fill. The inter relationship between L_U and L_S are shown in Figure 5.

If k and h are known, the spread of sand along strike and rise direction may be determined for any given volume of sand pushed into the mine void. This information is useful to the practicing engineers to locate the position of the next inlet hole at the time of filling a large area using multiple inlet holes.

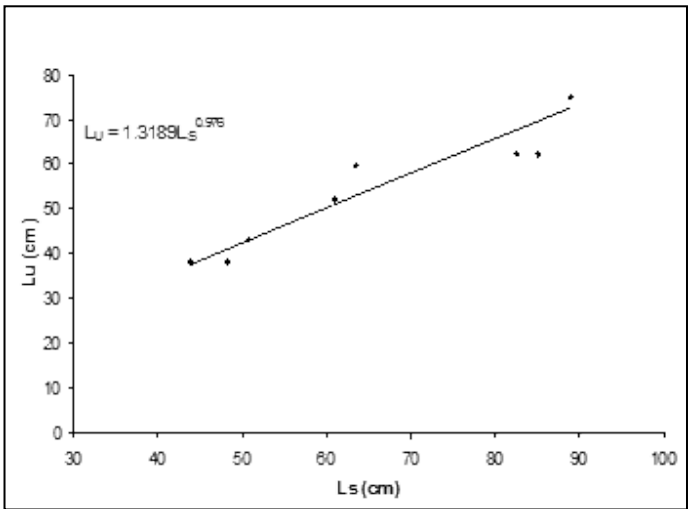

Figure 5. Relationship between L_U and L_S.

The results obtained from Section 3 indicate that with simple gravity blind backfilling method, a large area can be filled up from a single inlet hole by suitably controlling the slurry rate and the solid concentration.

4 FIELD INVESTIGATION

In the light of encouraging results obtained from the laboratory investigations, field implementation of the proposed simple gravity blind backfilling technique has been tried in an abandoned coal mine so as to observe the effectiveness of the suggested method under real field conditions. The relative spread of sand in different directions is measured using a remotely operated vehicle-mounted (ROV) camera. This endeavor is taken up for the first time in the world.

4.1 Drilling of Boreholes

As the mine is abandoned, water-logged and unapproachable, it has been a very difficult task to locate the surface position of the boreholes for successful connections to the underground workings. For this purpose surface control points are selected from the combined surface and underground map of the mine, and locations for drilling three holes are initially marked on the surface. After drilling of these three boreholes at their respective locations, it has been found that only one out of three could connect the underground workings. This failure has given rise to reconsideration of the survey procedure for marking the surface points of future boreholes. A complete survey two surface permanent stations, buildings, roads etc. is conducted to find out the correctness of the surface features of the available map with respect to the two shaft-mouths of the abandoned mine. After adjusting for a small error in location of surface features in the available mine map, the surface points of the further boreholes are positioned and marked in the field. A total of 45 holes are drilled with more than 80 percent success in connecting the galleries boreholes to underground mine. Different types of boreholes of varied sizes are drilled to serve different purposes. The Figure 6 shows the position of different types of boreholes in the mine map. Twenty four air holes are drilled mainly at the rise-most locations covering the entire top part of the filling zone. The purpose of these holes is to release the trapped air which often enters the mine along with the feed of the sand-water slurry through the inlet feeder hole. About 10 large diameter boreholes have been drilled with inside steel casings of 355 mm for insertion of underwater ROV Camera to observe and plot the spread of sand-bed along different directions. Two medium sized boreholes of 250 mm diameter are drilled for installation of submersible pumps which are used to supply water from the water-logged mine into the mixing vat for preparation of sand-water slurry. Water in slurry when fed through mother borehole flows back to the mine, thereby creates a closed-circuit flow of mine water. Six mother boreholes are used for feeding sand-water slurry into the mine to fill-up a section of the mine.

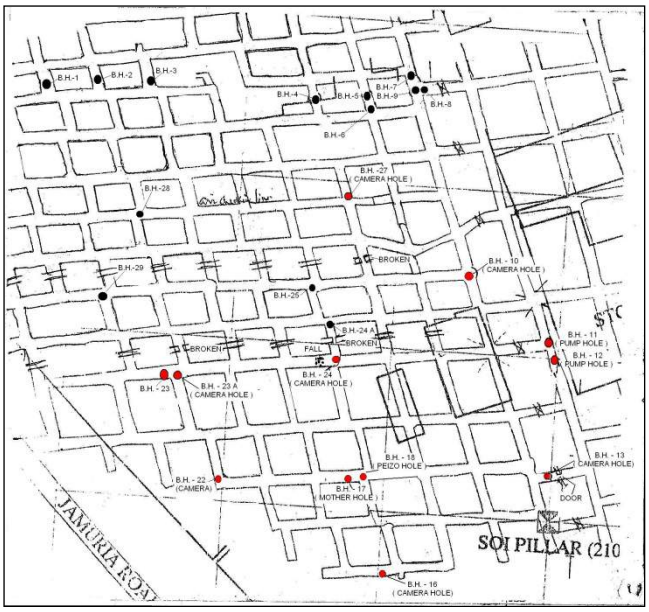

Figure 6. Map of a section of mine showing positions of different types of boreholes.

4.2 Surface Arrangements

Surface arrangements are made to mix measured proportions of sand and water in a mixing vat and send the homogeneous mixture to water-logged abandoned mine by gravity through a mother or feeder borehole.

4.2.1 Water pumping

Two 22 kW power and 2.3 m^3/min capacity, each, submersible pumps are installed at a depth of 40 m below the surface inside Borehole Nos. 11 and 12 connected to two dip-rise crossings of the underground mine. (Fig. 7)

The pumps can be operated either from the pump house or from the movable filling laboratory via wireless antennas. This wireless operation for starting and stoppings of the pumps has been designed for convenience of re-connection of the pumping units after shifting the movable laboratory to a new location for filling through the next feeder borehole.

Figure 7. Pump house for two submersible pumps.

As there has been shortage of storage space on the surface, the sand is procured in stages of about 300 to 500 m^3 and filling is continued in phases.

4.2.2 Sand flow control and measurement

A Payloader is used to load sand on to a small bunker near the movable laboratory, from where a measured amount of sand is fed into the mixing vat through a bucket elevator (Fig. 8).

Figure 8. Sand feeding arrangements.

The sand feed rate by the bucket elevator is calibrated with the speed of the driving sprocket of the sand conveyor. An electrical vibrator motor is fitted at the lower side of the sand bunker for permitting continuous flow of wet sand from the bunker, which otherwise gets stuck at the mouth of sand bunker causing jamming of sand flow from the bunker to the bucket elevator. A proximity switch type rpm indicator is fixed to measure the rotary speed of the driving sprocket of bucket elevator. Two electro-magnetic valves are fitted on the two water inlet pipelines to indicate the water flow rates delivered by the individual submersible pumps. Suitable 4 to 20 mA signals are sent to the data logger for recording of the pumping data during continuous filling operation.

4.2.3 Slurry mixing and feed monitoring

Figure 9 shows the picture of a movable backfilling laboratory was designed and fabricated in the form of a caravan, which is positioned exactly above the mouth of mother borehole.

Figure 9. Caravan with the overhead tank.

Water from pumps and sand from bucket elevator is mixed together in a mixing vat constructed inside the caravan and the slurry is then allowed to flow down into the mine by gravity through the mother borehole. As a safety measure, an overhead water tank of $5m^3$ capacity is placed over the top of the caravan so as to release the water from the tank through a motorized valve to the mixing vat in case of sudden power failure. This additional flushing water will keep the flow channels open and prevent accidental jamming in the case an accidental power cut.

The backfilling laboratory is fitted with a control panel (Fig. 10), where different displays or indicators for different parameters like, individual pump flow rates, the total water flow rate, conveyor RPM, laser water level and piezometer based slurry head, are mounted. A high capacity UPS is also placed at the control panel for uninterrupted monitoring of various parameters in the case of sudden power tripping.

An eight-channel continuous data recording system is installed in the caravan for recording of water flow rates from pumps, sand conveyor RPM, fluctuations in laser water level as well as piezometer water level during filling operations. Figure 11 shows the front view of the continuous data recording system, in which fluctuations in the piezometer water level is indicated in the form of a graph with respect to time.

Figure 10. The control panel inside caravan.

Instantaneous rise and fall of water levels indicated by both laser distance meter and piezometer are also shown symbolically by the rise and fall of levels in two vertical bar-type indicators in the right-hand side of data logger window. Continuous fluctuation of the water level in the data logger window can provide a quick indication about an imminent jamming tendency.

Figure 11. View of data logger in control panel

4.3 Field Experimentation

Since filling from dip-most side has been found to be more effective in the laboratory experiment, the Borehole No.17, which is located towards the dip-most zone of the proposed filling area, is chosen to be the first mother borehole. The diameter of the mother borehole is kept at 200 mm so that the inlet velocity of the slurry becomes nearly 3 m/s. In the beginning of the filling work through the first mother borehole, sand concentration in the slurry has been kept at 15 percent and the slurry level in the mother borehole continuously fluctuates as witnessed in the data logger window. After sufficient progress of filling the flow path length increases, thereby increasing the flow path resistance. This in turn increases the slurry level in the mother borehole, which can be noted from the vertical red bar showing slurry head in the data logger window. When slurry level reaches within 2 m from the surface, the sand conveyor is stopped and plain water flushing of the borehole is allowed to continue for some time so that flow stabilizes and slurry level returns to normal range. Then the sand conveyor is restarted. In this way filling at 15 percent concentration is continued for some more time and then it is reduced to 12 percent concentration when the slurry level in the mother hole reaches within 2 m from the surface very frequently. In the same manner, the concentration gradually reduced to 9 percent as the filling progresses.

During downward movement of slurry through the borehole air bubbles get trapped and enters the mine, which are then released intermittently from other boreholes located on the rise side. Figure 12 shows the gushing release of air and water from Borehole No. 24 located in the rise side of the feeder borehole.

Figure 12. Effusive release of air bubbles

Filling through the first borehole continued with gradual reduction in volumetric concentration of sand from 15% to 9%. Finally the first mother borehole is jammed after injecting 6689 m^3 of sand. Next, the caravan or movable backfilling laboratory is shifted to Borehole No. 23 and re-connection of water pipelines from pumps and power line from nearest power pole are completed. The sand bunker is relocated at the new site. Then filling is started at Borehole No. 23. Due to presence of series of stoppings on the rise side of this mother borehole, filling through this could not be progress beyond 1427 m^3 of sand injection. In the same way filling has been continued in Borehole Nos. 28, 29 and 27 in sequence. The Borehole No. 29, being located in between the two series of stoppings, could not intake sufficient amount of sand and is jammed with a total sand throughput of 1544 m^3. Lastly the filling has been continuing in Borehole No. 3 with 1357 m^3 of sand being sent into the mine and the project was terminated in December 15, 2011. In this way, a total of 21,476 m^3 of sand has been sent into the mine. Table 1 displays the quantities of sand deposited through the respective boreholes.

Table 1. Details of sand filling

Sl. No.	Borehole No.	Sand Deposited (m^3)	Remarks
1.	17	6689	Unhindered filling
2.	23	1427	Hindered filling due to stoppings
3.	28	6236	Unhindered filling
4.	29	1544	Hindered filling due to stoppings
5.	27	4223	Unhindered filling
6.	3	1357	Incomplete filling (project terminated)

5 BACKFILL MONITORING

For the first time in the world the condition of the sand-bed in the underground gallery of a blind backfilling operation could be viewed using special underwater remotely operated vehicle-mounted (ROV) camera. The sonar-head mounted on the ROV camera is used to produce a map of the required part of the abandoned mine to show gradual progress of sand bed along different directions.

5.1 The Underwater ROV Camera

The main components of the Underwater ROV camera (Fig. 13) system are:

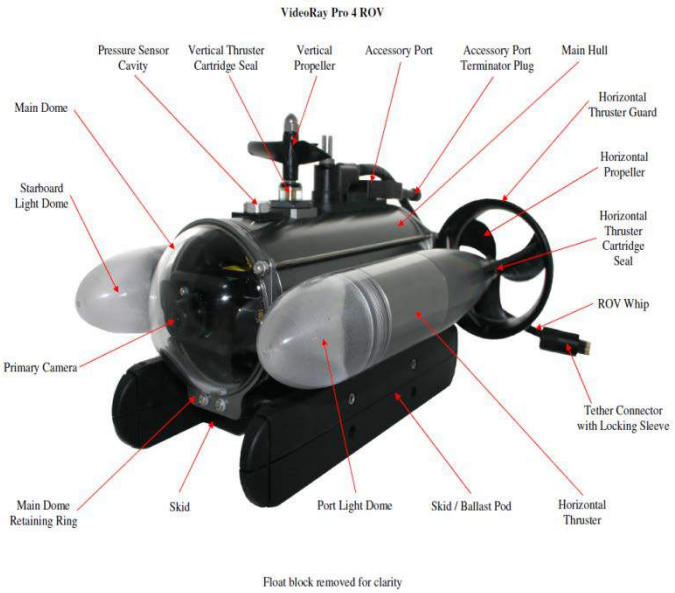

Figure 13. ROV camera

(i) Remotely Operated Vehicle
(ii) Front and back cameras
(iii) control panel
(iv) handheld remote operating device
(v) tether cable

The Remotely Operated Vehicle, or ROV, carries the cameras, lights and sensors or accessories to the underwater places to be observed. Thrusters in the remotely operated vehicle provide mobility and are controlled from the surface. The control panel includes the system's power and communications modules, computer and hand controller, and serves as the operator's console and video display. The handheld remote operating device or controller is used to control the operation of ROV camera system underwater and mainly consists of joystick, depth control knob, bright and dim buttons for lights, and camera tilt up and down buttons. The joystick controls the forward, backward, left and right movement of the ROV. The depth control knob controls the rate of ascent and descent of the ROV. When centered, the vertical thruster is idle. The lights buttons control the intensity of the lights. The camera tilt buttons control the up and down tilt of the front camera. The tether connects the ROV to the control panel and delivers power and control signals to the ROV, and returns video and sensor data (optional) from the ROV to the surface.

5.2 Mapping of the Filled-up Area

Filling work has been executed through six boreholes, out of which the first five boreholes are filled up to the final limit till jamming takes place. Filling from the sixth borehole has been continuing when the project term ended. Monitoring during filling in each borehole is performed from surrounding camera boreholes using ROV mounted camera.

The ROV camera is inserted into the mine through the 14″ diameter camera borehole using remote operating device for the camera system. On entering the mine gallery the camera is slowly moved towards the direction of mother borehole getting guided by the indicated azimuth from the built-in compass as well as from the sonar image. Different screenshots (Fig. 14) of sonar image were used to build a map of the path travelled by the camera. The orientations of camera during successive the screenshots were also noted and this information was used while superimposing the screenshots with one another. At least three well identified common points in the two successive screenshots were also utilized for their superimposition for construction of the mine map.

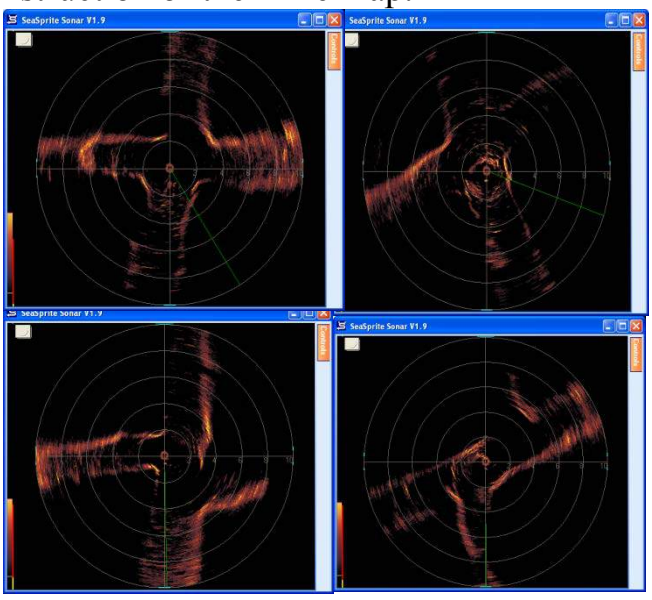

Figure 14. Four successive sonar screenshots

Normally water in underground mine galleries become very turbid during filling and visibility becomes very poor. Therefore filling is done in stages. After input of 400 to

500 m^3 of sand in each stage, filling is stopped for two days for allowing sand and dust particles to settle so that water in underground roadways become clear. Then the ROV camera is inserted from surrounding camera holes in a sequence and transported close to the deposited sand bed from different directions. Then, photographs of sand bed were taken and simultaneously sonar imaging of the underground gallery was done to obtain the exact position of the deposited sand bed with respect of the mine void. Figures 15 and 16 show the spread of sand after 7^{th} and 15^{th} stages of filling.

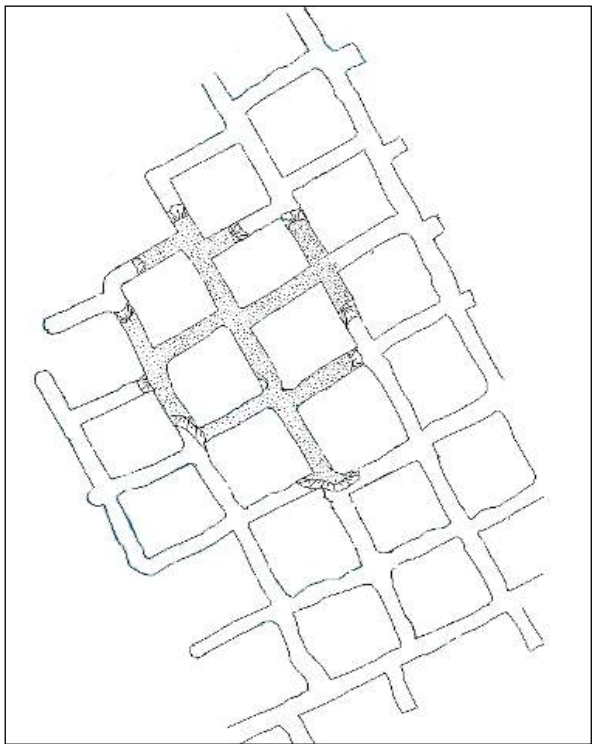

Figure 15. Spread of sand after 7^{th} stage.

The underwater photographs of the sand bed by the ROV camera when it is taken close to the sand bed from different directions showed that the height of deposited sand bed equals the height of the mine gallery, which means that there is no gap left between the sand bed and the mine roof. In normal backfilling or stowing of active underground mine a gap between the mine roof and the deposited sand bed always exists. So, in this method of backfilling yields 100 percent filling. This fact has also been verified in the laboratory study in the transparent model.

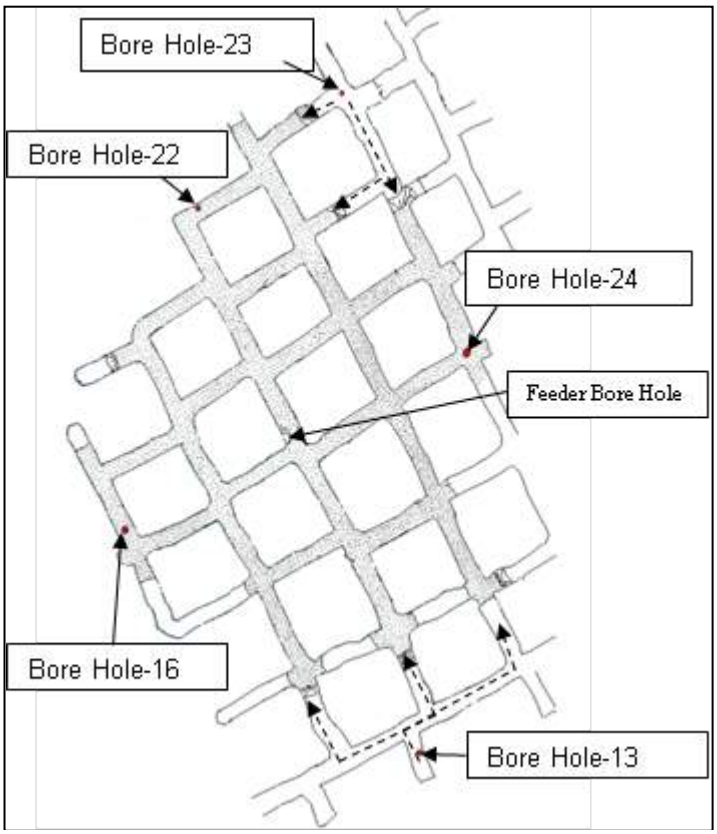

Figure 16. Spread of sand after 15^{th} stage.

Figure 17 shows a typical close view of the deposited sand bed taken by the ROV camera when moved very near to it.

Figure 17. Close view of deposited sand bed.

5.3 Empirical Relationships

During the model study experiments with flow rates varying from 15 lpm to 30 lpm, the nature variation of maximum sand throughput (V_S) with sand concentration (C)

has been observed in the form as given by the Equation (2), where the values of K ranges from 228 and 604, and n from 0.0822 to 0.1232. In the field experiment, a similar nature of variation between maximum sand throughput (V_S) and sand concentration (C) has been detected for the fixed water flow rate of 4.5 m^3/min, but in the field relationship of $V_S = Ke^{-nC}$, the K value becomes as high as 48089 and n becomes 0.227. The above relationship may readily be observed from Figure 18.

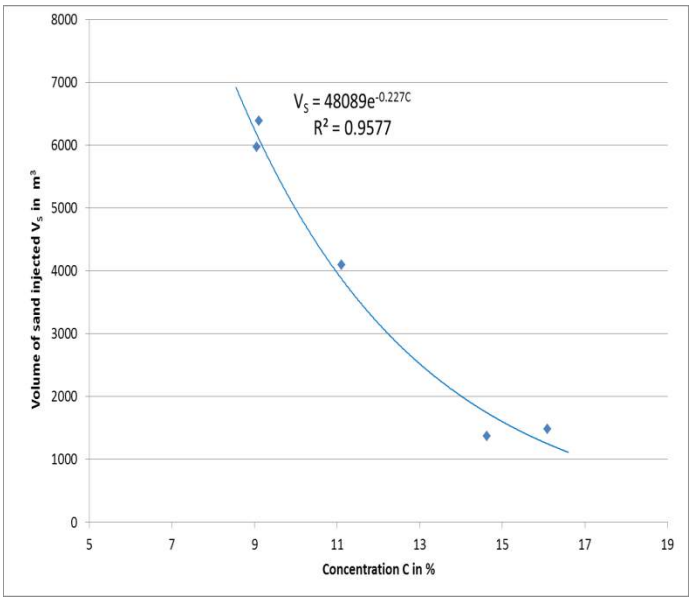

Figure 18. Plot of V_S against C for the

The maximum volume of sand deposited, V_S, has been found to be related with the slurry flow rate Q and sand concentration C in the form

$$V_S = 1.041 * h * Q^{1.313} / C^2 \quad (5)$$

This is similar to Equation (3) of model study. The spread of sand along rise, L_U, and along strike, L_S, are related to maximum volume of sand deposited as:

$$A = 10.55 * k * h * L_U^{0.509} * L_S^{0.764} \quad (6)$$

This is also similar to Equation (4) of model study. Unlike Figure 5 the relationship between L_U and L_S has been found to be non-linear for the case of field study and is given by the Equation (7).

$$L_U = 0.015 * L_S^{2} \quad (7)$$

6 CONCLUSION

From the study of simple gravity blind backfilling in the laboratory model study and in field trials, the following conclusions may be drawn:

I. The process of backfilling in the field study is perceived to be similar to that witnessed in the transparent model study in the laboratory. The process of blind backfilling has been found to be more similar to sediment transportation on river beds rather than slurry transport through pipe lines. The sequence of filling can be observed from Figure 2.

II. It has been observed in the laboratory from transparent model study that filling from rise side towards dip direction suffers from the difficulty of lower maximum sand throughput owing to counter-movement of the downwardly moving sand-water slurry against upwardly moving trapped air bubbles that enters the mine while feeding through vertical inlet borehole. Therefore it is inferred that it is always better to stat the filling operation from the dip-most area of the mine void.

III. The jamming phenomenon, especially the pre-mature jamming incidents are very sudden and arrive without any precursor. In such cases a system for continuous monitoring of the slurry level is helpful for sensing the imminent jamming tendency, and a timely appropriate action may be initiated to dodge any pre-mature jamming.

IV. In order to make the simple gravity backfilling process more efficient, the filling should start with high sand concentration of 15%, and then it should gradually be reduced to 9% or less. This will ensure maximum filling from single borehole at a quicker rate. In this manner up to 6000 m^3 of sand can be filled into the mine from a single mother borehole.

V. During progressive filling work successful monitoring of sand spread along different directions in the abandoned, water-logged underground mine, has been performed using a ROV

mounted underwater camera fitted with real-time sonar imaging system (Figs. 14, 15 and 16). This attempt of remote mapping of the deposited sand-beds in an unapproachable, water-logged underground mine has been made for the first time in the world and completed successfully.

VI. As monitored by the ROV camera the deposited sand bed in the underground mine gallery is packed tightly up to the roof (Fig. 17), thereby ensuring 100% filling by this technique.

VII. For field implementation of this method, empirical relationship for spread of sand along rise (L_U) and strike directions (L_S) with maximum volume of sand throughput (V_S) has been established to assist engineers to locate the position of the subsequent boreholes once the currently running borehole approaches its maximum limit (V_S).

VIII. Empirical relationships between maximum amount of sand throughput (V_S) and slurry flow rate (Q) as well as sand concentration (C) have been found to be similar for model study and field trial, except that these have different values of constants or co-efficients.

With suitable modification of sand concentration and flow rate, the life of the filling process from a single borehole can be extended to fill up considerably large area surrounding the inlet hole. Since sand-water slurry is fed into the mine by gravity and does not involve costly imported equipment, which requires frequent maintenance and replacement of wearable components. This makes it a simple and cost effective method that may be easily adopted by a developing country like India.

Mathematical Analysis Of Spontaneous Fire In Coal Mines For Designing More Efficient Fire Control Techniques

D. D. Tripathi, A. Sinha
Central Institute of Mining & Fuel Research, Dhanbad–826015

ABSTRACT Energy security is now prime issue to uphold GDP in India. Presently, coal is playing vital role in fulfilling the primary energy need of the country.But, thetendency of self heating of coal is playing a significant hazardinmining the coal. In fact, coal having molecular formula $C_{10}H_7O$; attains thermodynamic equilibrium over the years, but a little added oxygen tilts the thermal stability and leads to spontaneous heating or fire, hence the mechanism of spontaneous heating has been evaluated. The most effective way to investigate the dependency of spontaneous heating on various factors is mathematical modeling. Coal ignites spontaneously when temperature reaches above the critical temperature; at which the oxidizing process becomes irreversible thermo active -

$$\boldsymbol{T = \frac{E}{R} / ln(k_0/\mu)}$$

Where E is activation energy of burning reaction/mole: R=8.3144J/(mole^{0}K);universal gas constant, k_0 frequency factor, 1/sec; and gas constant, μ oxidation reaction rate constant for mechanically activated carbon. The critical temperature of coal self ignition can be loweredby decreasing activation energy in the fields of mechanical stresses.

Once a fire broke-up in the mines huge resources are required to combat, sometimes it's unnecessarily costly due to overuse or underuse of resources. Indeed, a cost effective fire combat techniques cannot be made without mathematical understandingof incubation period, quantitative analysis of fire risk potentials,the state and extent of fire,its direction of progress andair feeding to the seat of fire etc.

This paper summarizes the R&D carried out in CIMFR (Central Institute of Mining and Fuel Research, India) using mathematical approach for prevention and control of spontaneous fire has been summarized. Few successes storiesin realistic field have also discussed.

Keywords: Oxidative spontaneity, incubation period, mathematical simulation, fire fighting

1 INTRODUCTION

Coal mining in Indiahasstarted in August, 1774in Dishergarh seam at Aitura (Ethora),Chinakuri Colliery of Raniganj Coalfield; since those days, extraction is progressively continued. At present nearly 265BT coal reserve is available for mining and new resources get added years on years. Due to spontaneous nature of coal, mining industry is suffering from large extent of endogenous fires in their underground mines, open pit mines (virgin coal seam and developed galleries), stockpiles, discard dumps and moreover during transportationof coal through trains, trucks and ships [1].

Hazards of spontaneous fire have long been a problem in the wining of coal. At present, 87% coal is produced by open pit mines, but most of big open pit mines are facingthe large extent of active fires.Besidethis, only 15% geological reserves are amenable by open pit mining within economical depth (300 m). Difficulties in obtaining forest land and environmental clearances, high stripping ratio of coal seams and limited scope of large scale mechanizations;mining stalwarts are telling at every opportunity that greater attention should be paid to underground mining thus occurrences of spontaneous fire will increase in future.

2. MATHEMATICAL SIMULATION OF OCCURENCES OF SPONTANEOUS FIRES

Coal implicates energy therefore we have to save it from self-heating; but themeasures are not adequate for defeating the very purpose of it. The problems commonly met are, infrared thermometer and other temperature detecting devices can't outline the temperature profile of isolated area of the mines and composition analyses of fire gases are unable to locate the seat of fire. Nevertheless, numerical models give adequate and feasible results

2.1 Perceptives of Heating due to Aerial Oxidation

Oxidative spontaneity in coal is too common therefore, prior to designing long term mining plan it is indispensable to understand occurrences of spontaneous fire. Coal interacts with atmospheric oxygen at ambient temperature with varying rate of oxidation 2000-10 ml/kg/hr; depending on the extent of weathering of coal [2].

$$C + O_2 = CO_2 + \Delta H \quad (1)$$

The process is exothermic, evolves heat (25-0.3 J/ml O2 absorbed) which raises the temperature of coal.

$$dQ/dt = Cp(T)/H\ dT/dt \ \ ml/kg/hr \quad (2)$$

Where Q, amount of oxygen consumed per unit weight of coal, dT/dt, rate of temperature rise; H is heat of reaction; Cp (T), specific heat capacity of coal.Rate oxidation of coalbecomes double for every 10^0C rise in coal temperature.

2.2 Spontaneous Heating Predictive Models

Energy Conservation equation (3)

Heat accumulation at a point = [Heat produced due to exothermic oxidation of coal – Conductive heat transfer - Convective heat transfer - Heat to drying or wetting]

$$C_{ps}\,P_s\,\frac{\partial T}{\partial t} = H_0\{D_0 \in \frac{\partial^2 \rho_0}{\partial x^2} - V_g\,\frac{\partial \rho_o}{\partial x}\} \quad - \left\{-k\frac{\partial^2 T}{\partial x^2}\right\} - C_{pg}\,\rho_g\,V_g\,\frac{\partial T}{\partial x} - H_w\left\{-D_w \in \frac{\partial^2 \rho_w}{\partial x^2} - V_{wd}\,\frac{\partial \rho_0}{\partial x}\right\} \quad [3]$$

Oxygen mass conservation equation

Oxygen accumulation = {Diffusion of O_2 - Convective transfer of O_2}

$$r_0 = D_0 \in \frac{\partial^2 \rho_0}{\partial x^2} - \ V_g\,\frac{\partial \rho_o}{\partial x} \quad (4)$$

Moisture mass conservation equation

Rate of drying = {Diffusion of water vapor– Convective transfer of water vapor}

$$r_w \ = -D_w \in \frac{\partial^2 \rho_w}{\partial x^2} - V_{wd}\,\frac{\partial \rho_0}{\partial x} \quad (5)$$

Symbols have their usual meaning.

One dimensional transient pseudo (local mass accumulation is negligible compared with mass transfer) steady state model equations, in which mass transfer of both oxygen and moisture occurs by diffusion and convection, are used - to avoid the complexity in finding the exact solution.

2.3 Simulation Of Spontaneous Fire

Heating of coal corresponds to the third stage in which the moisture present in pores is dried out and at any instant increase in surface oxidation of coal becomes over. Mass transfer of oxygen and moisture both occurs through convection. Implementing the conditions - energy balance equation transform into-

$$k\frac{\partial^2 T}{\partial x^2} - H_0 V_g\,\frac{\partial \rho_o}{\partial x} \ - C_{pg}\,\rho_g\,V_g\,\frac{\partial T}{\partial x} - H_w V_{gd}\,\frac{\partial \rho_{wd}}{\partial x}\} \ = 0 \quad (6)$$

with boundary conditions-

at x = 0 ; $\quad k\frac{\partial T}{\partial x} = C_{pg}\,\rho_g\,V_g\,(T_i - \ T_a)$

$\rho_0 \ = \rho_{0,i} \ = \rho_{0,a}$; $\quad \rho_{wd} \ = \rho_{wd,i} \ =$

$\rho_{wd,,a}$ (7)

at x=1; $k\frac{\partial T}{\partial x} = \frac{\partial \rho_o}{\partial x} = \frac{\partial \rho_{w,d}}{\partial x} = 0$

Integrating equation (4) and substituting the boundary conditions -

$$\Delta Tmax = \frac{H_0}{C_{pg}\,\rho_g}(\rho_{0,a} - \rho_0) + \frac{H_w}{C_{pg}\,\rho_g}(\rho_{w,d,a} - \rho_{w,a}) \quad (8)$$

The equilibrium temperature rises up to $\approx 90^0$C. As a result, the occurrences of spontaneous combustion of coal in an underground mine panel i.e. in realistic mining conditions can be controlled by both reduction in oxygen concentration and reducing the relative humidity in gas stream.Moreover the rate of mass of coal can spontaneously ignite only when it reaches some temperature T^0 C above critical.

T > TCr **(**9)

The process of transition of spontaneous heating to spontaneous ignition depends on partial pressure of oxygen and heat exchange in the coal mass and surroundings and described with equation -

$$dT/dt = H/Cp\,(T)\,A \exp[-E/RT - bQm]\,(Po_2 / 0.21)^n \quad (10)$$

Where Q, amount of oxygen consumed per unit weight of coal, dT/dt, rate of temperature rise; H is heat of reaction; Cp (T), specific heat capacity of coal. A, pre-exponential factor; E, activation energy; R, universal gas constant; b and m are constants, T, absolute temperature; P_{02}, partial pressure of oxygen and n, the order of reaction belonging to the range of 0.5-1.0; for freshly to wreathed coal.

Numerical simulation of equation (10)provides estimated time in which spontaneous heating may setup inspecific panel or place.

3. SIMULATION AND ANALYSIS OF PROPAGATION OF FIRE

3.1 Propagation of Surface and Subsurface Fires

Spontaneous heating generally starts at a single point or several independent points at a time and heat transferoccurs through conduction, the equation, rate = driving force/resistance, can be applied directly. The driving force is the temperature difference per unit length of heat-transfer path, also known as the temperature gradient. Instead of resistance to heat flow, its reciprocal called the conductance is used. The rate of heat transfer=driving force x conductance,i.e. [4]

$$\delta T/\delta t = \alpha \delta^2 T/\delta x^2 \quad (11)$$

$$T = Ts \text{ at } x = 0;\ T = f(x) \text{ at } t = 0 \quad (12)$$

α, thermal diffusivity. Using boundary conditions, equation (1) transformed into probability integral as-

$$T_f - T_0 / T_s - T_0 = \phi(\gamma\eta) = 2/\pi^{1/2} \pi e^{-\beta^2 d}\beta \quad (13)$$

Where $\phi = \frac{1}{2}\,\alpha^{1/2}$ t, t is time to attain the temperature T_f at a distance x from heat source.

The moment thermodynamic equilibrium is reached, cellular convection setup-

$$q/k\rho c = 1/(\pi t)^{1/2}(T_f - T_0) \quad (14)$$

Where, q is heat flux at the surface of the solid (W/m^2), k is thermal conductivity, ρ is density and c is specific heat capacity.

Since, intervening strata of coal seam comprises different formations like shale bands nevertheless sandstone bands as intricate part of the seam, then heat absorbed by their respective boundaries are-

$$q_1 / k_1\rho_1 c_1 = q_2/ k_2\rho_2 c_2 = q_3/ k_3\rho_3 c_3 = \ldots = q/ k_i\rho_i c_i \quad (15)$$

Where scripts 1, 2, 3, ---- i are the boundary element of enclosures. Moreover total heat absorbed per unit area by its constituent boundaries are-

$$1/(k\rho c)^{1/2} f_0^{\pi} q\,dt \quad (16)$$

Where, π is the length of the solid exposed to sense the convective heat flow. Shale and sand stone in the solid form are more risky in propagating the fire.

4.RAPID COOLING OF STRATA HEATED BY FIRES

4.1 Cooling of Hot strata by Water percolation –model approach

Water is one of the most useful and cost effective in all available fire extinguishers. Under pressure and controllable-discharge, water infiltrate and knockout deep-seated fires. The general model of infiltration of water from surface ponds to a fire area is based on Darcy law or its modifications [5]-

$$V = -(\kappa/\mu)\Delta P/L \quad (17)$$

V, average fluid velocity through the pores with pressure drop ΔP measured across the system,κ, permeability, μ, viscosity, L length in flow direction.

The rate of water percolation from surface ponds, into a fire area depends on permeability of soil that gives passage to flow through it's inter connecting voids. The effect of inertia, on the flow, through porous media is characterized by Forchheimer equation i.e. modified Darcy Law [6],

$$-\Delta P/L = \alpha\mu V + \beta\rho V^2 \quad (18)$$

α, reciprocal of permeability, β inertial parameter. Bothα andβ depend on porosity of the material. Equation (18) can be derived by Navier Stroke equations for one-dimensional, steady, incompressible, laminar flow of a Newtonian fluid in rigid porous medium -

$$f = 1/Re' + 1 \quad (19)$$

Where $f = -\Delta P/L\beta\rho V^2$ and $Re' = \beta\rho V/\alpha\mu$. We obtain a frictional factor - Reynolds number type correlation, which is successfully used to correlate large variety of porous materials and broad range of flow conditions.

5.FIRES IN JHARIA COALFIELD (JCF)

Jharia Coalfield (JCF) is worldwide famous for coal fires; and lie within latitude 23^{03}9'N - 23^{04}8'N and longitude 86^{01}1'E-$86^{0\ 2}$7'E in Damodar river basin. The mining activity in JCF was started in 1894 and occurrence of fire was noticed in 1916 at XIV/XIII seam of Bhawra colliery and causing devastation since last 100 years or so. Coalfield having 18 regular coal seams (XVIII-I, top to bottom) and 46 coal horizons. Several seams are consists of discontinuous splits namely top-bottom, upper-lower and local seam with nomenclature (0, A, B, -- --; etc.) with varying thickness of 0.5-55M and gradient 5-40^0 up to a maximum depth of 1200m. Area is geo-spatially disturbed with dyke, sills, igneous intrusions, extensive folding and more than 250 faults. Indeed, coal seams existing at shallow depth have been mined out unscientifically in the beginning; caused spontaneous fire in due course. Initially, these fires are inadequately sealed and monitored, so, gradually; they had grown up to the surface and spread over a long region as shown in Figure 1.

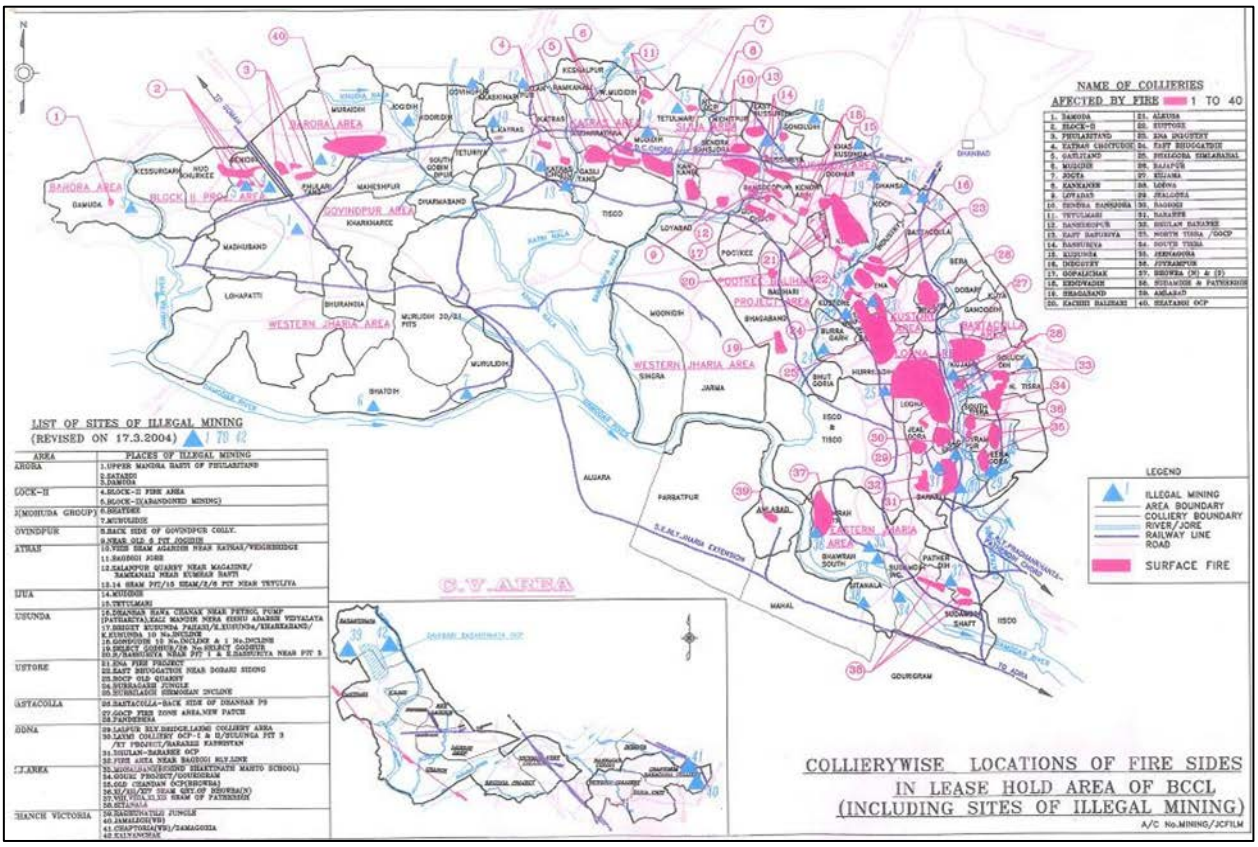

Figure 1. Fires in different collieries of Bharat Coking Coal Limited in Jharia coalfields

5.1 Impacts of Coal Fires

Emission of greenhouse gases—carbon dioxide (CO_2), methane (CH_4), carbon monoxide (CO), nitrogen oxides, sulfur dioxide and other toxic organic substances into the atmosphere is major environmental concern of open coal fires. Although, contribution of CO_2 and CH_4 into global atmospheric pool is nothing from small fire but can't be overlooked.

Fires affects air water, and land; smoke, from these fires contains poisonous gases that causes lung and skin diseases. Fires also pollute water by contamination of sulpher that is present in coal. In Jharia coalfield shallow depth underground fires had come up to the surface at many places and threatening the life of habitant.

5.2 Simulation of Firefighting

a. Inertization

The most important feature of dealing subsurface fires is oxygen depletion; whether, by sealing or inertization using inert gases CO_2 or N_2. Simultaneously to check the success of firefighting operation the knowledge of varying oxygen concentration at any point is quit important. There expression for changing O_2 concentration at time t has been given-

$$t = V/ CO_2 \, 1n \, Oc/ Ocrt \qquad (20)$$

Where, V is volume of the sealed of fire area; CO2 is flow rates into sealed off fire area m^3 /min; C_o initial oxygen concentration at t=0, C_t , concentration of oxygen after time t min.

In a perfectly sealed of area of volume V, the quantity of inert gas Q, necessary to reduce the O_2 concentration from 21% to 2 % will be Q = 2.3 V. Ratio, Q/V must be kept considerably higher than 2.3 in actual field condition owing to inherent air leakage.

5.3 Rapid Cooling Of Strata Heated By Subsurface Fires

Two water pods of dimension 504mX66mX2m and 540mX70mX2m were made in the fire.Insitu temperature was reported as360^0C (maximum). Then, ponds

were filled with water up to a height of 2m. Boreholes C_1, C_2, C_3, C_4 andC_5 exist in the vicinity of pods. Then, duration of lowering the water level in the ponds, temperature, gases and effectiveness of cooling by water percolation has been monitored weekly for one year. The inferences drawn are given below.

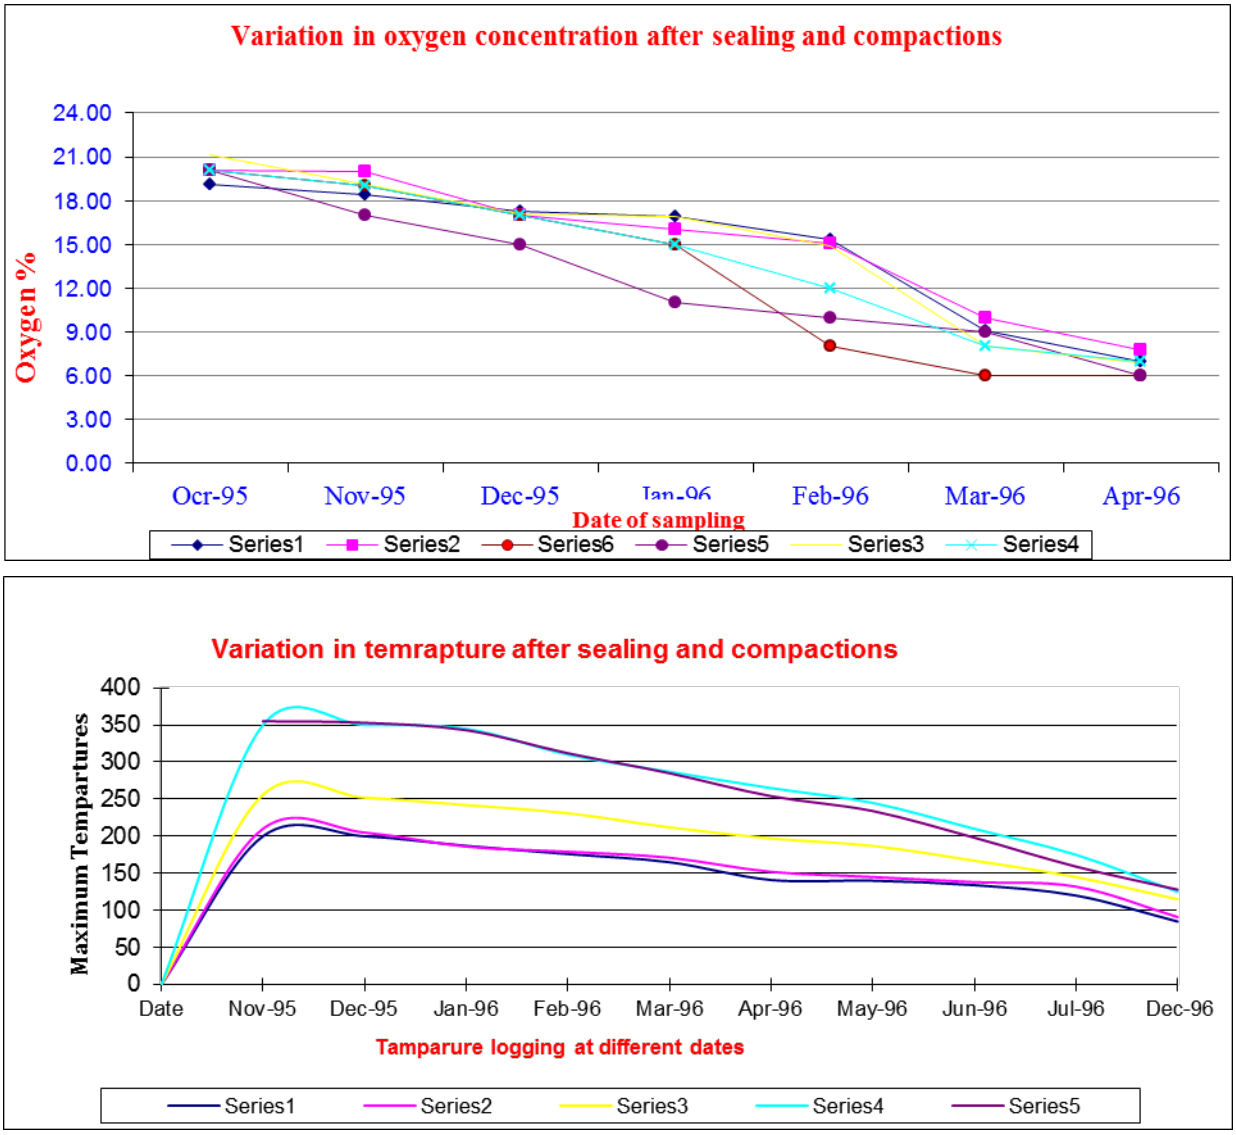

Figure 2. Above figures are showing the oxygen concentration and temperature variation after sealing the fire area and cooling through water ponds on surface.

5.4 Direct Dealing Of Fire With Water Mix Additives

In western quarry of Chasnalla Colliery (SAIL-ISP) most of the exposed coalfaces were under blazing fires. Examining the situation, e.g. location, depth, size and intensity of the fire; dealing of fire started primarily with-flame suppression and rapid cooling of hot strata.

Due to high heat capacity (4.2J/g0K) and latent heat of vaporization (2442J/g), water is most commonly used to deal the fires. Water expands 1700 times while it changes to vapor. This diluted the oxygen concentration and subsequently creates an oxygen exclusion barrier near the seat of fire; and smothering the fire.

Due to risk of water gas explosion water alone can't be recommend for flame suppression and dealing the glowing fires. Surface tension of water does not allow it to penetrate, in flaming fire, water droplets blow away before reaching the flaming zone. Additives mixed water significantly improved the effectiveness of fires fighting operations - by means of rapid cooling, retarding surface oxidations and minimizing the possibilities of re-ignition. Concentration

of solution varies from 0.01% to 0.1% according to intensity of fire. Spray volume discharged from a nozzle, spray angle and penetration distance is very much useful and determined by the formula-

$V = \frac{1}{3}\pi \{\tan\frac{\theta}{2}\}^2$

Where θ is the spray angle.

Table 1. Spray volume with spray angle and penetration distance.

Spray angle (o)	30^0	60^0	90^0
Spray volume (m3) (2 m of penetration)	0.3	1.39	4.18
Spray volume (m3) (3 m of penetration)	0.676	3.14	9.42

The spray volume with a spray angle of 90^o is approximately14 times larger than that with a spray angle of 30^o.

In theory, small droplets are more efficient in cooling and diluting the gases than large droplets, because of the larger total surface area available for evaporation and heat extraction. As shown below in table 2, when the droplet diameter is reduced from 1000 μm to 100 μm, the total surface area increases 10 times from 6 m^2 to 60 m^2 for 1 liter of water.

Table 2.Droplet size (μm), droplet number and surface area (m^2).

Droplet size (μm)	1000	100	10
Total number of droplet	1.91×10^6	1.91×10^9	1.91×10^{12}
Total surface area (m^2)	6	60	600

These analytical results are consistent with experimental results and more effective in cooling hot gases than traditional straight or narrow angle attack due to the fine droplets and wide spray angle. However, water fog technique is that excess steam may be generated as large amounts of fine droplets are discharged. This can reduce visibility and cause comfort problems to the firefighters [7].

Modeling of Turkey's CO_2 Emissions Using Economic and Demographic Variables

I. Karakurt, G. Aydin, S. Kaya
Karadeniz Technical University, Mining Engineering Department, Trabzon, Turkey

ABSTRACT: In this paper, regression analysis (RA) was applied for modeling the CO_2 emissions of Turkey. Real gross domestic product (GDP), total and urban populations and energy consumption were considered as economic and demographic variables. The developed model was tested using a test data set which were not utilized during building of the model. Additionally, the developed regression model was verified using various statistical approaches. The result of regression analysis was also used to determine the significant variables affecting the CO_2 emissions. Furthermore, the performance of derived model was measured for showing the accuracy levels in predicting the CO_2 emissions.

Keywords: CO_2 emission, economy, demography, regression analysis

1 INTRODUCTION

The world depends heavily on fossil fuels to meet its energy requirements. It seems that they will remain the dominant energy source for the next 30–50 years as well (Garg and Shukla, 2009; Panwar et al., 2011). However, fossil fuels are inflicting enormous impacts on the environment. The increasing use of fossil fuels causes a significant increase in greenhouse gases (GHGs), especially carbon dioxide (CO_2) emissions (Karakurt and Aydin, 2013). Among several GHGs, CO_2 has solely a rate of 74% in total anthropogenic GHG emissions and the rest follows CO_2 (Fig.1) (Aydin et al., 2010). Globally, 35094.4 million tons CO_2 were released to atmosphere in 2013. The six largest emitting countries and/or regions in the world are China (28%), United States (16%), European Union (11%), Indian (6.8%), Japan, (6.2%) and Russian Federation (5.1%) respectively.

Turkey is a rapidly growing country whose income level is moving towards that of the rest of the OECD area. This growing trend has been followed by a rapid growth of greenhouse gas (GHG) emissions, most notably carbon dioxide (CO_2) emissions. Turkey's total CO_2 emissions amounted to 328.8 million tones in 2013. That means, 0.9% of CO_2 emissions of world total comes from Turkey. Emissions grew by 53% compared to 2000 levels and by just over 130% compared to 1990 levels (BP, 2014). All energy consumption sectors (power, industrial, residential, and transportation) contribute to this increased CO_2 emissions. Although the country has a relatively low level of CO_2 emissions, rapid economic growth could significantly increase the emissions in the coming years. Hence, great efforts are required to deal with the adverse impact of the CO_2 emissions. Therefore, research on emissions should be conducted in adjusting related policies. Modeling and forecasting of CO_2 emissions are one of the best efforts to provide alerts, mitigation, adaptation, financial and sustainability policy options. Hence, this paper presents a modeling study based on the socio-economic and demographic variables of Turkey using regression technique.

2 REGRESSION ANALYSIS

Regression analysis (RA) is a branch of statistical methodology concerned with relating a response y to a set of independent, or predictor, variables $x_1, x_2, \ldots, x_k$. It aims at building a good model, a prediction

equation relating *y* to the independent variables (Gorucu and Gumrah, 2004).

2.1 Simple Linear RA

Simple linear RA builds models to explain the relationship between the dependent variable as a linear function of one independent variable. The general equation of the simple linear regression model is given below.

$$y = (\beta_0) + (\beta_1)x \quad (1)$$

where β_0 donates the regression line intercept, the y axis, and β_1 is the regression coefficient representing the slope of the regression line (Yerel and Ersen, 2013).

2.2 Multiple Linear RA

Multiple linear RA builds models for explaining the relations between the more than one independent variable and dependent variable. The mathematical form of the multiple linear regression is given by Eq. (2).

$$y = (\beta_0) + (\beta_1)x_1 + (\beta_2)x_2 + ... + (\beta_n)x_n \quad (2)$$

where *y* is the dependent variable, x_1; x_2;... x_n are the independent variables, *n* is the number of independent variables, β_0 is the intercept, and the regression coefficient of descriptors is β_n (Yerel and Ersen, 2013).

3 DATA AND METHODOLOGY

To build regression model, real gross domestic product (GDP), total and urban population (TP, UP) and energy consumption (EC) are considered as independent variables while CO_2 emissions (E) are considered as dependent variables. Both the independent and dependent variables have been collected from BP (British Petroleum) Statistical Review of World Energy as a period of 1965-2012 (BP, 2014). The data was divided into two groups. First group (between 1965-2006) was used for building the model and second group (between 2007-2012) was used for testing the model. The used data are presented graphically in Figure 2.

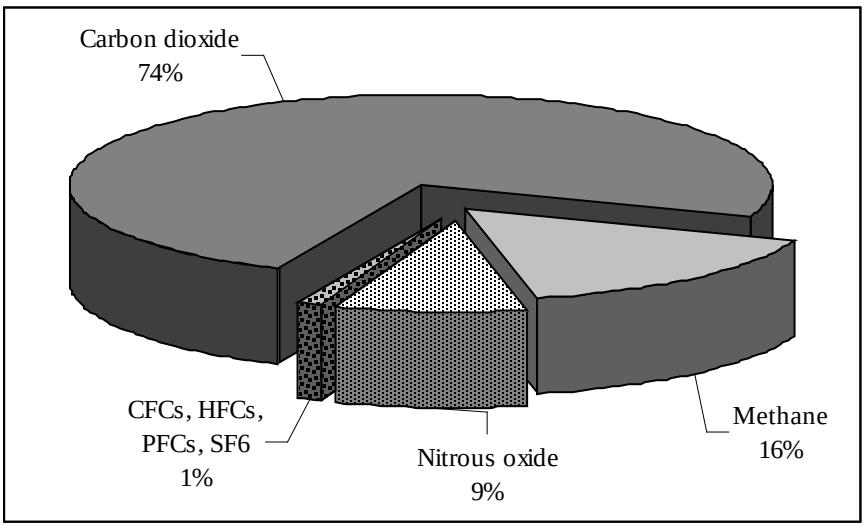

Figure 1. Anthropogenic GHG emissions (Aydin et al., 2010).

After preparation of the data belonging to the independent and dependent variables, the regression model was build. The model building was carried out using a statistical package program called SPSS 21. Following the building model, the confirmation and statistical significance of the estimated variables were done by considering the determination coefficient (R^2), F-and t-tests for both overall fit and individual variables respectively. The residual plots of the error are also studied to determine the appropriateness of the model.

4 MODELING RESULTS

The developed regression model for Turkey's CO_2 emissions is given in Eq.(4). As it is seen, the R^2 value for the developed model is 0.998 indicating a high degree of relationship between the UP, EC and CO_2 emissions. The coefficient of determination also indicates that 0.002% of the variation in the CO_2 emissions is due to all causes other than the predictors. From the weighs of coefficients, energy consumption (EC) was determined as the most significant variable affecting the CO_2 emissions.

$$E = (-0.2943) + (0.9515) * (\mathrm{UP}) + (2.2993) * (\mathrm{EC}) \quad (4)$$

where, E is the CO_2 emissions (Mtoe), UP is the urban population (million) and EC is the energy consumption (Mtoe).

4.1 Validation of the Developed Model

The statistical results of the developed model (Eq.4) is presented in Table 1. As seen, the tabulated F (3.13) is much smaller than the calculated F value. Therefore, it can be concluded that Eq. (4) is significant at the 95% confidence level. The t-test results for the coefficients are higher than the tabulated t-values (1.729). That is, the coefficients in Eq. (4) are significant in their use in the final model. The plots of the residuals against the predicted CO_2 emissions for the model case are also shown in Fig.3(a). The figure indicates that the residuals appear to be randomly scattered about the line, confirming the accuracy of the model.

4.2 Performance Measure

To measure the model performance, there are several methods in the literature such as mean absolute percentage error (MAPE), root mean scored error (RMSE) and mean absolute error (MAE). The accuracy of prediction is evaluated based on the estimation of error, thus the smaller the value of MAPE, RMSE and MAE, the better the prediction is. Among them, the criterion of MAPE whose equation given below (Eq.3) is the decisive factor since it is expressed in easy generic percentage term (Aydin et al., 2014). Table 2 shows the criteria of MAPE for model evaluation.

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{e_i}{Y_i}\right| * 100 \quad (3)$$

where n is the total number of measurements, e_i is the differences between actual and predicted values and y_i is the actual values.

Table 2. MAPE for model evaluation (Lewis, 1982).

MAPE (%)	Evaluation
>50	Weak and inaccurate prediction
20-50	Reasonable prediction
10-20	Good prediction
<10	Highly accurate prediction

The MAPE value was determined as 2.39% for the developed model. This result has shown that the derived model can give adequate prediction for Turkey's CO_2 emissions. The model can be also classified as a high accuracy prediction model because its MAPE is in the ranges of 10% (see Table 2). Moreover, it can be deduced from Fig. 3(b) that the predicted CO_2 emissions are close to the actual CO_2 emissions.

5 CONCLUSIONS

Recently, anthropogenic GHG emissions and global warming have become the most important research topics in the fields of both science and politics. The existing studies indicated that CO_2 has solely a rate of 74% in total anthropogenic GHG emissions and the rest follows CO_2. Hence, modeling and predicting the CO_2 emissions are of critical importance in adjusting policies in countries all over the world. In this paper, Turkey's CO_2 emissions was modeled by considering economic and demographic variables using regression technique. The modeling results showed that the developed regression model can successfully be used as a tool for predicting the CO_2 emissions of Turkey. Additionally,

energy consumption was determined as the most significant variable affecting the CO_2 emissions. As the modeling approaches are useful for policy makers and scientists to examine the future scenarios on the CO_2 emissions, different modeling techniques should be applied and the results should be compared with RA in order to select the best ones in future studies.

Table 1. Statistical results of the developed regression model.

Independent Variables	**Coefficient**	**Standard error**	**Standard error of estimate**	**t-value**	**F-value**
Constant	-0.2943	1.8010	2.4601	-0.1633	15704.46
UP (Million)	0.9515	0.1944		4.8932	
EC (Mtoe)	2.2993	0.0894		25.6932	
Tabulated t-value	1.729	**Tabulated F-value**	3.13	**R^2**	0.998

ABSTRACT The specific objectives of this paper are to formulate answers to the following questions: a. which is the accurate possibility of assessing environmental impact for geothermal waters, what are its stages? b. can we develop the types of impact assessment? c. what are the prospects for our research, what are the limits of research in this case? Our subject is inciting through the timeliness and importance in the present context of a globalized economic environment, further less the challenge for the European and national authorities to build a proper correlation between the environmental policy and a renewable resource of energy. We chose the geothermal area Beiuş (north-western Romania), while being a leading example for investments in geothermal heating system with available geothermal primary source through its main characteristic: it stands for the benefit of citizens by way of keeping a clean environment.

Keywords: Environmental impact assessment, Beiuş, Geothermal heating system

1 INTRODUCTION

Europe 2020 Strategy, launched by EU leaders in 2010, highlights the need to modernise the economy, to focus on economic growth and employment by addressing the challenges of globalisation and demographic changes and to support economic, social and environmental objectives.

Our subject is related to the present context of a globalized economic environment through the reach of the European and national authorities to build a proper correlation between the environmental policy and a renewable resource of energy (Speth 2002, 2003).

We performed the Life Cycle Assessment (abbreviated, LCA) of geothermal water by following steps such as: purpose and objectives, life cycle inventory, life cycle impact assessment and interpretation of results of life cycle assessment. In this case, the boundary research is the lack of defining and analysing the impact categories, because they are the subject of a long and thorough study and the interpretation of the data is performed by dedicated software (Preiss *et al.*, 2008).

2 EUROPE 2020

Europe 2020 Strategy, launched by EU leaders in 2010, highlights the need to modernise the economy, to focus on economic growth and employment by addressing the challenges of globalisation and demographic changes and to support economic, social and environmental objectives. The Strategy aims to address the shortcomings of the European growth model and to create the conditions for three mutually reinforcing priorities smart growth (developing an economy based on knowledge and innovation), sustainable growth (promoting a more resource efficient, greener and more competitive economy) and inclusive growth (fostering a high-

employment economy delivering social and territorial cohesion).

A number of five headline targets are interrelated and critical to the overall success for the European Union by 2020. These cover (EC 2005, EC JRC 2010):

– employment: 75 % of the population 20-64 year-olds to be employed;
– research and development: 3% of the EU's GDP to be invested in R&D;
– climate/energy: The "20/20/20" climate/energy targets should be met (including an increase to 30% of emissions reduction if the conditions are right) – greenhouse gas emissions 20% (or even 30%, if the conditions are right) lower than 1990, 20% of energy from renewables and 20% increase in energy efficiency;
– education: The share of early school leavers should be below 10% and at least 40% of the 30-34–year-olds should have a third level education;
– social inclusion and poverty reduction: at least 20 million fewer people in or at risk of poverty and social exclusion.

The targets are illustrative for the three priorities of smart, sustainable and inclusive growth, but they are not far-reaching: a comprehensive range of actions at national, international and EU levels will be necessary to reinforce them.

Therefore, seven flagship initiatives were put forward to catalyse progress under each priority theme (EC JRC 2010):

– Smart growth: "Innovation Union", "Youth on the move" and "A digital agenda for Europe";
– Sustainable growth: "Resource efficient Europe" (to help decouple economic growth from the use of resources, support the shift towards a low carbon economy, increase the use of renewable energy sources, modernise our transport sector and promote energy efficiency) and "An industrial policy for the globalisation era";
– Inclusive growth: "An agenda for new skills and jobs" and "European platform against poverty".

Thus, we focused one the most appropriate way of evaluating the impact on the environment, as well as on the economy, of a natural resource, by giving answers to the research questions listed above. We came to the consensus of doing that through the life cycle assessment methodology.

Therefore, we focused on the geothermal resource situated in the north-western side of Romania, Beiuş area.

3 GEOLOGICAL SETTING

From geological viewpoint, this geothermal area is an easternmost part of the regional thermal anomaly located under the Pannonian basin and the Neogene sedimentary basins splitting the western margin of the Apuseni Mountains. The geothermal water is collected into the sole of the Neogene Beiuş basin, with Triassic dolomites and limestone belonging to the Inner Dacides (Codru Nappe System; Bleahu *et al.*, 1981, 1994). Some drillings crossed these rocks, allowing the recovery and exploitation of the geothermal water in Beiuş town (Codrea & Călburean, 2013).

Apart the older three hypotheses concerning the evolution of the Pannonian Basin exposed by Meissner & Stegena (1988) - i.e.: gabbro-eclogite phase transition, lithospheric stretching and mantle diapirism -, another structural pattern belongs to Ren *et al.* (2012) with a molten astenosphere sandwiched between the crust and deeper former sunken cold slabs.

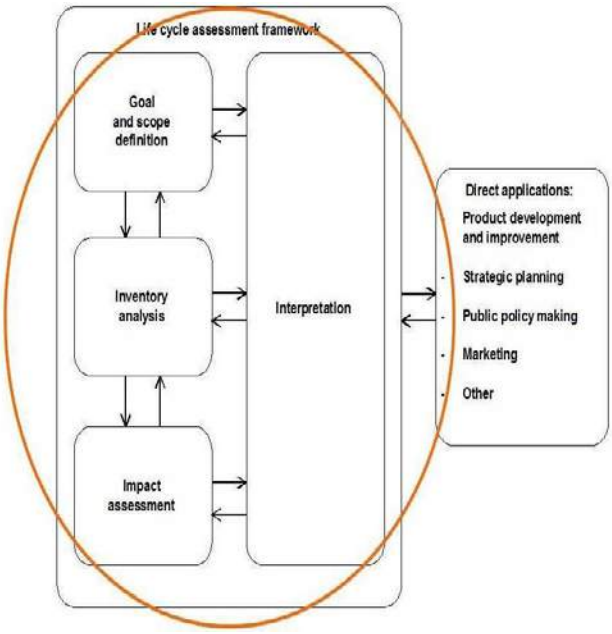
4 LIFE CYCLE ASSESSMENT

The use of the LCA technique goes back to the 1960s (Curran 1996, Owens 1997, Ekvall *et al.* 2005). The Society of Environmental Toxicology and Chemistry (SETAC) was the first international body to work on the development of LCA methodology, with its initial participation starting in 1989 (Guinée, 2002). SETAC put out a science-based platform for development of LCA, and they formalized the LCA methodology by outlining the terms to describe LCA as well as laying down the initial framework (Curran, 1996).

The development of the code of practice by SETAC (Consoli *et al.*, 1993) was an important step towards standardization of LCA as the code acted as the forerunner to the activities of the International Organization for Standardization (Guinée, 2002). The International Organization for Standardization (ISO) started working on standards relating to LCA in 1994. The first of the ISO 14040 series of standards (Environmental management – Life Cycle Assessment), which laid down the procedure for performing LCA, was first released in 1997 (Baumann & Tillman, 2004).

The United Nations Environmental Programme (UNEP) is another important international player in LCA, having taken on the role of stimulating global use of LCA (Guinée, 2002). Their work mainly centres on encouraging the application of LCA, particularly in developing nations. In 1996 the UNEP published a user-friendly guide to LCA, as part of their effort to encourage wide application of LCA (Guinée, 2002).

As shown in Fig. 1 (after ISO 14040 2006, modified), a LCA is carried out in four distinct phases (SETAC 1997):



– Step 1: Goal definition and scoping. Identify the LCA's purpose, the products of the study, and determine the boundaries. (what is and is not included in the study);
– Step 2: Life-cycle inventory. Quantify the energy and raw material inputs and environmental releases associated with each life cycle phase;
– Step 3: Impact analysis. Assess the impacts on human health and the environment;
– Step 4: Report results. Evaluate opportunities to reduce energy, material inputs, or environmental impacts at each stage of the product life-cycle.

In the context of the environmental impact of geothermal waters, we have chosen the most appropriate instrument in order to make an accurate analysis that takes into account mainly the environmental component. Furthermore, we shall discuss briefly the LCA methodology applied to the geothermal waters in Beiuş area. Each of the four distinct phases can easily be the topic of other papers while having a comprehensive character.

4.1 Purpose and Objectives

We studied in Beiuş the stages of the economic product geothermal waters regarding its life cycle, and we listed them as follows: the extraction of geothermal water out of the exploitation well, the transport of geothermal water to the heating unit, the production of heat (thermal energy is distributed to final consumers) and the transportation of the waste geothermal to the discharge system: sewerage and injection well. Once the water exits the heating plant during the life cycle, the geothermal water is considered a residue (Mangena & Brent 2006, Reich 2005). Therefore, we speak of a "cradle-to-grave" assessment: the product is recovered after the exhaustion of its useful life. It is recovered in both cases: after extracting thermal energy it is recovered and transported to discharge into surface emissaries or to the injection well where it enters its natural cycle.

Geothermal water is in Beiuş area is capitalized through two ways: in form of cubic meters of geothermal water, for consumers who own heating units, and in form of thermal energy, the local investor has its own heating plants for preparing heat,

which is for heating and hot water consumption.

In Beiuș, two wells serve for the exploitation of geothermal waters (3001H, 3003H) while the other one (3004H) serves to the re-injection of the used thermal water. Until now, the outputs are around 40 l/s, while the temperatures recorded at the well heads are 70 0C at well 3003H and 84 0C at 3001H (Codrea & Călburean, 2013). The production level of the year 2013 was 828.323 m^3: a volume of 417.736 m^3 has been extracted from 3001H and a volume of 410.587 m^3 out of 3003H (Tab. 1).

4.2 LCI – Life Cycle Inventory

During a year time, 828.323 m^3 of geothermal water were extracted out of the Beiuş perimeter. From 436.226 m^3, a quantity of 15.081,53 Gcal were prepared as thermal energy, while the difference of 392.097 m^3 was sold as m^3 (Tab. 1).

Table 1. Total extracted geothermal water in Beiuş, year 2013

	Thermal energy	m^3 equivalent for thermal energy preparation	Capitalization under form of m^3	Total used geothermal water
3001H well	7125.1	171002	246734	417736
3003H well	7956.73	265224	145363	410587
	15081.83	436226	392097	828323

In this aspect, a volume of 329.312 m^3 was discharged in the sewerage. The difference of 106.915 m^3 between the extracted geothermal water (436.226 m^3) and the one discharged in the sewerage (329.312 m^3) was injected in 3004H well (Tab. 2).

Table 2. Volume of discharged geothermal water Beiuş, year 2013

Well	m^3 discharged
3001H	64087.03
3003H	265224.47
Total Beiuş	329311.5

4.3 LCIA – Life Cycle Impact Assessment

Given the context of the injection of all the waste geothermal water, we wouldn't be speaking of an impact on the environment, while the geothermal water would have been circulating in a closed system – from the production to the injection well.

Under the assumption that can be practiced in Beiuş, namely partial injection and discharge of geothermal water into the sewerage, environmental impact in form of thermal pollution may appear only if problems occurred at the heating plant. We cannot speak of pollution from chemical point of view, given that studies showed that the mineralization of geothermal water is lower than that of surface water that supplies drinking water for the inhabitants of Beiuş.

4.4 LCIA – Life Cycle Impact Assessment

Our studies showed that discharge temperatures didn't exceed 35 °C. The national environmental law stipulates a temperature above 40 °C for waste geothermal water being transformed into a pollutant while entering the surface emissaries.

Although the ideal solutions would be the injection into the geothermal deposit, the thermal conditions don't take place, as: there isn't a collecting pipe for waste geothermal water that collects it from all consumers (only the geothermal water used by the local investor in thermal energy production modules is collected), and the responsiveness of the injection well is below the flow extracted by the two production wells, which gives her a limited character.

5 CONCLUSIONS

While being the European's Union ten-year strategy, Europe 2020 is more than just overcoming the crises from which the economies are recovering; it is also about creating the conditions of a smart, sustainable and inclusive growth.

That is the case of a globalized economic environment through the establishment of a proper correlation between the

environmental policy and a renewable resource of energy. Geothermal energy stands for a leading example in this matter – it stands for the benefit of citizens by way of keeping a clean environment.

Therefore, we performed the life cycle assessment (LCA) of geothermal water, a technique to assess environmental impacts associated with all the stages of a product's life cycle. LCA compiles an inventory of relevant energy and material inputs and environmental releases, evaluates the potential impacts associated with identified inputs and releases and brings us to the interpretation of the proper results.

Given the context of the geothermal area Beiuş, LCA was performed by following steps such as: purpose and objectives, life cycle inventory, life cycle impact assessment and interpretation of results of life cycle assessment.

Overview of Zone Monitoring of Flotation Tailing Dump "Veliki Krivelj",Serbia

M. Mikić, M. Ljubojev, D. Kržanović, I. Jovanović, D. Urošević
Institute of Mining and Metallurgy Bor, Zeleni Bulevar 35 19210 Bor, Serbia

ABSTRACT The flotation tailing dump Veliki Krivelj,Serbia, is the tailing dump of valley type and occupies the area in a former river bed of the Krivelj River. Flotation tailing is divided into the first field (the old tailings), field 2 (new tailings), which is located downstream of the field 1 and field 3. The concrete collector, total length 2075 m, was built in the Field 2 to remove the Krivelj River outside the boundaries of the tailing dump.

Overview of zone monitoring is presetned in this paper which includes monitoring period of 12 months, between january 2013 till january 2014. Monitoring covered water quality and air pollution at the site of flotation tailings „Veliki Krivelj“.

Keywords: Monitoring, collector of the Krivelj river, flotation tailing dump, Veliki Krivelj

1 INTRODUCTION

Near the open pit Veliki Krivelj, near Bor,in Serbia, is the Flotation tailing dump Veliki Krivelj, which has been in operation since the beginning of exploitation at the open pit. Flotation tailing dump Veliki Krivelj is a tailing dump of a valley type and occupies space in the former bed of the Krivelj River (Miomir Mikić,et.al., 2011). Downstream of the tailing dump is the village Oštrelj and upstream the belt conveyor system to waste transport from the open pit Veliki Kriveljs to the Old open pit in Bor and open pit Veliki Krivelj (Daniel Kržanović,et.al., 2011).

Since the beginning of its work in 1982 until 1989, the Flotation plant Veliki Krivelj has dumped tailings in the old tailing dump - Field 1. Field 1 is formed by closing the valley of the Krivelj River by two dividing sand dams, an upstream dam 1 and downstream dam 2. For water evacuation of the Krivelj River, a tunnel was built through the rock massif with the route from the left bank of the original watercourse. The tunnel has diameter of 3 m, and its length is 1414 m.

In 1990, the Flotation tailing dump Veliki Krivelj was extended downstream taking an additional space in the bed of the Krivelj River. Thus was formed a new tailing dump, which was called the Field 2. Construction of only one dam – Dam 3 was enough for contouring the new tailing dump. For drainage the Krivelj River water, a collector, diameter of 3 m and 2075 m in length, which is a continuation of the existing tunnel, was constructed at the bottom of the Krivelj River.

Considering that the current state of the collector is threatened, as it is shown in this work, and that overflow effects of the dam and collector destabilization are the ecological disasters of great proportions, a constant monitoring is necessary for the Flotation tailing dump dams and collector (Miomir Mikić,et.al., 2012).

The importance of such monitoring is enormous, both for the local population of the Bor municipality and population of neighboring countries in the Danube Basin, in which the Krivelj River flows (Miomir Mikić,et.al., 2012).

2 STATE OF THE EXISTING COLLECTOR

Program of monitoring the existing collector includes the monitoring of collector state by visual observation and measurements along the entire route of the collector. Visual observation monitors any changes on

collector. Measuring monitors the temperature, flow rate of air, oxygen amount and concrete brand. Monitoring program performed between January 2013 and January 2014.

2.1 Auscultation of the collector chainage

The complete collector is divided into chainages, which were repaired depending on the rehabilitation phase: with the phase of restoration: a stable outlet of the collector from chainage 0+0.00 to the chainage 0+200, rehabilitated part of the collector from chainage 0+200 to the chainage 0+903, from chainage 0+903 to the chainage 1+457 is the collector zone in which the first phase of rehabilitation was carried out by chainages 1+012 to 1+097 and 1+160 to 1+172, and chainage from 1+320 to 1+457, and the other parts to 2+026 is a zone which requires rehabilitation.

The starting chainage of the Veliki Krivelj collector is below the dam Veliki Krivelj 3A, where the zero chainage is defined, Figure 1.

Figure 1. Start of the collector route below the Flotation dam 3A and Flotation tailing dump of the Field 2

Damages were observed along the entire route of collector. These damages are manifested in the form of: breaking up of concrete to the reinforcement and large cracks, Figure 2, concrete cracks in larger number of places, where the aggressive flotation water comes out under pressure.

Figure 2. The appearance of concrete damages to the reinforcement in the side part of calotte

Figure 2b, chemism that occurs as the effect of aggressive flotation water and concrete.

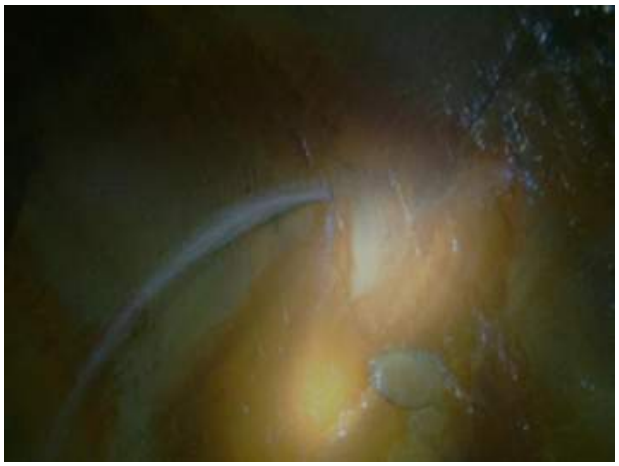

Figure 3. A set of cracks on the left side of campade through which water comes out under pressure

Figure 4 shows large number of cracks through which, in addition to the water outflow under pressure, the chemism of this water occurs that sprays onto concrete.

According to the visual observation of collector concrete, there are large number of aggressive water penetrations from the Flotation tailings, as well as chemism of aggressive water and concrete. Based on the measured concrete brand by sclerometre, it can be concluded that the concrete construction of collector is stable and secure in terms of functionality.

Figure 4. Chemism of concrete and aggressive water

Winter period was characterized by high rainfall. This has affected the level of water in the collector is high. Due to this, all measuring and recording the collector in this period was difficult.

These weather conditions have caused a significant drop in air temperature in the collector (Table 1).

Based on recordings and measurements observed a significant increase in the level of water and also the Krivelj 's water clearing appear despite turbulent motion.

State of the atmosphere in the observed part of the collector is satisfactory, there is the toxic gases that would have a negative impact on human health.

Due to the rapid melting of snow in the spring there was a massive influx of water at the entrance portal. This situation has caused damage in the form of pulling and major damage to metal cladding panels.

Analyzing the results, we can see that there has been no significant damage other than loss calotte tin lining. Significant damage to the concrete does not exist, and therefore the concrete structure is stable and safe in terms of functionality.

Table 1. The measureed values on the collector in the observed period

Year	Month	Flow rate of air, m/s	Oxygen amount O_2 %	Temperature C	Concrete brand MB Mpa
2013	January february march	*1,4*	*21*	*-0,025*	*30/35*
	april may	1,16	20,5	17	30
	june July August	1,78	21,77	16,3	30
	September October November December	-	-	-	-

3 MONITORING PROGRAM OF THE QUALITY OF WATER AND AIR

Monitoring program of the quality of water and air is carried out for twelve months from January 2013 to January 2014.

3.1 Program for Monitoring Water Quality

The water quality monitoring program includes weekly and monthly monitoring of groundwater and surface water. Monitoring of surface water quality was performed at 8 measuring points, as follows: Waters of Saraka stream (MP[1] * -1), Krivelj river before flows into the Saraka stream (MP-2), Krivelj river after empties into Saraka stream (MP-3), Bor river below the dam 1 (before entering the collector) (MP-4), Krivelj river below the dam 3 of flotation tailings Veliki Krivelj (MP-5), Bor River before joining the Krivelj river (MP-6), Krivelj river before flows into the Bor river (MP-7), the waters after the mergering of Bor river and Krivelj river and mine waters (MP-8).

Measuring the concentration of metals in the water was used standard SRPS EN ISO 11885.

MP8	19,4	0,091	3,6	284,0

The quality of surface water at eight mesurng points, for analysis, chemical parameters were taken – the pollutants - heavy metals.

Analasys of quality water is compered acording the new regulations of Repubic Serbia which defines the limit values for substances, levels of emissions to surface water quality assessment annually.

Acordinglly, increased content of copper and iron is characteristic for almost all the water at this location, and ranges up to 152,1 mg / L for copper and up to 5,2 mg / L of iron.

3.2 Program for Monitoring Air Quality

Air quality monitoring program includes daily air temperature, humidity, precipitation, atmospheric pressure, wind speed. Monitoring of air quality (particulate matter) is performed on six measuring points: Above Saraka landfills, above field 2 of flotation tailings Veliki Krivelj, abowe the dam 3 (village Ostrelj), Below the dam 3 (Manastirište), LC Sloga and village Slatina.

3.2.1 The results of air quality monitoring

During summer, the average monthly temperature values have ranged from 11,6 °C to 26,5 °C. The values of relative humidity were in the range of 35% to 80%. Atmospheric pressure ranged from 964,2 to 982,2 mbar. The total amount of precipitation was on average about 19 mm / m^2. The prevailing wind direction was from the WNW. Mean wind speed ranged from 0 m/s to 2,9 m/s.

In the winter, average monthly temperature values have ranged from -4.3 °C to 19.5 °C. The values of relative humidity were in the range of 34% to 100%. Atmospheric pressure ranged from 949,7 to 990,8 mbar. The total amount of precipitation was on average about 20 mm/m^2. The prevailing wind direction was from the WNW. Mean wind speed ranged from 0 m / s to 2,6 m/s.

Period- winter

Particulate matter

liquid phase

The average monthly pH value is constant and ranged from 3,8 to 7,1.

Mean values of sulphate ranged from 0,3 mg/m^2/d to 13,9 mg/m^2/d.

Mean values of soluble substances ranged from 1,3 mg/m^2/d to 112 mg/m^2/d.

Solid phase

Mean monthly values of insoluble matter ranged from 8,3 mg/m^2/d to 158 mg/m^2/d.

Mean values of combustible materials ranged from 0,5 mg/m^2/d to 61,8 mg/m^2/d.

Mean values of ash ranged from 3,1 mg/m^2/d to 144 mg/m^2/d.

Ash analysis was established that:

- Lead, cadmium, and nickel were below the lower limit of determination.
- Arsenic ranged from <0,3 to 34,3 μg/m^2/d,

Total particulate matter

Mean monthly values of sedimentary matter are ranged from 39,7 mg/m^2/d to 201 mg/m^2/d. Pursuant to the Decree on conditions and requirements for monitoring air quality („Sl.Glasnik RS No.11/2010, 75/2010, 63/2013) increased values were not reported.

Period - summer

Particulate matter

liquid phase

The average monthly pH value is constant and ranged from 5,7 to 7,6.

Mean values of sulphate ranged from 7,2 mg/m^2/d to 27,9 mg/m^2/d.

Mean values of soluble substances ranged from 20,1mg/m^2/d to 72,1 mg/m^2/d.

Solid phase

Mean monthly values of insoluble matter ranged from 21,3 mg/m^2/d to 179 mg/m^2/d.

Mean values of combustible materials ranged from 0,8 mg/m^2/d to 54,5 mg/m^2/d.

Mean values of ash ranged from 12,4 mg/m^2/d to 87,7 mg/m^2/d.

Ash analysis was established that:

- Lead, cadmium, and nickel were below the lower limit of determination.
- Arsenic ranged from <0,4 to 64,6 μg/m^2/d.

Total particulate matter

Mean monthly values of sedimentary matter are ranged from 38,7 mg/m^2/d to 407 mg/m^2/d. Pursuant to the Decree on conditions and requirements for monitoring air quality („Sl.Glasnik RS No.11/2010, 75/2010, 63/2013) increased values were not reported.

4 CONCLUSION

Flotation tailing dumps present a constant threat to the ecological environmental factors both theu are in operation, or after termination of dumping and filling the landfill space. The causes of accidents in the flotation tailing dumps are technical defects and natural catastrophic disasters (Miomir Mikić,et.al., 2012).

Chemical haful materials which can get to living environment at damages, can cause endangering of ecological factors (soils, water, air) and through them the whole ecosystem of the area.

From the results obtained it can be inferred that surface waters contain increased concentrations of heavy metals regarding III and IV class water standards (Table 2-4).

Samples collected from surface waters, where the tailing dump has increased water pollution systematic analyses willbe needed.

From the results obtained for air quality it can be inferred that increased values for particulate matter were not reported.

This paper presents the auscultation of dams of the Flotation tailing dump Veliki Krivelj, near Bor, Serbia and chainages of collector. Based on the presented situation and measuring results, it can be concluded that there is a problem of preservation the Flotation tailing dump in operation.

ACKNOWLEDGEMENT

This work has resulted from the Project No. TR33021, funded by the Ministry of Science and Technological Development of the Republic of Serbia.

Predicting the Levels of Noise from Quarry Operations

K. J. Bansah
Mining & Nuclear Engineering Department Missouri University Science and Technology Rolla-Missouri, USA

E. Assan, C. Bosompem
Safety & Environmental Research Consultancy Limited Tarkwa, Ghana

ABSTRACT Mining activities impact on surrounding environments. Notable among these impacts is noise emission from sources such as machinery, drilling, blasting, dumping and crushing. It is important therefore, to determine the levels of noise to be generated by mining, and its impacts on surrounding communities so that potential impact(s) could be averted. A 24-hour noise monitoring was conducted for 25 days at a proposed quarry site and five surrounding settlements to obtain baseline noise levels. The noise to be generated by the proposed machinery on the quarry site were obtained and used to predict the noise levels at various receptor locations. Activities during the day at the quarry site were found to have the potential of altering noise levels in the surrounding settlements by 2 dB(A) to 10 dB(A), though the composite noise levels in these settlements compared well with permissible limits. Moreover, it was deduced that the quarry will not impact on night noise levels in the surrounding settlements. A few recommendations were given to further reduce the noise levels from the quarry site.

Keywords Mining, Quarry, permissible limit, receptor location, impact, health implication

1 INTRODUCTION

Noise is most often defined as “unwanted or objectionable sound”. Noise pollution adversely affects the lives of people (Anon, 2011). Problems related to noise include stress related illnesses, high blood pressure, speech interference, hearing loss, sleep disruption, and loss of productivity. Research has shown that exposure to constant or high levels of noise can cause countless adverse health effects (Anon, 2011). Quarrying mainly generates noise from overburden excavation, blasting, loading, hauling, dumping and crushing. Noise levels however, must be controlled to allow nearby land holders to relax or sleep during evening hours, reduce noise burdens, and also protect the hearing of employees.

A medium scale quarry company acquired roughly 16.50 acres granite rock concession in the Western Region of Ghana to undertake medium scale quarry projects. The quarry concession is however, surrounded by five major settlements anonymously referred to as Site 1, Site 2, Site 3, Site 4 and Site 5. The locations of these settlements are such as to be affected by noise emission from the quarry operations. It is therefore, necessary to predict the levels of noise that may be propagated from the quarry site and determine the potential impact on inhabitants of the surrounding settlements.

2 BRIEF INFORMATION ABOUT THE STUDY AREA

The Quarry site, Sites 1, 2, 3, 4 and 5 are all located in the Shama District of the Western Region of Ghana. The topography of these areas is generally undulating with elevations ranging from 32 to 95 m above mean sea level. The landscape is located within the moist semi-deciduous vegetation. However, the original vegetation structure has been altered due to intense farming activities by the inhabitants of the settlements.

The minimum and maximum temperatures of the area are respectively, 23 °C and 27 °C, with a mean annual temperature of 26 °C. Average rainfall is around 12 mm, with peaks in the months of June and July. These periods are generally characterized by high rainfall values in Ghana. Average wind speed is 0.5 m/s, with predominant direction of West (Anon, 2013).

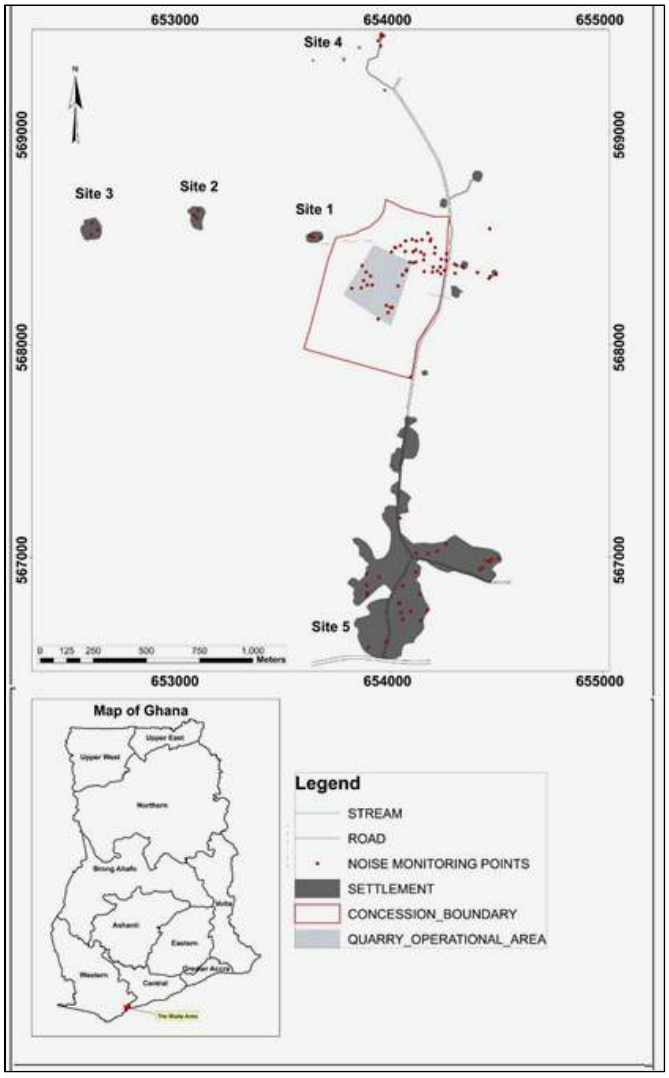

Figure 1. Map of Study Area

Site 5, the largest settlement (over 400 building structures) in the area, is located to the south of the quarry concession. The closest structure in this settlement is about 500 m from the boundary of the quarry's operational area. Site1, with nine building structures, is located 245 m to the North-West of the quarry operational area. Sites 2 and 3 are also located to the North-West of the quarry concession. While Site 2 has total number of 24 building structures and is 754 m from the quarry operational area, Site 3 has 13 building structures and is 1200 m from the edge of the concession. Site 4 is however, to the North of the concession, with 14 structures at 900 m from the periphery of the operational area. Figure 1 shows the quarry concession and the locations of the surrounding settlements.

3 DATA COLLECTION, RESULTS AND DISCUSSIONS

The following sections summarize the data collection procedure; the results obtained and the discussions of the various results.

3.1 Noise Monitoring

Noise monitoring was carried out with sound level meters at the quarry site and surrounding communities. The monitoring activity was categorized into two parts: "Day" and "Night", in accordance with the Environmental Protection Agency of Ghana (EPA) criteria. "Day" monitoring went from 6:00am to 10:00pm, while "Night" monitoring was carried out between 10:00pm and 6:00am. The monitoring locations fall within Zones "A" and "B2" of the EPA criteria as shown in Table 1. It must be noted however, that the quarry site becomes a heavy industrial area and therefore have permissible noise levels of 70 dB(A) when operations commence. The noise levels obtained from the monitoring activities were summarised and presented in Figure 2.

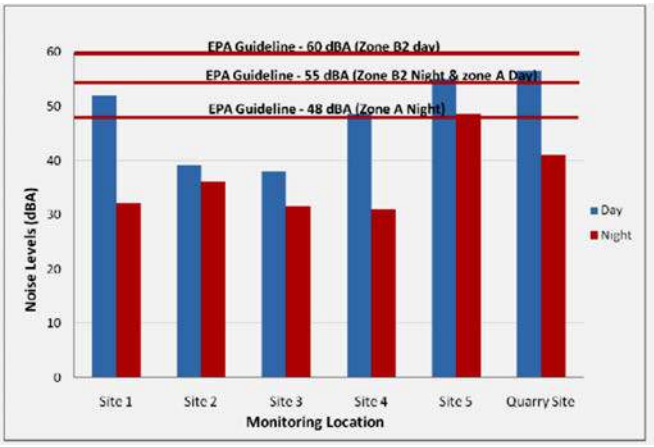

Figure 2. Mean Noise Levels at Monitoring Locations

Table 1. Description of Monitoring Locations According to EPA Criteria

Monitoring Location	Description of Area of Noise Reception	Zone	Permissible Noise Level dB(A)	
			Day (0600-2200)	Night (2200-0600)
Quarry site	Area with some commercial or light industry	B2	60	55
Site 1	Residential area with negligible or infrequent transportation	A	55	48
Site 2	Residential area with negligible or infrequent transportation	A	55	48
Site 3	Residential area with negligible or infrequent transportation	A	55	48
Site 5	Residential area with negligible or infrequent transportation	A	55	48
Site 4	Residential area with negligible or infrequent transportation	A	55	48

The mean noise levels at the monitoring locations generally compared well with permissible limits. Mean noise levels at all the monitoring locations were lower compared to their respective recommended levels, except “Day” noise levels at Site 5, which exceeded the threshold limit by about 1 dBA. On the average, “Night” noise levels at Site 5 were the highest; this is due to pronounced domestic activities. Site 5 is likely to experience population increase due to migration of persons in search of jobs and related businesses at the Quarry. This may lead to increased domestic and other activities, which may cause higher noise levels than the baseline. It is also observed that the noise level at the Quarry site is lower than permissible by 3 dBA for “Day” and far lower at “Night”. The high noise level at “Day” could be due to usage of heavy earthmoving machinery and trucks during day time at the Quarry site. Nonetheless, the “Day” noise levels at the Quarry will be far lower compared to permissible limit (70 dB(A)) of a heavy industrial area. Since there were virtually no activities at the Quarry site at night, noise levels were generally lower. Sources of noise at Site 5 may include vehicular movements and domestic activities, while that of Site 1, 2, 3 and 4 were purely of domestic origin.

3.2 Sound Pressure Level Modelling

Sound pressure level (SPL) modelling was conducted to predict noise levels that may propagate from the Quarry site to residents of Site 1, 2, 3, 4 and 5. The major source of noise expected at the Quarry site is heavy machinery provided by the Quarry management and shown in Table 2.

Table 2. Types and Number of Machinery provided by Quarry Management

Plant	Number	Noise Level (dBA)
CAT 336D Wheel Loaders	4	105
CAT972H Wheel Loaders	5	111
CAT950H Wheel Loaders	5	111
CATD735 Articulated Dump Truck	6	79
Toyota Hilux	7	73
Terex Pegson Prim./Sec. Crusher	1	116

Anon (2013a) suggests that the noise level measured from Cat D735 articulated dump-truck is 79 dB(A). While noise levels generated by both Cat 950H and Cat 972H wheel loaders are respectively, 111 dB(A) (Anon, 2013b), noise level from Cat 336D is 105 dB(A) (Anon, 2013c). Also, according to Anon (2013d), Toyota High-Lux DC generates 73 dB(A) while noise emitted by Terex Pegson primary/secondary crusher is 116 dB(A) (Anon, 2013e). Given the number of each of these machinery, and assuming that the machinery operate simultaneously, the noise levels were composited together with the highest baseline noise (67 dBA) measured at the Quarry site at "Day" to obtain a total of 122 dB(A). The sound pressure level Lp_2 at a distance r_2 from the source (Quarry site) was then estimated using equation 1 (Amegbey, 2011).

$$Lp_2 = \mathrm{Lp}_1 - 20\log\frac{r_2}{r_1} - Ae_{1,2} \quad (1)$$

Where Lp_1 is the sound pressure level measured at location 1 (Quarry site), $Ae_{1,2}$ is attenuation along path r_2 - r_1 between location 1 and 2, and represents factors affecting sound propagation. Such factors include atmospheric absorption, ground attenuation, wind or temperature gradient, trees, barriers or buildings (Anon, 2002). As a rule of thumb SPL is reduced by 6 dB(A) when the distance from the source is doubled in free field conditions. As a conservative estimate, a value of 5 dB(A) to 5.5 dB(A) is used to account for ground reflections. Assuming 6 dB(A) for each of the remaining attenuation parameters, $Ae_{1,2}$= 13 dB(A) and using Equation 1, noise levels that may be propagated from the Quarry site were estimated and shown in Table 3.

The predicted noise levels at "Day" compared well with permissible limits of noise for an "area with some commercial or light industry (Zone B2)", but higher than that of "residential area with negligible or infrequent transportation (Zone A)" within a distance of 500 m.

Table 3. Predicted Noise Levels

Distance (m)	Predicted Noise Levels (dBA)	
	Day	Night
100	67	30
300	57	20
500	53	16
700	50	13
900	48	11
1100	46	9
1300	45	8
1500	43	6
1700	42	5
1900	41	4

It must however, be noted that noise levels at day exceeded the Zone B2 guideline by 7 dB(A) within a distance of 100 m of the periphery. Beyond 500 m, the noise levels fell within permissible limits of Zone A. This suggests that inhabitants beyond 500 m may not be affected by noise generated at the quarry. Predicted noise levels at "Night" appear to be very low because of virtually no activity during the night at the quarry site. From the predicted noise levels (Table 3), only building structures that fall within a distance of 500 m from the operational area will receive higher than permissible noise levels.

To determine the composite noise levels in the settlements, the predicted noise levels were added to the mean baseline noise levels. Table 4 is a summary of the composite noise levels at the various settlements.

From Table 4, it can be observed that the total noise levels at Site 5 for "Day" exceeded the permissible limit by 2 dB(A). "Night" noise level at Site 5 was exactly equal to the threshold limit. Site 1 at night had total noise level of 58 dB(A), exceeding the recommended levels by 3 dB(A). Site 1 has the highest total noise level due to its closeness (245 m) to the quarry operational area. Site 2, Site 3 and Site 4, all had noise levels lower than permissible. It can be deduced that activities at the quarry site do not impact on night noise levels at the specified settlements.

Table 4. Composite Noise Levels in the Settlements

Settlement	Baseline Noise Level (dBA)		Baseline + Predicted Noise Level (dBA)	
	Day	Night	Day	Night
Site 1	52	32	52+57=58	32+20=32
Site 2	39	37	39+48=49	37+11=37
Site 3	38	31	38+45=46	31+9=31
Site 4	49	31	49+48=52	31+11=31
Site 5	55	48	55+53=57	48+16=48

4 CONCLUSIONS

This work studied the potential impact of noise to be emitted by quarry operations on five surrounding settlements. Firstly, noise monitoring was conducted at the quarry site and the surrounding settlements to obtain baseline noise levels. Secondly, noise levels that may be propagated from the quarry operations were predicted and added to the mean baseline noise levels in the settlements to obtain composite noise levels. After compilation of data, it was deduced that activities at the quarry site have the potential of altering background noise levels at day, in the surrounding settlements by 2-10 dB(A). It is however, worthy to note that the composite noise levels generally compared well with the permissible limit, though that of Site 1 and some parts of Site 5 exceeded the permissible limit by 3 dB(A) and 2 dB(A), respectively. While the noise levels at Site 1 may be due to activities at the quarry site that of Site 5 is purely of domestic origin. Nonetheless, Site 1 falls within the Minerals Commission of Ghana regulatory buffer (500 m from the quarry operational zone), and is therefore likely to be resettled. It can also be concluded that the quarry will not impact on night noise levels in the surrounding settlements. Continuous ambient noise monitoring however, should be conducted at the quarry site and surrounding communities to ensure that noise levels are kept below acceptable limits. Also, management of the quarry should ensure the quietest equipment available is used at the quarry site to further reduce noise levels.

ACKNOWLEDGEMENTS

The contribution of every individual who made the study a success is acknowledged.

Protection of Cultural Heritage from the Area of Future Open Cast Mine Radljevo

N. Drljevic, G. Tomic
EPI Serbia, Mining Basin Kolubara, Serbia

ABSTRACT From the coal in lignite mines in Kolubara coal basin, more than 52% of Serbian electricity has been obtained. To maintain this ratio, it is very important to continue corresponding development of the new coal deposits.

Within spatial boundaries of the Kolubara basin there is a great number of existing settlements. Geographical position of coal basin and the fact that it runs through valley of river Kolubara and its numerous tributaries, indicates to centuries-old continuity in human settling in this significant area.

One of the human merits is a need to build object for everyday life, for cultural, religious or some other purposes. A great number of these buildings still exist at this space.

Inside defined boundaries for the new open cast mine Radljevo there are significant number of objects of cultural heritage and assets inscribed in appropriate registers.

Because of that, it is important to determine and establish extent and level of protection for each of them. Accordingly, the negative influence from the open cast mine on the population that dwells in this area will be reduced.

Keywords: coal mine, development, population, protection, cultural heritage and assets

1 OPEN CAST MINE "RADLJEVO"

Future open cast mine Radljevo is situated at western part of Kolubara coal basin, along with the active open cast mines Tamnava-West field and Veliki Crljeni.

Based to extensive exploration and other calculations a "Preliminary design of coal exploatation" has been made, where all elements, which are necessary for working, were defined for the purposes of coal exploatation.

Area, which future mine "Radljevo" covers, is with slightly wavy and flat terrain from alluvium of river Kladnica and streamlet Stublenica. These water-bodies are permanent, along with their tributaries: Negica stream, Orlovac stream and Stojkovac stream. A torrential flow characterizes all water occurrences in this area. The land is mainly for agricultural purposes. There are also parts under woods mostly in valleys of rivers and streams.

1.1 Territorial distribution

Settlements that exist in forest-highland of river Kolubara and its tributaries and which are within the area of future open cast Radljevo, are very rich in archaeological sites and objects of cultural heritage. First communities at these areas were formed in period of Vinca's culture (6000. b.c.), and they had a continuity during time throughout all periods of human and society development.

Open cast mine "Radljevo" is located at area of municipalities Ub (cca. 95%) and Lajkovac (cca. 5%). Settlements that belong to municipality Ub, and also are in area of future mine, respectively in zone of mine's influence, are: Kalenic, Brgule, Radljevo, Sarbane, Stublenica and Paljuvi. To the municipality of Lajkovac belongs settlement Jabucje.

1.2 Opening and further development of open cast mine

Inside the projected boundaries of future mine "Radljevo" calculated reserves of coal

are about 340 mill.of tons. Based to the technical documentation, it has been predicted that coal exploatation will start in year 2018-2019. Development was planned in two phases:

1) first phase-fulfillment of planned annual production of coal up to 7 million tons per year,

2) second phase-up to achievement of projected production of 13 million tons per year and until the end of the exploitation.

Prior to coal exploatation is overburden excavation, meaning overburden work will begin in 2017-2018 year. At figure 1 is a view of mining advancement at future open cast “Radljevo” during years.

Figure 1. Development of mining work

1.3 Aspects of the impact during mining

Development goal in Kolubara coal basin is efficient, rational and organized usage of natural resources in socio-economic, spatial and ecological view. All of this implies detailed planning and creation of conditions for efficient coal exploitation on new fields, development of energy facilities, rational connection between settlement’s net, reconstruction and improvement of existing systems, construction of the new objects, harmonization of social development and improving the quality of life of local population, rational use of water resources, environment object’s control etc.

Beside the importance from the opening of new mine ”Radljevo” for continuity in lignite production, negative impacts of mining activities at nearby environment will be evident, and the most significant are:

- partial and complete relocation of the settlements and population with all existing objects,
- impact on the water resources important for water supply of settlements in area of mine’s influence and nearby surrounding, and decreasing of water-flows potential along with underground water level with direct impact to the draining of agriculture land,
- relocation of roads-public roads of II order and local roads
- degradation of natural ecosystems because of the occupation of large areas under agricultural and forest land,
- devastation of relief, population, settlements, cultural goods,
- social and socio-economic influences

All of these influences must be analyzed in details in order to define appropriate activities through planning processes, projecting, preparations for work, performing of the work, supervision, financing, legislation, expropriation etc.

2 CURRENT STATUS OF CULTURAL HERITAGE AT THE AREA OF FUTURE MINE “RADLJEVO”

Continuity of human settlement in the area since the period of the Vinca culture until recent history has been confirmed with previous archaeological researches and findings.

These finding are supported with the existence of the immovable objects of cultural goods, archeological sites, buildings of architectural heritage, monumental landmarks, cemetery etc.

2.1 Object of cultural heritage

According to the “Study of preservation and revitalization of the immovable cultural heritage for the purposes of development of Urban Plan for Radljevo”, as well as conducted archeological and monumental research, along with field reconnaissance, a large number of various objects of cultural heritage on the area of future mine Radljevo has been recorded.

All of these objects were divided into groups according to characteristics:

1. Group of the immovable cultural heritage includes:

- church Shroud of the Holy Mother of God in Radljevo,
- church house (parish house) in Radljevo,
- tombstones with monumental values at village's cemetery in Radljevo, Sarbane and Kalenic,
- cemetery in u Sarbane, Kalenic, Radljevo and Brgule,

2. Group of archaeological findings includes:

- site "Popovica imanje", from the period of Late Antiquity and the Iron Age, in Brgule and Radljevo,
- site "Crkvine", Middle Age, Ottoman period - Radljevo,
- site "Makvine", Bronze and Iron Age - Radljevo,
- site "Stare kuce", Late Antique - Kalenic.

3. Group of valuable buildings of architectural heritage includes:

- primary school's building in Radljevo,
- primary school's building in Sarbanu,
- house of Nade Tesic, former village tavern,
- house of Velje Milicic in Radljevo,
- house of Milovana Matijasevic in vilage Sarbane.

On figure 2. is spatial distribution of all of these objects on area covered by future open cast mine Radljevo.

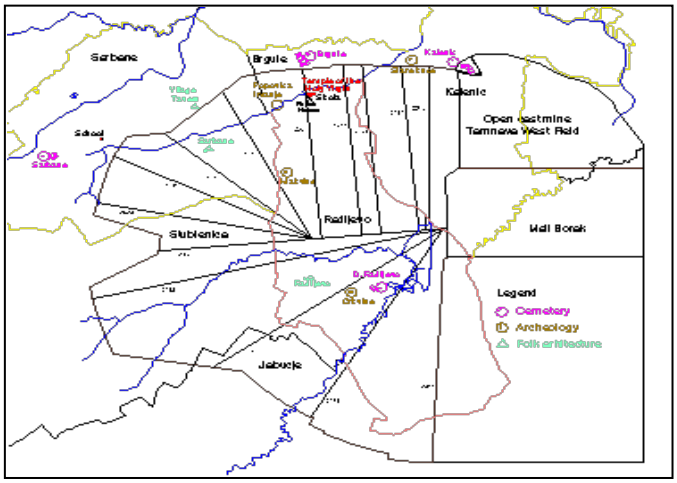

Figure 2. Objects of cultural heritage

2.2 Limitations and conveniences for cultural heritage protection

Primary limitations concerning protection of cultural heritage are reflected in direct physical endangering to the cultural monuments and archeological sites which are under development of open cast mine. Also there is an inefficient and untimely investment in protection of cultural heritage, and accordingly there is a great devastation of buildings with architectural heritage in villages under influence of future mine Radljevo.

But, beside these limitations there are certain benefits for heritage protection, and they are manifested through:

- existence of institutions responsible for the protection,
- legal obligations for harmonization between mining work's development and the needs to protect cultural heritage,
- the possibility of finding the new archaeological sites and presentations of findings in museums or other suitable places,
- the possibility of preservation some of the endangered objects by moving them at new location or by making of new technical documentation for purposes of data preservation.
- raising of the awareness about the importance of cultural heritage preservation.

3 PLAN SOLUTIONS FOR THE PROTECTION OF CULTURAL HERITAGE

Significance of cultural goods and objects that exist in the area of the future mine Radljevo implies a detail overview of their current state and definition of the methods of protection that will be conducted. The overall protection plan predicts activities that will enable permanent preservation of these objects, and thus continuance of their importance to the historical definition for all structures that exist in this area. With the conservation, restoration and revitalization of objects, the conditions for further preservation will be obtained. This allows continuity in historical testimony of identity

of area itself and civilization's cultural range from the settlers.

3.1 Activities for the protection

Concerning to the analysis from the archaeological site's aspects and from the objects of cultural heritage, in order to protect cultural goods, it is necessary to conduct:

- for all evidenced archeological sites, a protection of archeological excavations must be provided, and for so far registered cultural goods certain spatial-plan measures for their protection should be carry out,
- intensify research work on the project area in accordance with the dynamics of the mine's development,
- if at observed area new significant objects emerges, it is necessary to do their previous conservation,
- provide conditions for mining mechanization's work that will disable damages of objects and other belongings of cultural goods,
- all users from this area are obliged to communicate between themselves as well as competent institutions, and accordingly to the international convention saying "monument is inseparable from history which he is witness and from environment where he's placed",
- keeping adequate record of objects and archeological findings belonging to the cultural heritage with the provision of technical expertise,
- provide continuous care for the monuments and objects protection at observed area,
- during rebuilding of new or reconstruction of existing objects, all elements of traditional folk architectures should be used, and the area for their placement must be protect from degradation and improper use,
- to amend the classification and registry of cultural - historical heritage.

3.2 Concept for the protection

For the purposes of protection for the cultural heritage in the area that is affected by mining operations of the future mine Radljevo, following activities must be anticipated:

- for all evidenced immovable cultural goods that won't be relocated, it is necessary to make detailed technical documentation (project of current state, and photo documentation), and to plan new location for their construction. For the objects which will be relocated, it is important to define spatial units, on which they will be relocated,
- continuity in exploration of archeological sites according to developed Plan for the archeological researches protection, that was done by competent institutions.

3.2.1Church "Shroud of the holy mother of God" and parish house in radljevo

Church was built in 1873. at position of former log-house church from 1826. Building style belongs to Baroque and Neoclassical, typical for the churches in Vojvodina in 18. and 19. century. Church is single-nave edifice elongated shape, with narthex, nave and altar. On western part there is high belfry with the dome decorated in Baroque style. Inside, the church is decorated, and especially valued is iconostas with icons which are made with oil paints on canvas.

In churchyard is Parish House with two units and hall built in 1939. House is single-storey building with elongated base and central entrance, and with covered porch containing four massive stone pillars, and two sidewise entrances. The roof is complex, in more directions and covered with pepper tiles. This object is typical example of Modern style in Serbian architecture between two wars.

Both of these objects, (figure 3.) along with the others built later, are unmovable objects foreseen for demolition. This means that detailed technical and photo documentation will be done prior to demolition. After that, with the agreement of

local population and church authorities, new church and additional objects will start to be built. This location will be defined according to the demands of local population, which will be relocated from the mine's area and which will use the church.

Figure 3. Church and parish house

3.2.2Cemeteries in villages

Inside the area, which will be endangered by mining work, there are local cemeteries in villages Sarbane, Kalenic, Radljevo and Brgule. All of these objects belong to movable cultural goods and they are predicted for relocation to new places defined between all subjects (local population, municipalities, scorch organs, Mining Company, etc.). Also, on these cemeteries there are a large number of monuments with historical values from further and closer past, and they are very important for preservation of national identity and history.

Activities for the preservation of these objects means development of appropriate time-plan which will define conditions for suspension of burial on existing cemeteries, area and conditions of location for new cemetery, refinement of rights for the graves trustees, exhumation, equipment, transfer and burial of the remains in accordance with the legislation. Last, there are activities in order to bring area to it's purposes, respectively excavation of land after cemeteries relocation and sanitation.

Considering the importance of these objects and sensitivity and connection of local population with them, it is crucial to solve this conflict carefully and precisely with the presence of all involved sides.

On figures 4. and 5. are images of cemeteries in some of the villages.

Figure 4. Kalenic cemetery

Figure 5. Radljevo cemetery

3.2.3 Objects with the attributes of folk architecture

In the villages belonging to the future planed mining area there is a large number of objects of folk architectures (village schools and residential houses) which will be endangered by mining works from the future open cast mine Radljevo. Relocation of these building to the new locations has been planned.

Schools in Radljevo and Sarbane, foreseen for demolition, technical and photo documentation will be done previously in order to preserve information about their characteristics and importance for local population.

For the residential houses under the protection of State, a documentation that shows current state will be done, along with photo documentation. Information from these documents will be exposed on appropriate locations (planned ethno parks), with the possibility to apply traditional elements of folk architectures during reconstruction or building of new similar objects on the area under the influence of mine's work.

Figure 6. School in Radljevo

Figure 7. Family house of M. Matijasevic-Sarbane

3.2.4Archeological localities

For the all listed localities at observed area (see.2.1, figure 8.), findings and movable exhibits are foreseen to be relocated to the new locations which will be previously defined. Before that it is necessary to obtain detailed reconnaissance of the terrain, exploration and excavation, marking and restoration, protection of all moving parts and objects, and then their packing and transportation to new site.

Considering that the zone of future mining works is situated within two municipalities, a place for the relocation of archeological exhibits from all localities will be determined, whether it is museum or ethno-park with special assignment according to the age of the archeological findings, probability for reconstruction of some of the excavated objects etc.

Figure 8. Archeological site "Crkvine" in Radljevo

4 CONCLUSION

Electric production from coal combustion in power plants, and significance of it doesn't necessarily means that all objects under the influence of mining work should be demolished and devastated. The importance of objects that suggests continuity of settling in this region shows existence of the good geographical and other conditions, and that enables cultural and nation's development and shows important historical facts significant for region itself.

Thus, all necessary activities for the purposes of protection of these objects of cultural heritage must be done for the sake of existing and future population which will be connected with this area and for the preservation of national consciousness and history in general.

The Life of Tires on Wheeled Heavy Duty Mining Vehicles from Point View of the Environmental Apprehension

I. Celik

C. Sensogut
Dumlupinar University, Mining Engineering Department, Kutahya, Turkey

ABSTRACT The tires are important elements of a wheeled vehicle as they carry the weight and the load of the vehicles. While they realize this work, they are worn out on rough ground conditions accounting for significant spare parts and repair work costs as well as environmental impacts. Discarded tires have been a disposal problem in the past and continue to accumulate throughout the world today. In the present work, the wears of tires on heavy duty vehicles operating at Western Lignite Corporation (WLC) in Turkey have been investigated. The main purpose of the current research in general was to investigate the reasons for leaving scrap of tires and the wear conditions according to their location on the vehicle.

The main outcome of the work in concern is that cut-out brought about by sharp stones on mining area is the primary cause for disposal of tires. Additionally, the deterioration of the tires changes depending on the location of tire on the vehicle.

Keywords: Tire life; mining; rubber; truck

1 INTRODUCTION

The tires mainly carry the weight of load and vehicle. The torque formed by the engine and traction force is transferred onto road by means of them. Shocks coming from road and the motion of the vehicle are also absorbed by them. The break effect is transferred onto road while the vehicle is decelerating; the lateral forces are carried while the vehicle is turning the bend by means of tires.

Tire accounts for the most important cost following fuel for the heavy duty vehicles therefore the life of tire is desired to be as long as possible. In addition, discarding is always an important problem from the view of environmental care. If the factors affecting the life of tire are investigated, surface of the road is seen to be one of the most important factors. If tire always works on the stony ground, its life is reduced by 80% compared to smooth asphalt road. The wear of tires which are on the drive axle is higher than other tires of non - driving axle. Besides, the wear of tire is directly affected by wheel alignments varying for each vehicle (caster, camber, toe - in angles). If the tire overheats, strength of the rubber may decrease causing the life of tire to decrease too. In order to avoid this situation in hot weather, the tire pressure can slightly be increased by the value of the catalogue. If the vehicle works for a long period, tires simply heat up. However, in case the vehicle stopped for a while, the heating of the tire can be prevented. Another important factor which affects the life of tire is the speed of the vehicle. The overspeed causes the overheat of tires resulting in the wear resistance to decrease. Therefore, maximum load and speed limits prescribed at the tire sidewall must not be exceeded. Otherwise, the life of tire decreases and the safety of driving is jeopardized. If the load decreases, the life of tires increases. In order to get the optimum performance, maximum load and speed limits must not be exceeded.

Rubber is a viscoelastic material and its friction behaviour is governed by

viscoelastic material properties. Additionally, rubber friction force depends on the operating speed and temperature. Further, viscoelastic losses and dependence on frequency can also affect the tribological behavior of rubber (Baek and Khonsari, 2005).

Some of the works conducted regarding the life of tires, its environmental effects and precautions to be taken are emphasized below:

Lower tire pressure not only leads to decreased fuel economy, but also causes many unnecessary injuries and loss of lives. Under inflated tires can increase the stopping distance of a vehicle, particularly on wet or slippery surfaces. In addition, when tires are under inflated, their sidewalls flex increasing the temperature more and resulting in failure (Pearce and Hanlon, 2007). At works of Kocsis et al (2008), it was noted that if carbon black (CB) increase, specific wear rate also increases (Kocsis et al., 2008).

US drivers do not adequately monitor the tire pressures in their vehicles. The study of Joshua et al (2007) indicates that substantial benefits would accrue if vehicle-care facilities offered complimentary tire pressure checks with oil changes to systematically regulate tire pressure including: increased safety, reduced fuel consumption, increased customer discretionary spending that could be recouped in retail/auto stores, reduced pollution and emissions and enhanced national security (Pearce and Hanlon, 2007).

Discarded tires have been a disposal problem in the past and continue to accumulate throughout the world today. Recent figures from the US Environmental Protection Agency show that over 279 million discarded tires are being added to an estimated 2~3 billion tires currently stockpiled around the U.S. (Jang et al., 1998). The discarded tires can present both health and environmental hazards (EPA, 1989). The rubber coating life is related to running conditions, i.e. the load, the velocity and the displacement amplitude (Baek and Khonsari, 2005).

There are currently more than 1900 facilities in the U.S. and Canada. However, the number is shrinking nowadays due to the decreased markets for passenger retreats. The decline is primarily because of low prices of new tires. Truck tires are often re-treaded three times before being discarded and the truck tire re-treading business is, therefore increasing. Most of the good truck tire casings are being re-treaded owing to the high cost of new truck tires (Jang et al., 1998).

Wik and Dave (2009) summarized the existing knowledge on the occurrence of tire wear particles in the environment, and their eco-toxicological effects. They suggested that management should be directed towards the development and production of more eco-friendly tires and improved road runoff treatment (Wik and Dave, 2009).

The average passenger car tire lasts for 40000 km before it is worn out, and during its lifetime about thirty percent of its tread rubber is eroded away off and emitted into the environment (Dannis, 1974).

For tire and brake wear emissions, average wear rates and heavy metal contents of different materials were utilized to develop emission factors for tire and brake wear. Road transport is the cause for heavy metal emissions like arsenic, cadmium, chrome, lead and nickel that emerge from the abrasion of tire tread and brake linings. Although their amount is highly uncertain, the conclusion can be drawn that activities from this sector are contributing to some extend to the total anthropogenic heavy metal emissions. A comparison with other anthropogenic sectors like the production of industrial goods or small combustion installations shows that this contribution can reach up to 13% for lead in the business as usual scenario. As transport activities will continue to increase in the future, this will also gain more importance (Kummera et al., 2009).

Higgins et al (2008) were formed a friction map to determine friction regimes in the range of velocities 0.005 ms^{-1} to 2.6 ms^{-1} and temperatures -33 °C to -0.5 °C. The values of μ in the map range over two orders of magnitude from 0.01 to 1.14. Low friction is observed at high velocities. A maximum in

friction was measured for low velocities at 0.005 ms^{-1} around -25 °C (Higgins et al., 2008).

The tire companies support the re-grooving (re-treading) operation to extend tire life. In this process, the teeth on the worn tires can be re-opened without damaging the tire casing with the re-grooving machine and the lives of tires can be extended for a while (Michelin, 2011).

Celik et al (2007) have expressed the importance of tire pressure. They examined the tires of wheeled heavy duty machines and stated that if the tire pressure is checked daily according to the catalogue value, an extension of tire life can be made possible for a longer period.

In this study, the tires of heavy duty vehicles used at the opencast mining area were investigated in detail. The discarded tires for various reasons were evaluated between the years 2007-2012. The purpose of the present research in general was to investigate the reasons for leaving scrap of tires and the wear conditions according to their location on the vehicle.

According to the results obtained from, some suggestions were made in order to increase life of tires. There are a large number of heavy duty vehicles utilized in opencast mining areas such as wheel and track-type loaders, trucks, road roller, bulldozer, angledozer, grader, excavator, driller, etc. The cost of an average tire is about $ 7000 - $ 7500 for trucks which have a capacity of 77-85 tons. In addition, a single tire cost of truck with a capacity of 156 tons can reach up to $ 19000. Prolonged life of the tire is essential from the point of economics and environmental reasons.

2 MATERIALS AND METHODS

In this study, the tires of heavy duty vehicles have been investigated at Western Lignite Corporation (WLC) between the years 2007-2012. During this period, a total of 770 tires were examined to find out the main reasons for them to be left to the scrap. According to the result of the present research, five main events have been determined taking place at discarded of tires which are;

a- the blowout (Fig. 1),
b- the wear of the teeth (Fig. 2),
c- the tread separation (Fig. 3),
d- the stone cutting (Fig. 4),
e- the damage of the toe (Fig. 5).

Figure 1. The blowout

Figure 2. The tire wear

Figure 3. The tread separation

Figure 4. The stone cutting

Figure 5. The toe damage

The reasons for disposal of tires were shown in Table 1 and Fig. 6. When Table 1 and Fig. 1 are assessed, it can be seen that the most important reason for disposal for tires is the stone cutting. Later, the reasons for the damage of tires are the wear, the tread separation, the blowout and the toe damage, respectively.

Table 1. The disposal reasons of tires for heavy duty vehicles (between 2007-2012 years)

Cause of Damage	Number of Tires
Blowout	25
Wear	232
Tread Seperation	36
Stone Cutting	468
Toe Damage	9
Total	**770 pieces**

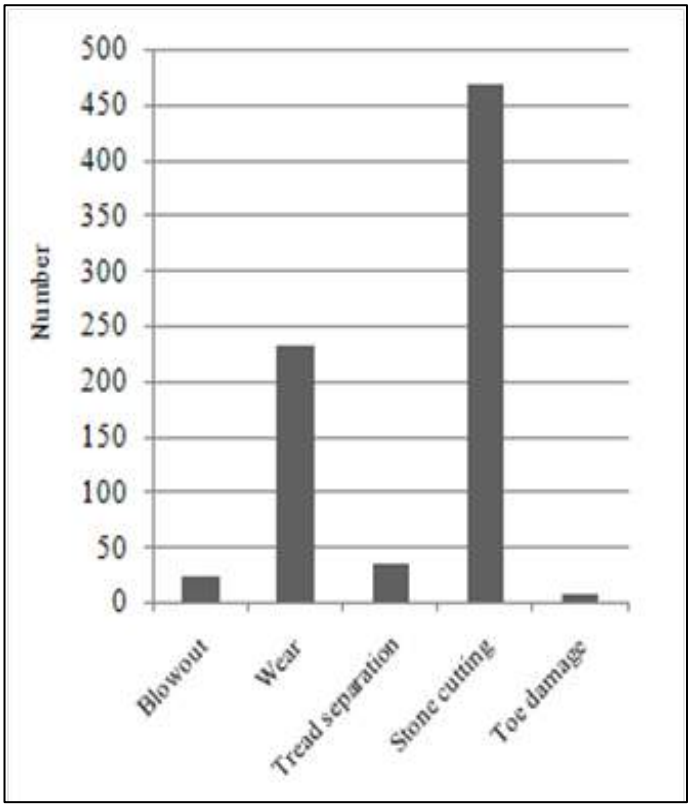

Figure 6. The main reasons for the disposal of the tires

It is desired that the tires are only discarded with the wearing. However, it is not possible in practice. Especially, the stone cutting is more than double exceedance the wear. Nevertheless, it is possible to reduce this damage by taking a number of measures. The hard and sharp objects such as stones, rocks,

metal parts, trees etc. mainly cause the stone cutting. If the truck is overloaded, the stones, the rocks and the mineral particles are eventually poured onto the roads. If the bucket of the loader and the excavator is overfilled during the trucks loading, the stones, the rocks and the mineral particles are also poured onto the working area. Therefore, the vehicles like loader, excavator, trucks etc. should not be charged more than their load capacity. In addition, the hard and sharp materials on the roads and the working areas should be frequently cleaned away. In addition to these precautions, the production chains should be attached to the tires of loaders and excavators during the working on hard ground conditions.

The hard and sharp materials scattered around on the ground can also cause the blowout of tires. Other causes of the blowout (sudden explosion) are the overloading of vehicles and high inflation pressures of tires. Several works carried out indicate, and the consensus among tire manufacturers is that under inflation in tires is also a major contributor to the tire failure (Federal Motor Vehicle Standards, 2001; Aguirre, 1986).

3 RESULTS AND DISCUSSIONS

In addition to the above described general tire damages, the six-wheeled truck tires were also examined. The situation of 311 pieces of the truck tires and the wear conditions were evaluated according to their locations on the truck. In this study, the tire numbering was used for each tire according to their locations on the truck. The tires were fitted at the same shaft location even if they were changed. Fig. 7 shows the numbering and the positions of the tires on the vehicle.

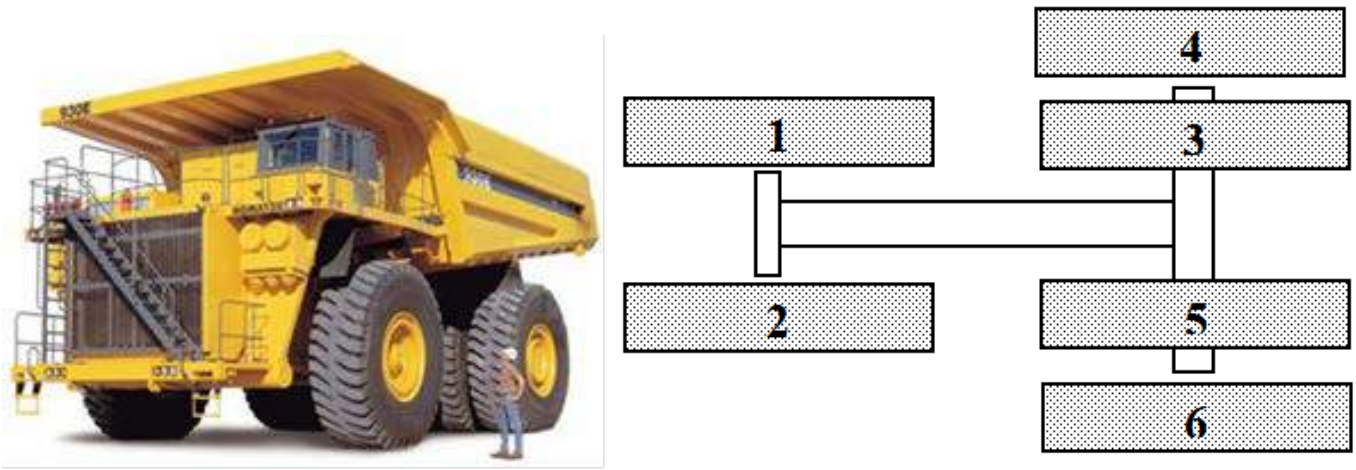

Figure 7. The truck and its the numbered tires

Table 2 shows the life of the tires mounted on trucks between years 2007-2012. The working hours of trucks were also recorded when both the tires were mounted as original on the truck and then the tires were discarded at the end of their application lives. In this way, the average lives of tires were studied according to their location on the truck. In this study, only the tires discarded due to wearing have been evaluated. The disposed tires owing to the stone cutting, the blowout, the tread separation and the toe damage have not been evaluated. The examined tires are the new and the original products. The coated tires have also not been taken into evaluation. The tires having been in the same location on the trucks were paid attention during the studying period. The tires were fitted at the same shaft location even if the trucks were changed.

As shown in Table 2, 43 tires were used at the 1st numbering location on the trucks while 47 tires were used at the 2nd numbering location. However 45, 53, 58 and 65 tires were utilized at the 3rd, 4th, 5th and 6th numbering locations respectively. The

working hours (lives of tires) were recorded for each tire as well. The values at A columns in Table 2 are original values which are not statistically assessed. The values at B columns in Table 2 are the regulated ones. This regulation will be described below.

The statistical evaluations are shown in Table 3 for the group of every tire. The values at the column A in the Table 3 are the average lives and standard deviations for tires calculated from the column A of the Table 2.

However, in the column A of the Table 2, some values shown in bold are outside the range of their standard deviations for group of every tire. The values which are outside the standard deviations were deleted and the column B of Table 2 was generated. For example, for the 1st tire life, 2898 value (in the column A of Table 2) is outside the standard deviation which is 6277 (7779-1502) in the column A of Table 3. Therefore, this value was deleted. In this way, 11 values were not shown in the column B of Table 2 considering standard deviation values in the column A of Table 3.

The column B of Table 2 contains the regulated values for the group of every tire. The column B of Table 3 show statistical values which are the average life of tires and the standard deviations from the column B of Table 2. The tire lives were determined according to the column B of Table 3 for the six wheeled trucks.

Graphically, the average lives of tires based on the data in the column B of Table 3, are shown in the Fig. 8.

When the column B of Table 3 and Fig. 8 are examined, it is seen that the longest-lived tires are the 1st numbered ones which are working on the right-front axle. The life of these tires is about 8018 hours. Then, the 2nd numbered tires have the life of 7223 hours. The 2nd numbered tires are the front tires of the trucks too. The front tires are not at the driving (traction) axle. As the front tires are not at the driving axle, they are less worn out. However, the 2nd numbered tires are worn out more than the 1st numbered tires. These left-front tires have been worn out 9.92% more when compared with the right-front tires. The reason of this situation is that left-front tires are working on the harder ground. The traffic flow is on the right hand side at the working area. Therefore, the left tires are in contact with the harder ground.

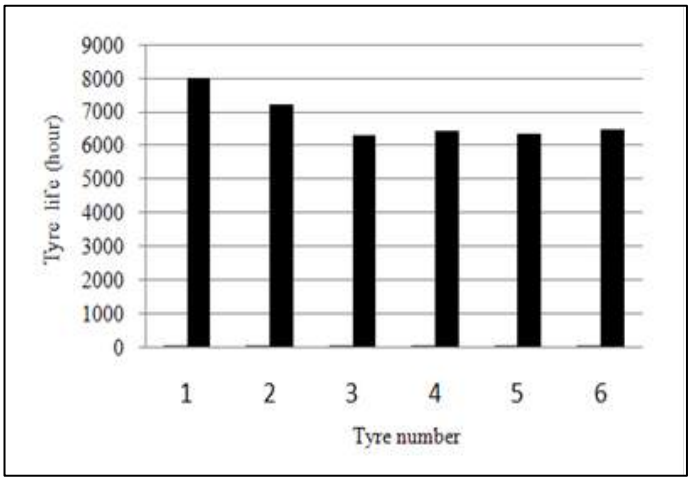

Figure 8. The life of tires on the heavy duty trucks

The shortest-lived ones are the 3rd numbered tires (6322 hours) and the numbered 5th (6356 hours) tires which are working on the rear axle. The rear axle is the driving axle and the numbered 3rd and 5th tires are on the inner side along the rear shaft. The weight of the truck and the load carried is handled by the the rear-in tires more. Fig. 9 shows the geometric dimensions and the mass center of the trucks utilized.

For these trucks, the weight distribution is as follows: empty front axle is 47%, empty rear axle is 53% and loaded front axle is %32, loaded rear axle is %68 (Komatsu, 2011). The numbered 3rd and 5th tires are more worn out due to the effects of the weight and the traction. On average, the rear-in tires have shorter life 16.82% by compared to the front tires in this calculation, the average life of the two front tires is 7621 hours, the average life of two rear-in tires is 6339 hours.

The numbered 4th and 6th tires which are on the outside along the rear traction shaft have 6431 and 6490 hours life respectively.

The average life of the numbered 4th and 6th tires is 6460.5. These tires have a longer life by 1.92 % with a comparison of the numbered 3rd and 5th tires which are the inner side on the same axle.

Table 2. The lives (hour) of tires on heavy duty trucks

Number	1st tire Life		2nd tire life		3rd tire life		4th tire life		5th tire life		6th tire tife

Table 3. Average life and standard deviation of heavy duty truck tires (from Table 2)

	1st Tire Life (hour)		2nd Tire Life (hour)		3rd Tire Life(hour)		4th Tire Life(hour)		5th Tire Life(hour)		6th Tire Life(hour)	
	A	B	A	B	A	B	A	B	A	B	A	B
Average Life	7779	**8018**	7724	**7223**	5947	**6322**	6321	**6431**	6162	**6356**	7779	**6490**
Standard Deviation	1502	823	2154	1288	1918	1138	1663	919	1518	983	1844	965

At the same time, 4th and 6th tires are less worn out by 15.32% with a comparison of two front tires.

Moreover, the base of road is convex in cross-section. The middle part of road is a little higher than the edges in general. It means that the rear iner tire is more in contact with the ground. All these events are causing the more wear on the rear in tires.

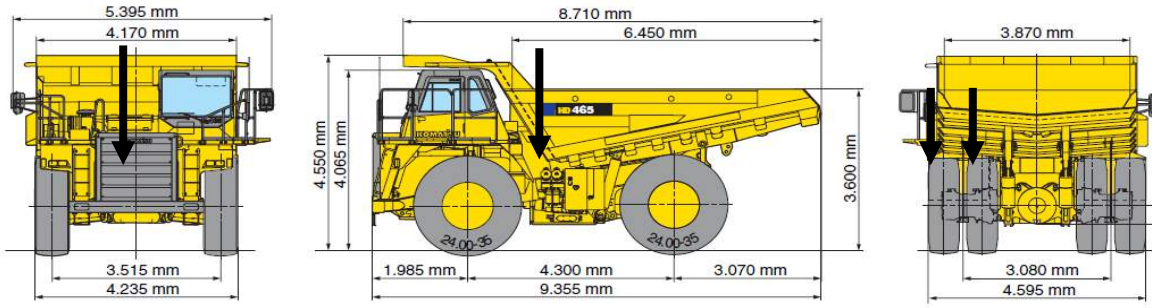

Figure 9. Geometrical dimensions and the mass center of the trucks

4 CONCLUSIONS

Between the years 2007-2012, 770 pieces of tires were examined in an opencast mining area at WLC. At the end of this experimental research work, it can be said that the most important reason for the disposal of tires is the stone cutting. Later, the wear, the tread separation and the blowout are ranked, respectively while the toe damage is the least damage. The cost of tires comes second after fuel consumption for a mining company. However the damages of the tires can be decreased out of the natural wear by taking same measures. The falling and scattered parts which are hard and sharp rock materials on the working area and the roads should be cleaned frequently. The carrying capacities of the vehicles must not be exceeded. The overloading should not be permitted at all. Tire inflation pressure should also be kept in the range of normal values.

In addition, at the same working area, 311 pieces of tires of the heavy duty truck with six tires were examined according to their location on the trucks. The results obtained from this study can be explained as follows: the most worn out tires are on the rear traction inner side. The outer tires on the rear traction shaft were less worn out compared with the inner tires on the same shaft. The longest-lived tires are the front tires on the truck as there is not the traction effect at these tires. Moreover, the tires which are at the front-right are less worn out. The reasons for the different tire wears are the load distribution on the truck, irregular distribution of hardness on the road from the edge to the middle and traction effect on the tires. While the inner tires which are on the rear traction shaft most worn out, the right-front tires are the least worn out ones. As a result of the present work, for the trucks, it is recommended that the rotation can be made between the rear in side tires - the front tires on the same line (not cross) for a homogeneous wear.

ACKNOWLEDGEMENT

The authors thank to the management of Western Lignite Corporation in Kutahya/Turkey for their valuable support and permission to this study.

ABSTRACT The underground mine workings induce instability risks in the surface that can cause subsidence and collapse. These risks can occur as well during and long term operation phase after abandonment of the work. The magnitude of these risks depends on the mechanical and physical characteristics of the rock mass, the geometric dimensions of ore bodies, their spatial arrangement, the overlay protective pillars and the state of the exploited space. In the case of preventive measures of security and technology are not taken into account for this purpose, the environment will be affected.

The main objective of this work is to assess these risks by scientific, analytical and numerical methods based on geological, hydrogeological and Geotechnical characteristics of Boukhadra rock mass possibly to put into place the preventive measures.

The obtained results have allowed us to get an acceptable safety factor and to quantify subsidence base into 2D with Plaxis 8.2 software.

Keywords: Abandoned underground mining openings, stability risk, 2D analysis

1. INTRODUCTION

In underground mining, the phenomenon of instability of surface land is quite common in the case of the exploitation of vein deposits and erecting by the methods of empty rooms as shown in Figure 1. These instabilities can cause severe damage to structures, fatal accidents, blockage of transportation routes, stopping production, negative impact on the environment, etc...

Many factors affect the stability of underground mines. A quote from global geological, hydrogeological, Geotechnical and technology.

The mine stability condition can be evaluated using analytical and / or numerical. These methods determine the safety factor which is the ratio of the resistance of protective pillars and mono axial stress of overlying rocks.

In this work, we take Boukhadra mine Algeria as case of study. The two approaches used in this work are the analytical method and numerical modelling using a computer code by finite elements, application of Plaxis2D version 8.2 software.

The main objective of this paper is to design crown pillar and operated space, to ensure the stability for the short and / or long term with an optimal extraction rate for ore with an acceptable safety factor.

2. RESEARCH OF METHODOLOGY

The problem of the rock mass instability caused by underground mining has been supported by many investigators around the world such as: Deck O. (2002), DRS-05-55102 / R02. (2005) Gadri et al. (2012), Laouafa F. (2004) Pastarus & Toomik (2000), Hutchinson, DJ Phillips. (2002) and others, because it is the one of the priorities of their research. The exploited voids can be the cause of the appearance in the short and / or long-term the subsidence and the collapses after D. Hantz.(2012), as shown in the Figures 2-3-4. These phenomena are very dangerous and can ruin all structures on the surface. To overcome this problem, numerical, analytical and empirical methods have been developed by scientists. Numerical methods yield to significant results because they are very reliable and adapt to different conditions and Oraee Hosseini (2007) Oraee et al (2008). Numerical methods such as finite elements, distinct elements, finite difference and boundary elements are optimal only in special situations (Oraee , al. 2009).

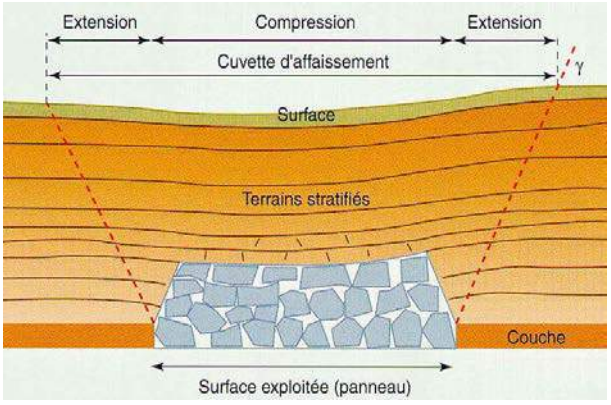

Figure 2. Collapse of a mine (According to INERIS paper)

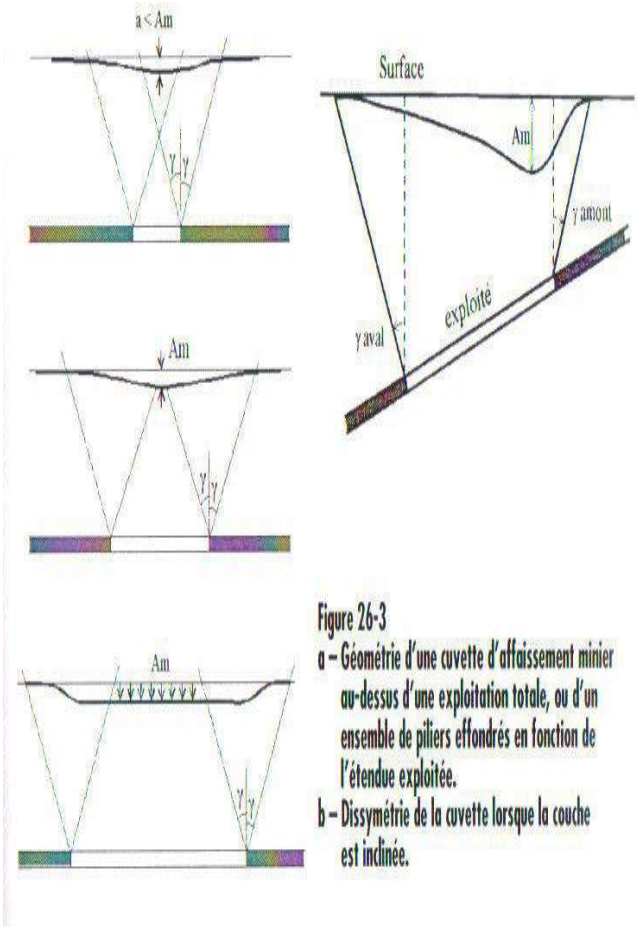

Figure 3. Subsidence: Case of the Deposits aligning and horizontal

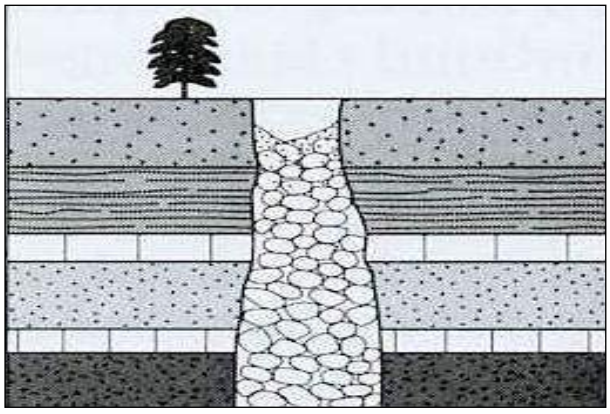

Figure 4. Sudden and localized collapse

Modeling of the exploitation of salt deposits has been the object of the study by Laouafa F, (2004).This work led to important results as shown in figures 5, 6. The validity of the results are only for the case of flat deposits.

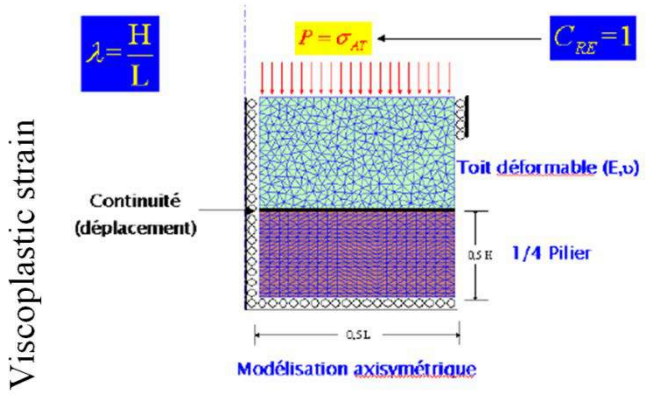

Figure 5. Basic model for the determination of the coefficient of correction

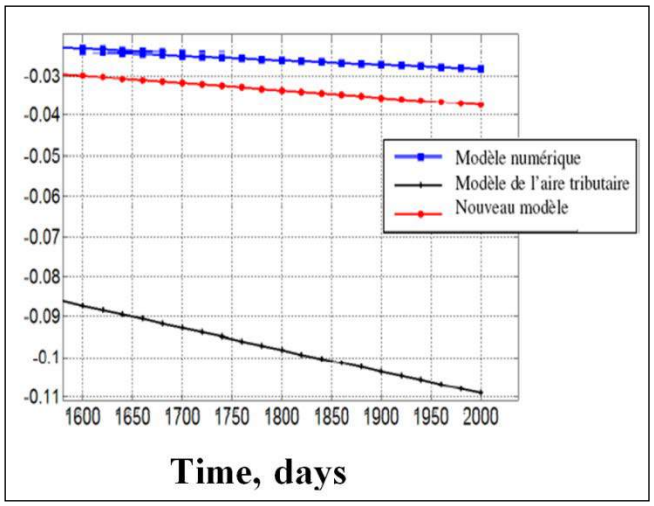

Figure 6. Evolution of the viscoplastic deformation versus time

In the report DRS-05-55102 / R02 (2005), the researchers have supported the case of disorders observed at the surface resulting from the operation slope deposits and flat. They highlighted the characteristics associated with failure mechanisms and stress distributions with high dip of the deposit. The obtained results of their research have categorized the surface phenomena in several disorders including:
A. Localized collapse associated with a breakage protection of the stot (crown pillar) when the operation has reached close to the surface 6.
B. Localized collapse due to the rupture of an underground stop a barrier and
stripping of fillers to deeper empty;
C. Localized collapse due to a rupture of the roof room (fragility of the walls);
D. Subsidence asymmetrical.

In the same report, the authors defined the main criteria to be considered in an assessment of hazards in slope deposits and / or vein which are:

• The geometry of the work (width exploited panels);
• The opening of the underground workings;
• The method of operation (presence of residual voids, backfilled stopes, reclaim rate, etc.);
• The dip of the layers;
• The depth of the panels;
• The thickness of the stot surface protection;

• The nature and characteristics, including mechanical recovery of rock mass, the presence of faults, surface topography, etc…
In their analysis, the authors explain that the concept of pillar "crown" is different from the traditional notion of pillars in the case of the abandoned room and pillar method.
This term refers to the field in place slab between the surface and the shallow adit (Crown pillar: pillar closest to the surface, Figure 7. Hutchinson, Phillips and Cascante [2002]).

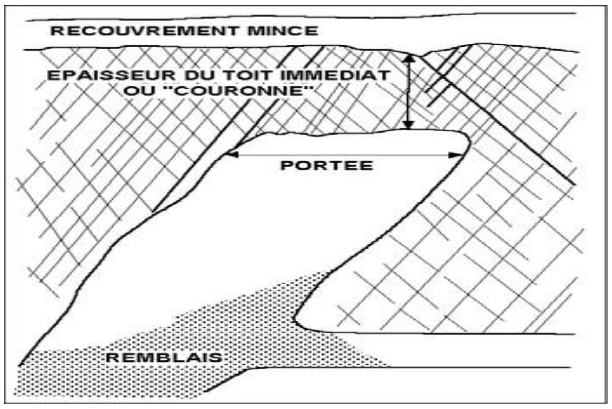

Figure 7. General scheme of a "crown" (according to Hutchinson, Phillips and Cascante [2002]).

The method proposed by the author can be applied for viscoplastic materials. The analytical method developed by the conditional height Talve (1978), Pastarus & Toomik (2000) has given significant results in the Estonia mines stability. The types of model showed in the figure 8 which allowed them to assess long-term stability of the mine of the basis conditional height. The formulas

1, 2, below have crowned their work:

$$C = \frac{\text{H.Sr}}{\text{Sp}} \quad (1)$$

$$Ccrit = \frac{Ha.L^2}{\sum Spi}, m \quad (2)$$

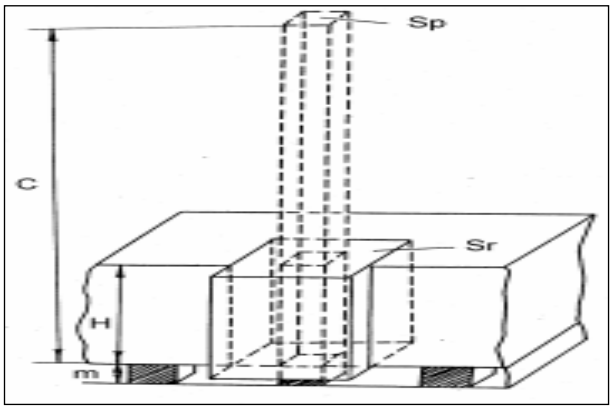

Figure 8. Geometrical interpretation of conditional thickness

Where:
C- The width of the critical operation panel
Cc - conditional thickness of the critical area, m;
Ha - average thickness of waste rock in the critical zone, m;
Spi - sectional area of the II pillar in the critical area, m.

In his study, D. Hantz. (2012) developed a methodology for calculating the average load on the pillars by the following formulas:

- Force exerted on the entire area

$$F = \gamma \, h \, S \text{ totale} = \sigma p \, S \text{ pillars}, \quad (3)$$

- The average stress in the pillars

$$\sigma p = \gamma \, h \, S \text{ totale} / S \text{ pillars}, \quad (4)$$

The methodology proposed by the author can only be applied for the exploitation of deposit flats.

Conclusion:
After analysis of the literature review, it appears that a significant number of influential factors directly implicated on the stability of underground mines are as follows:

- The geology of the deposit, particularly its lithological and structural aspect;
- The state of the rock mass;
- The spatial arrangement of the deposit;
- The physical and mechanical properties of the rock mass;
- The geometry of the deposit, the parameters of the method of operation and the empty space.

The different scientific methods used in their research have shown instabilities related to the solutions or preventive character which is highlighted to address the problems posed.

3 CASE OF STUDY

3.1 Presentation of the Boukhadra Mining Site

The Djebel Boukhadra is located in eastern Algeria, 45 Km north of Tébessa city, 13Km from the Algerian-Tunisian border (figure 9).

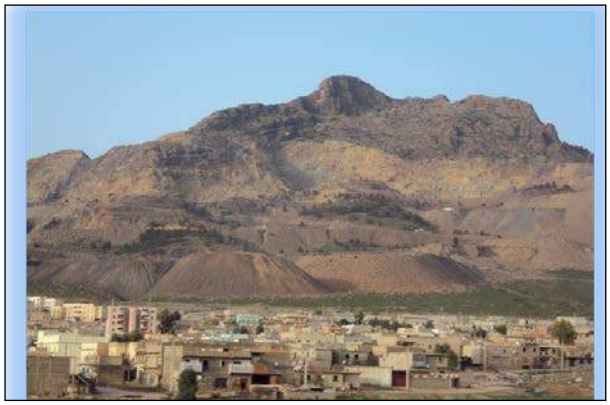

Figure 9. Mine in Boukhadra

3.2 Geological and Hydrogeological Approach.

Stratigraphy of Mount Boukhadra to show that these layers with subvertical orientation (N0 0E) which can accelerate the landslide phenomenon rocks.

Tectonics of Jebel Boukhadra to show that it is hit by a diapirisme causing an upheaval of all existing layers. This is endorsed by the existence of diaclase and internal fragmentation of the different layers also by the existence of

the Triassic formations. The discontinuity present in the solid leads to their quantifications (geometry, and geology) . The water table is below the mineralization that does not affect the mine workings so the water problem does not arise in the conditions of the mine.

The visual field geological study has enabled us to achieve a schematic section of existing training and their dimensions (Figure 10).

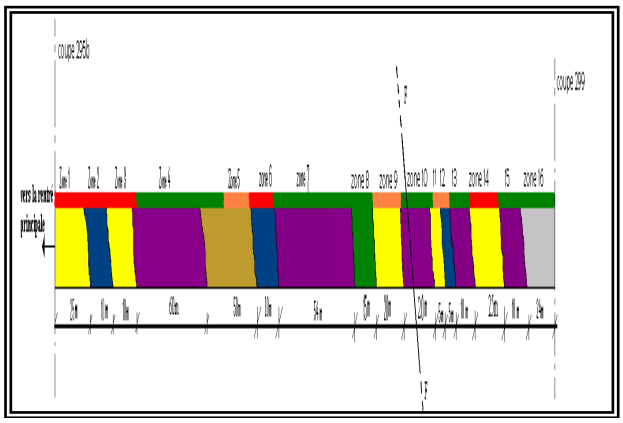

Figure 10 . Schematic section of existing training

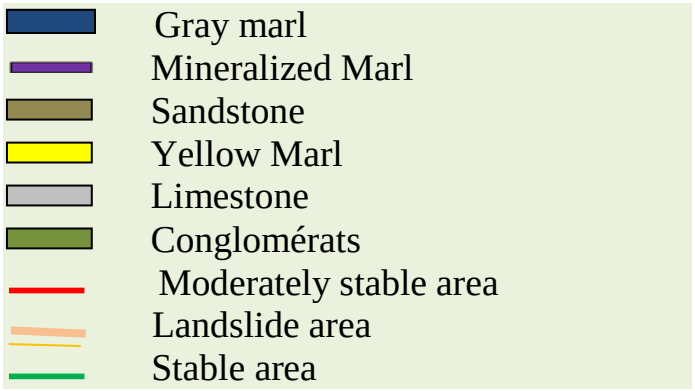

In the mining work, the deposit studied is operated by the method of sub levels slaughtered as part of the methods of empty rooms (figure 11).

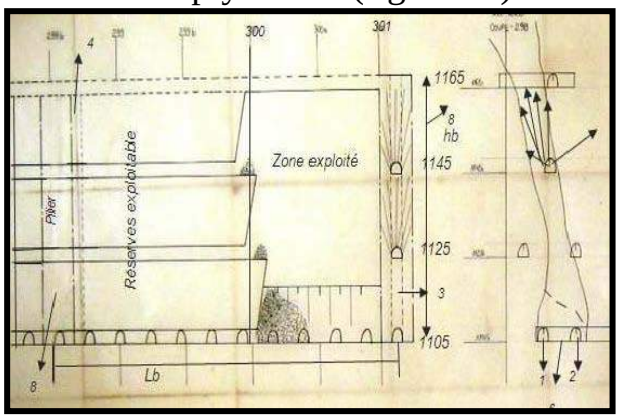

Figure 11. Method in slaughtered levels

The geometric parameters of the deposit are presented in Table 1

Table 1: Geometrical Parameters

	Dimensions
Length of the field, m	500m
Height of the operating block, m	60m
Deposit thickness, m	5m à 50m
Dip angle of the deposit, in degrees	50° à 70°
Length of the operating block, m	40m
The thickness of the crown pillar, m	10m
Width of the barrier pillar between the blocks, m	10m
The thickness of the basic block pillar, m	10m
Distance between recoupes loads, m	7,5 m à 10m

Conclusion

The geological and hydrogeological conditions are determining the degree of difficulty and cost of realization of any underground work and also they have a great influence on the choice of the excavation methods and supporting system. Gadri .L & all (2012).

Other parameters such as degree of weathering, strength of intact rock and water flow are also important in the process of the design rock support system. The knowledge of the former conditions has been of a great help in the identification of potential problems and the suggestion of appropriate solutions, i.e. special supporting system, drainage system, and/or treatments of the encountered problems.

4 NUMERICAL MODELING

To better understand the problem, we modelled two-dimensional structures in the room and pillar (square pillars) in the case of the mine study. The Boukhadra mine rock mass is composed of layers

of Gray marl, Mineralized Marne, Sandstone, Yellow Marl, Limestone And Conglomerates.

For the stability calculation, the assumption of plane strain is adopted. The mechanical behaviour of materials follows the Mohr-Coulomb criterion. The mechanical and physical properties of the materials were determined from laboratory tests at the University of Tebessa Gadri & all (2012),

The mean values of the results are presented in Table 2.

Numerical modelling is performed on the basis of a parametric study, which includes four cases with the variation of the geometric parameters of the real signs of the mine table 1. These cases were calculated analytically by the analytical method which is validated by the modelling method.

Table 2. Physicals and mechanical characteristics of Boukhadra rock mass.

Rocks	**E [GPa**	**ɣ h [g/ cm3]**	**ɣ sat [g/ cm3]**		**C [Bars]**	**α [°]**	Hardness	Rc [Mpa]

4.1 Presentation of the Geometrical Model

Since the Boukhadra deposit is erecting the model was presented by its thickness, to better understanding when modelling the total displacements and deformations of the pillars levels (Figures 12ab).

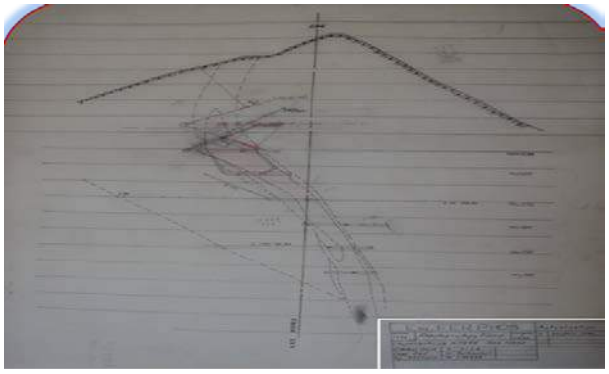

Figure 12a. Vertical section of the northern axis.

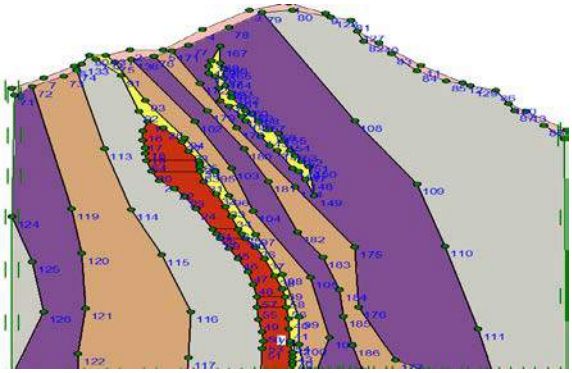

Figure 12b. Overview of the geometric model.

The pattern boundaries are fixed horizontally and vertically at the lower end and equally are fixed horizontally at the terminal sides. The model consists of triangular
elements, each element of 15 nodes and stres s points. The boundary conditions and mesh study are present in the Figure 13.

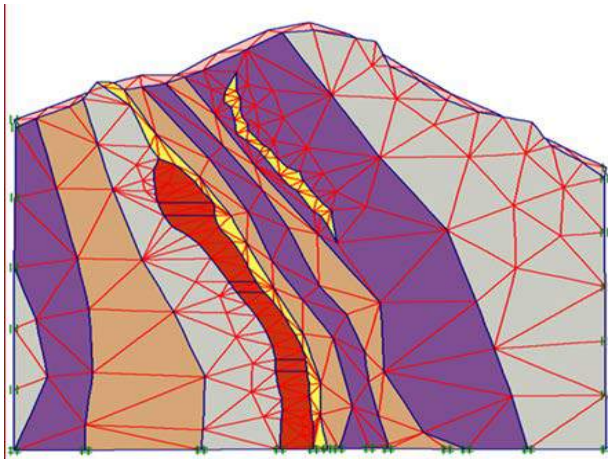

Figure 13. Boundary conditions and mesh of the study.

4.2 General Information About the Model

Our model consists of 426 triangular elements, 3501 nodes with 15 nodes for each element of 5112 points of tension and 15,27m of medium-sized items

4.3 Results of Numerical Analysis with Finite Element Method

Phase after operating

The results obtained allowed us to have the values of total travel (vertical and horizontal), the relation: point of charge – total displacements and distribution of plasticity see Figures 14-15-16.

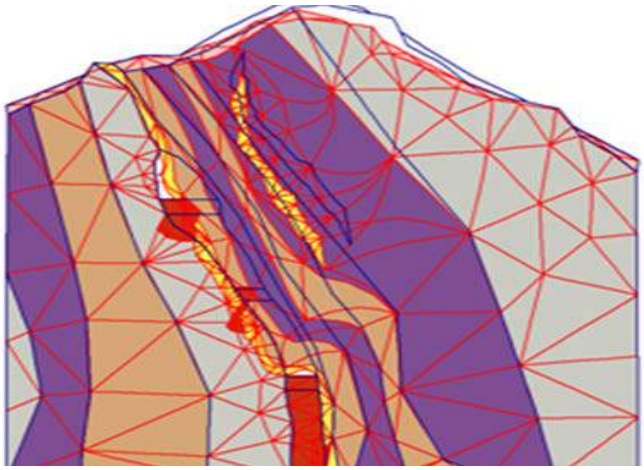

Figure 14. Average total displacement **Utotaux** = 31, 3.10^{-3} m

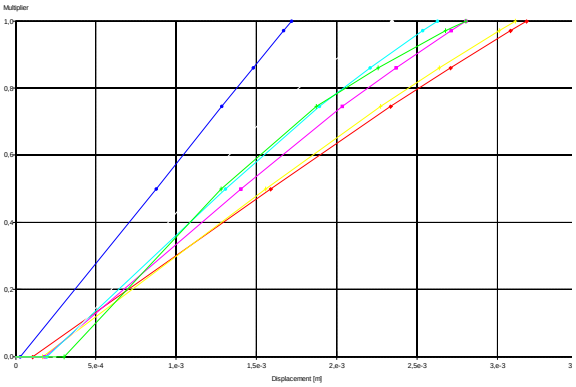

Figure 15. Relation: Point of charge –total displacements

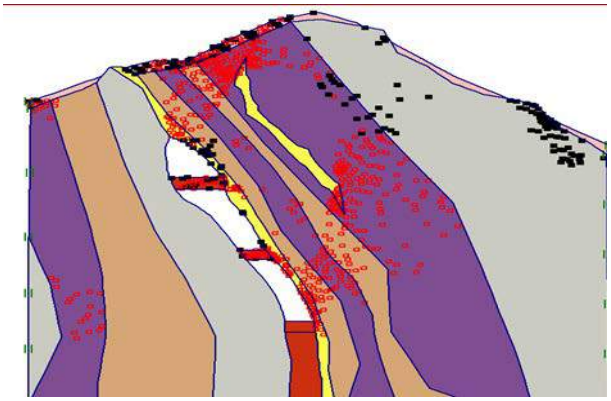

Figure 16. distribution of plasticity

5 CONCLUSION AND OUTLOOK

The study undertaken as part of this research has allowed us to draw the following conclusion:

One of the main objectives of the underground mining is to ensure the stability above all which is an important parameter for the safety of minors.

The geological study of Boukhadra deposit is generally a very complex structure (heterogeneity of the rock mass and the presence of significant discontinuities). (Gadri et al 2012). This complexity results in the short and long-term instability of the mine.

In analytical methods used by different scientists in their studies, the factor of time has not been the subject of extensive study, while this parameter is important for the stability of the mines.

The obtained results of numerical modeling for the case of Boukhadra mine showed

large displacements of the order of $31.3.10^{-3}$ m, and high plasticity distribution at the crown of pillars in the form of a localized collapse. (D. Hantz. (2012).

In order to remedy to the problems, we recommend:

1. The application of a paste backfill system, including in areas of the past mining works and tablecloths.
2. A systematic control of stops rocks. Using the convergence-confinement method.

Department of Civil Engineering ; University of Skikda, Alegria.

ABSTRACT: The recycling of quarries waste may offer interesting advantages and solutions in order to preserve the environment and should be considered as a supplementary source of construction materials.

The main objective of this study is to technically show the possibility to recuperate the dust of the marble wastes as a substituted addition in the cement and mortar.

The basis of this study is the effect of marble waste fillers substitution in the cement and mortar paste (0, 5, 10, 15 and 20%) with a fineness lower than that of the cement, to compare the results obtained through control samples of cement paste properties in the fresh condition and the mechanical performances of mortar in the hardened condition.

The obtained results show that the marble wastes fillers can be technically used as an addition in cement.

Keywords: Waste, valorization, fillers, marble, substitution, cement, mortar

1 INTRODUCTION

In this study, we recovered the wastes of white marble from the quarry of FILFILA (the deposit is located at 25 km at the eastern side of Skikda City, Algeria) in the manufacturing of cement.

2 CHARACTERIZATIONS OF THE USED MATERIALS

The used materials for this period are:

- Cement CEM I class 42.5 coming from the cement works of HADAJ SOUD
- The additions of marble wastes are obtained by crushing the mass rejects in a crusher, then a grinding in a grinder with a standard nut.
- The mortars are prepared with a standard sand CEN according to the norm EN 196-1, this natural siliceous sand with an apparent voluminal mass of 1.63 g/Cm3 and an absolute voluminal mass of 2.5g/Cm3, this sand is inert from a chemical point of view with fineness module of 2.33

Results of Characterizations Tests are shown in the Table 1:

Table 1. Characteristics of Used Materials

Sample	CEM I 42.5	Marble Wastes Fillers	Sample	CEM I 42.5	Marble Wastes Fillers
Mvabs g/cm^3	3,33	2,79	R . Insoluble	0,85	0,035
SSb Cm^2/g	4457	2997	Free CaO	0,4	--
CaO	61,31	55,29	MS	2,52	--

3 EXPERIMENTAL PROGRAM

In the experimental program, we study the substitution of a cement part by the marble wastes additions, through varying the substitutions rate (0%, 5%, 10%, 15%, 20%).

Campaign 1: manufacturing starting from cement CEMI and marble wastes fillers of cement pastes with substitutions rates (0%, 5%, 10%, 15%, 20%).

Campaign 2: manufacturing starting from cement CEMI and marble wastes fillers of mortars with substitutions rates (0%, 5%, 10%, 15%, 20%).

The parameters and tests made for the Campaign 1 are shown in the table 2:

Table 2. Parameters and tests made for the Campaign 1

Scoring	Type of Cement Paste
Witness (0%)	Cement paste made of CEM I
FM2 (5%)	Cement paste made of 95% of CEM I and 5% of marble wastes fillers
FM2 (10%)	Cement paste made of 90% of CEM I and 10% of marble wastes fillers
FM2 (15%)	Cement paste made of 85% of CEM I and 15% of marble wastes fillers
FM2 (20%)	Cement paste made of 80% of CEM I and 20% of marble wastes fillers
Constant Parameters	W/C = 0.27
Variable Parameters	Substitution Rate
Tests Made	Consistency Setting Steadiness

The parameters and tests made for the Campaign 2 are shown in the table 3:

Table 3. Parameters and tests made for the Campaign 2

Scoring	Type of Mortar
Mot (0%)	Normal Mortar made of CEM I
Mo2(5%)	Normal mortar made of 95% of CEM I and 5% of marble wastes fillers
Mo2(10%)	Normal mortar made of 90% of CEM I and 10% of marble wastes fillers
Mo2(15%)	Normal mortar made of 85% of CEM I and 15% of marble wastes fillers
Mo2(20%)	Normal mortar made of 80% of CEM I and 20% of marble wastes fillers
Constant Parameters	W/C = 0.5 Sand
Variable Parameters	Substitution Rate
Tests Made	Compressive strength in 2, 7, 28, and 90 days. flexural strength in 2, 7, 28, and 90 days.

4 EFFECT OF RECYCLED FILLERS ON THE CEMENT PASTE CHARACTERISTICS

4.1 Consistency

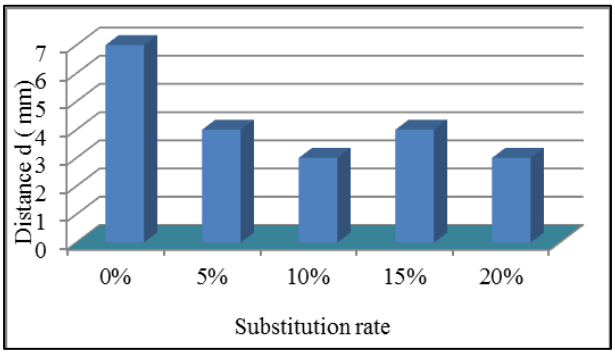

Figure 1. Variation of Consistency according to the substitution rate

For SSb Marble wastes fillers inferior to SSb Cement (Figure 1), we obtain a decreasing variation until a substitution rate of 10%, beyond 10%, we notice a light decrease of the cement paste consistency, correlated with the results obtained with A. Messan (2006).

Generally, and according to S. Caré and al (2002), the addition of marble wastes fillers leads to ameliorate the consistency according to the decrease of SSb and the substitution rate until 10%.

4.2 Start and End of Setting

For a lower SSb (Figure 2) there is an increase in the time of end of setting up to 10% or the effect reverses. Beyond 10%, the variation between the start of setting and the end of setting is very close. Plus the SSb is lower and the substitution rate is important (Superior to 10%) more the time between the start and the end of setting is shorter (M. Benia 2011).

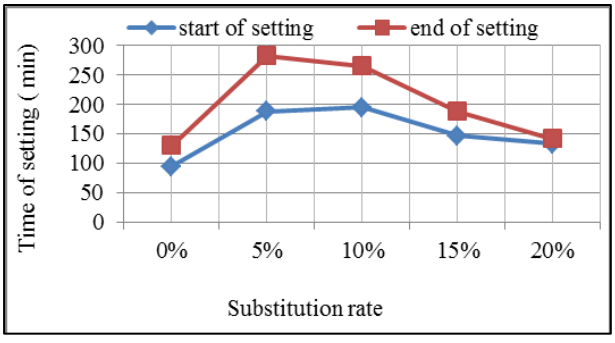

Figure 2. Variation of time of start and end of setting according to the substitution rate

4.3 Steadiness

Steadiness varies from a rate to another, this variation remains below 10mm. The steadiness decreases according to the decrease of SSb.

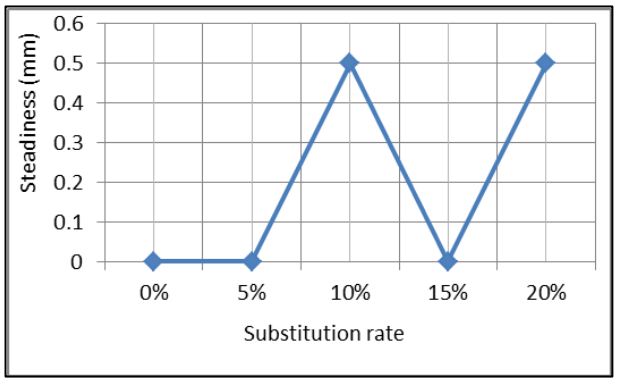

Figure 3. Variation of Steadiness according to the substitution rate

5 EFFECT OF RECYCLED FILLERS ON THE MORTAR CHARACTERISTICS

5.1 Compressive Strength

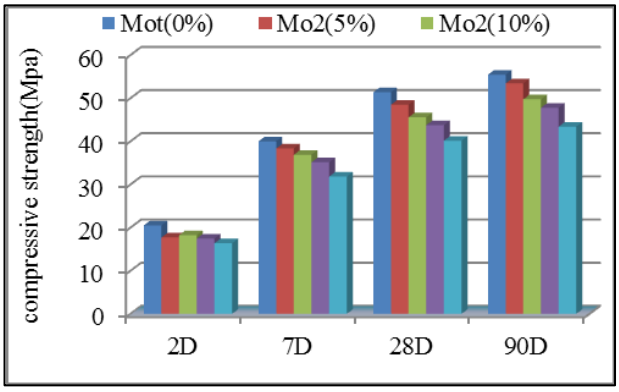

Figure 4. Influence of Substitution rate on the Compressive strength

For bigger marble wastes fillers particles (SSb lower), the best performances are obtained through the witness mortars, more the SSb is lower , more we obtain a fall of resistance for all the mixtures.

At the short term (2Days) more the SSb is lower, more the chemical reaction of hydration is disturbed by the introduction of the marble wastes fillers. The witness cement gives the best performances; this is due to the raised quantity of CaO which gives a higher resistance at the court term. At long term, the raised SiO2 gives lot of C2S because it reacts

with all the CaO and the cement hardens slowly, in accordance with (S. Caré 2002**,** M Benia. 2011, Ch. Amouri. 2009) and this explains the maximal resistance at the middle and long terms.

5.2. Study of the Influence of Age on the Variation of the Compressive strength According to the Substitution Rate

For a lower SSb, we notice a fall of initial resistance at the short term, and the pace of curves is a decreasing function with the raise of Substitution rate.

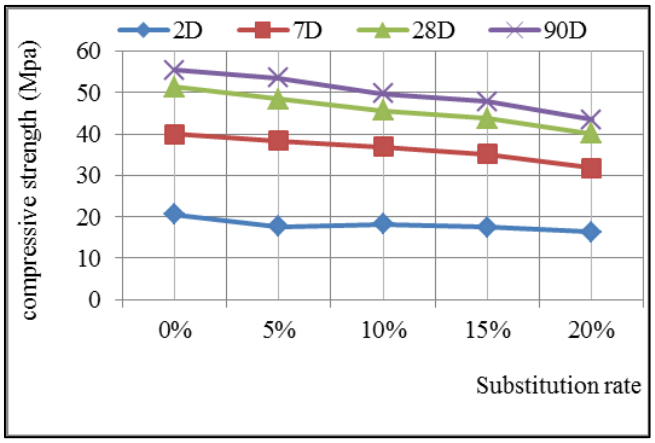

Figure 5. Influence of Age on the Variation of the Compressive strength According to the Substitution Rate

5.3. Flexural strength

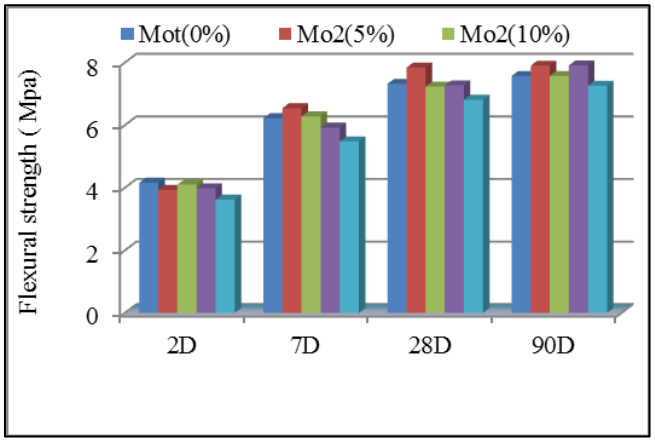

Figure 6. Influence of Substitution rate on the flexural strength

For lower SSb, we notice a decrease in the resistance for all ages.

5.4. Study of the Influence of Age on the Variation of the Flexural Strength According to the Substitution Rate

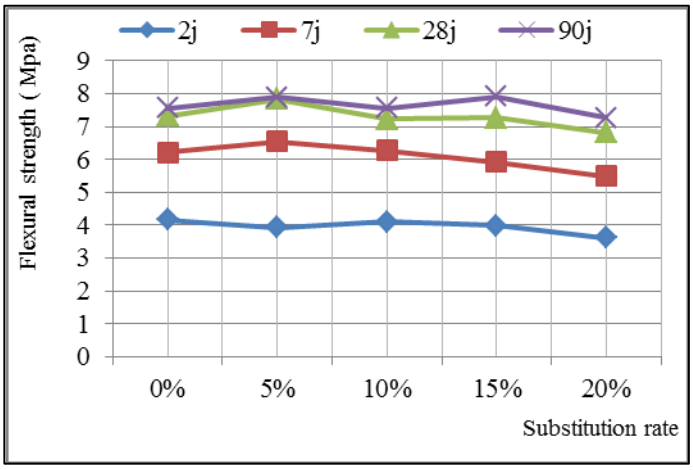

Figure 7. Influence of Age on the Variation of the flexural strength According to the Substitution Rate.

For bigger fillers particles, the curves at long term are very close and show the same pace.

6. CONCLUSION

This work carries on the study of the possibility to recover the marble wastes as an addition in the cement, the study shows that:
-The addition of marble wastes filers leads to ameliorate the consistence of cement paste, they cause a decrease of the C3A quantity.
-For lower SSb (SSb marble wastes fillers inferior to SSb cement CEM1), there is a raise of time of the end of setting.
-Introducing marble wastes fillers leads to increase the cohesion.
-The mechanical resistances decrease with the increase of the substitution rate of recycled fillers for a very weak fineness.
