PREFACE

For the Turkish Republic period, looking at a glance at the development of Turkish mining sector, about which the structure and problems have been always matters of debates, we see that the background of scientific organizations that must play a vital role to overcome these issues goes only back to 1960's. Those were the times when the young Republic was still passing through social and political turbulences, a period of major transitions. Significant efforts and attention were being directed towards industrialization, but the practice and the reality was far from these goals. Mining industry of the country, which should be a major driving force, was facing many faceted problems to be addressed. In addition, the mining industry was way below the desired level. It required not only powerful and ambitious moves, but also several radical, aggressive changes. This task was obviously to be undertaken by the mining people to a great extent. Being fully aware of this, the first time in 1969, a national event, the "Scientific and Technical Mining Congress of Turkey" was organized by the Chamber of Mining Engineers of Turkey of UCTEA (Union of Chambers of Turkish Engineers and Architects).

At the beginning, two major outcomes were anticipated: One for the Turkish mining industry; and one for the fore coming congresses. On one side it was aimed to increase the quality of the event and eventually to achieve international reputation and acceptance to make this event a tradition. On the other; the objective was to identify and to state issues and obstacles, to provide scientific-technical solutions to address these and, obviously to support the professional development of the young generations trained in mining.

This is how this ever-lasting journey started 46 years ago. Perhaps, the path undertaken is not too long, however, it has been a tough experience of many challenges. Since its start, even if our congress has sometimes had slight deviations, mainly on accounts of the conditions of the times, but the general tendency has always been upwards. And a further look into the details shows that significant progress has been made in such a short period. Such that, despite limited resources and several other restrictions, this congress became an internationally admitted event by 1973, thanks to the intensive and endless efforts and devotion of the amateur and volunteer staff of the Mining Engineers Chamber. Without an exception, the congress became a biannual event. To reflect this major achievement its title has been changed to "International Mining Congress and Exhibition" in 2001 when the event was organized for its 17th time.

Undoubtedly, the endeavors put forward are commendable. However, the role that technology has played should also be emphasized here. As very-well known, with the significant progress in information technologies that initiated particularly by 1990's, a broader geography became accessible. Such progress apparently contributed to increasing the scientific, sociological and cultural features as well as its international recognition. But, at the same time, these also put a pressure towards acquiring even further progress in such aspects as rapidly as possible. Within this context, the Chamber of Mining Engineers of Turkey now carries the vital responsibility to institutionalize this big mining event of Turkey and to make it one of the most reputable global mining organizations. In this respect, the 24th International Mining Congress and Exhibition of Turkey has been realized, showing that strong steps have been taken towards this major goal. This event of four days indeed became a means of gathering for academicians, scientists, engineers, managers, consultants, decision-makers, investors, industry experts, customers and suppliers from all across the world, as scientific, technical and social issues were discussed and recent mining technologies and latest products and developments in the mining industry were successfully exhibited. Further, the sessions held,

the social and cultural activities, tours and field trips have created even more opportunities for joint ventures, mutual cooperation and business relations among delegates. For this particular event, scientific contributions in the form of poster and oral presentations, broad participation raise our hopes for the future of Turkish mining industry.

As 44th Administrative Board of Turkish Mining Chamber and the Executive Committee of 24th International Mining and Exhibition of Turkey, we sincerely and initially thank to those who have carried on our chamber and congress since 1954, to those who made an effort for the organization of the congress, to the scientist who contributed the congress by their papers and presentations, to session chairs raising the scientific merits of the event and to all participating organizations and institutions.

2012 Effects In The South African Platinum Sector

B. Genc
Universitv of the Witwatersrand. Johannesbura. South Africa

ABSTRACT This paper studies the fundamentals affecting the South African platinum sector. It offers a brief overview of the current challenges faced by the platinum sector in general, and labour unrest related issues in the sector in particular. The difficulties the South African platinum producers have to deal with to plan their future production are also scrutinized. These include rising cost of labours, declining profit margins and the possibility of falling metal prices. It would be presumptuous to suggest solutions but this article nevertheless offers the reader an understanding of the challenges facing the South African platinum sector overall. In this light, where available, the financial performances of mining companies in the sector, obtained from published annual results, are also analysed, and on this bases the paper offers several recommendations.

Keywords: Platinum, cost, price, market

1 INTRODUCTION

South Africa is a mineral rich country and is the world's number one platinum producer. South Africa produced 73% (4.12 million ounces) of the annual global platinum output in 2013, up 0.7% compared to 2012 (Johnson Matthey, 2014) after the Marikana strike in South Africa in 2012. The strike was considered an important event in South African history, and was followed by similar strikes at other mining sectors such as gold and iron ore across South Africa. The mineworkers demanding better wages and improved living conditions initiated wildcat strikes in the platinum belt. These strikes led to a tragedy that took place in August 16, 2012 when 34 striking Lonmin mineworkers were shot dead by the police in Lonmin's platinum mine in Marikana. This shooting made international headlines. The strike lasted just over two months and ended in September 18, 2012.

The Marikana incident caused some production loses to the major platinum producers in South Africa. However, South Africa still managed to produce 4.09 million ounces of platinum in 2012, down 16% compared to 2011 (Johnson Matthey, 2014). Anglo American Platinum (Amplats), the number one platinum producer of the world, produced 2.32 million ounces of platinum in 2013, very similar production levels compared to 2012, which is equivalent to 40% of the world's annual platinum production. Impala Platinum (Implats), the number two platinum miner of the world, produced 1.58 million ounces of platinum in 2013, up 9.3% compared to 2012. Lonmin Plc (Lonmin), the number three platinum producer of the world, produced 0.75 million ounces of platinum in 2013, a similar figure compared to 2012. Although the South African platinum mines combined produced 72% of the world's annual platinum production in 2013, the 2014 platinum production outlook is expected to be 40% less than the 2013 figures as during 2014 the South African mining industry witnessed the five months long strike action in the platinum sector, the lengthiest strike action in the South African mining history, which ended on the 24th of June, 2014. This paper examines the reasons behind the long lasting industrial actions in the platinum belt, hence the impacts of the 2012 Marikana strike action in the South African platinum sector.

2 PLATINUM PRICES

Platinum prices are the main factors behind concluding if the platinum producers are profitable and determined by demand and supply figures. Total world supply for a

commodity is estimated by calculating the total amount of that commodity made available to the market. Mineral commodities are made available from primary production (which generates individual products, main products, co-products and by-products) and secondary production, i.e. recycling of scrap. Figures for both primary and secondary production are available in annual reports of producers, such as Amplats, Implats and Lonmin (Genc, 2008).

Platinum producers are required to publish their production results annually; they also publish their interim results as well as their quarterly reviews and production reports. This information can be obtained from the producers' internet web-sites and news reports. Once the underlying factors that affect supply and demand of a commodity have been well researched, a supply and demand balance can be calculated in such a way that analysts can determine future supply so that they can predict future platinum prices (Genc, 2008). If the supply figures come down and the demand stays the same, the platinum price should go up. Similarly if the demand drops and the supply stays the same, then the price should fall. Figure 1 shows daily platinum prices between 2010 and 2014. Platinum price averaged at USD 1 554 over the last five years (2010-2014).

While the platinum price is crucial for the South African producers, the exchange rate between the South African Rand (ZAR) and USD determines the levels of profitability. The reason behind this is that most costs associated with platinum productions are in ZAR while the revenues are wholly in USD making the USD to ZAR exchange ratio very important. This also means that a weak ZAR is good for the platinum producers. The platinum price was in the highest level during August 2011, reaching USD 1 900, in line with the global commodity price boom, mainly caused by high demand by the auto-catalyst sector in Europe.

3 CHALLENGES IN THE PLATINUM SECTOR

Since 2008, the financial market woes, hence the volatility in the global commodities markets is still continuing. Although the world's leading financial indices such as the Dow Jones Industrial Average, The NASDAQ Stock Market and The S&P 500 index are continuously breaking their all-time high records respectively in 2014, all these developments still were considered as a part of global recovery. Similar observation are also visible for the European markets too, as they are also coming out of recession. The European economy's well-being is very important for the platinum sector as it impacts on the platinum market due to auto-catalysts demand, most of which originate from Europe. This demand has a direct impact on the platinum price. Furthermore, China is the driving force behind the commodity market and platinum is no exception. The World Bank recently cut its global growth forecast sighting weaker outlooks for the U.S., Russia and China; China's economic growth was lowered to 7.6% for 2014, however it was 10% per annum in 2008. Overall, the platinum price averaged at USD 1 390 in 2014 compared to USD 1 490 in 2013, down 7%.

The above factors all contributed to uncertainty in terms of realising increased returns on investment and South Africa is no different. Companies operating in South Africa which are able to anticipate and plan for these uncertainties will undoubtedly secure a competitive advantage. A combination of challenges in the South African mining sector has had a negative impact on its mining industry. Frequent bad news headlines related to mining industry, long lasting strikes and the recent rating downgrades by Fitch, Moody's and Standard and Poor heavily impacted on this volatile industry. A similar downgrade occurred by the afore-mentioned rating agencies in 2012 preceding the illegal strike action by the Marikana miners.

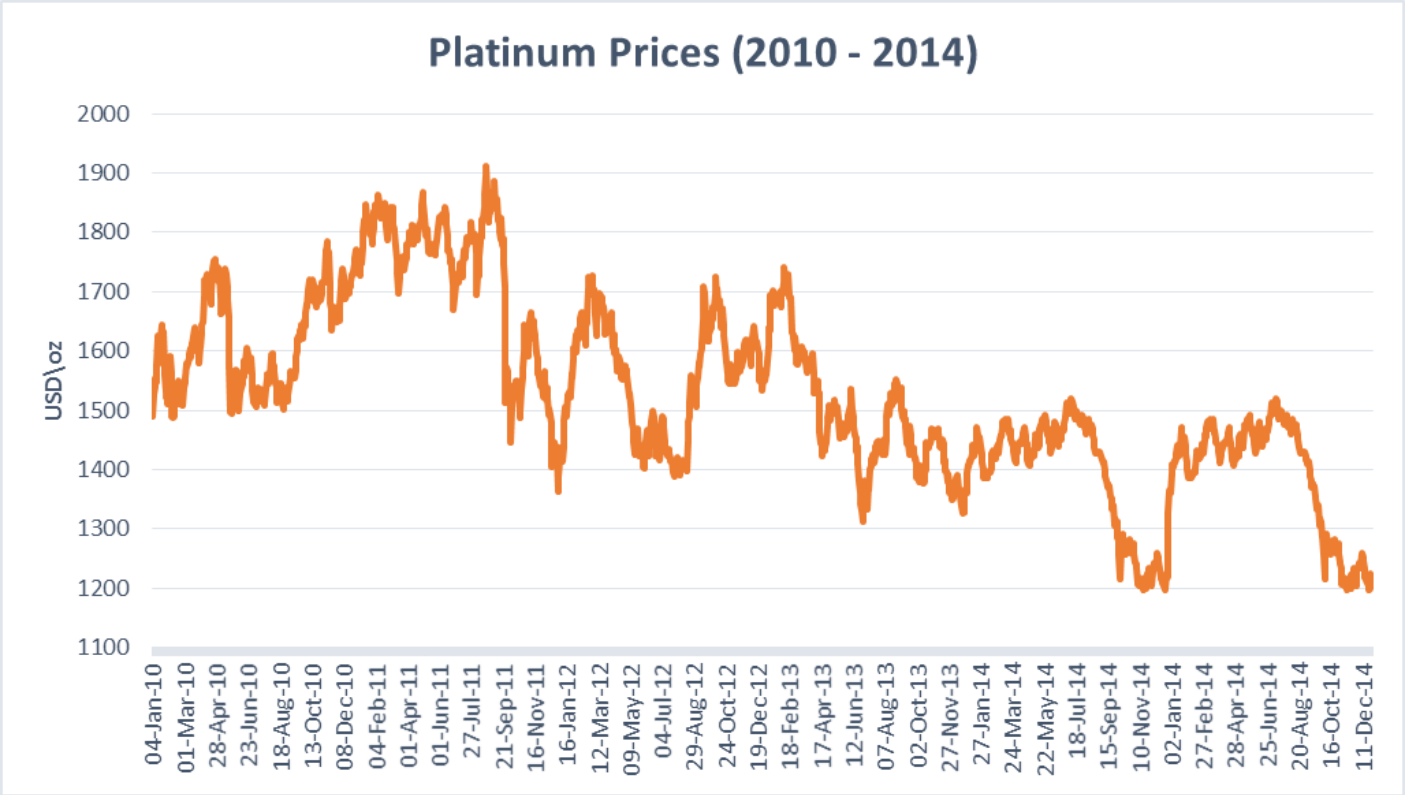

Figure 1. Platinum prices between 2010 and 2014 (adopted from Johnson Matthey, 2014)

4 POST 2012 EFFECTS IN THE PLATINUM SECTOR

As previously mentioned, the longest lasting strike action in the platinum belt ended on the 24th of June, 2014 after a five month long strike. Workers affiliated to the Association of Mineworkers and Construction Union (AMCU), which represents 70% of the work force in the platinum belt, has initiated the industrial strike action on the 23rd of January, 2014. The top three platinum companies employed around 136 000 people by the end of 2013. The AMCU workers were demanding a ZAR12 500 basic salary, an almost 30% salary increase, but employers were offering about 9%, which was higher than the inflation rate of 6.6% in June, 2014. This huge difference between what is offered and what employees' demands are could be linked to what happened in Marikana in 2012. The Marikana strike was also initiated with the same salary demand of ZAR 12 500. The strike forced all top three platinum producers to cease the operations until the strike was over as there has been some concerns about non-striking workers safety.

Post 2012, the mining sector overall became more fragile. Although no major strikes took place during 2013, workers demand for better wages continued. Wage demand related issues is only one of the challenges the platinum sector is facing; recently, the difficulties the South African platinum producers have to deal with to plan their future production are becoming very difficult to predict. These include the rising cost of labours, declining profit margins, and the possibility of falling metal prices, but the latest industrial strike action was not accounted for.

The real impacts of what happened in Marikana more than two years ago started to surface. The top three South African platinum producers have all been affected by the strikes. According to the Platinum Wage Negotiations website (2014), which was established by the platinum producing companies' revenues lost amounted to ZAR 24.1 billion while the employees' earnings lost was around ZAR 10.7 billion as of the end of the strike action on 24th of June, 2014.

In 2012, the South African supply of platinum fell to its lowest since 2001 as a result of the strikes. Failing productivity, the decline in grades, and the rapid escalating input costs also contributed to the crippling effect the mining industry experienced. Because of the rising costs of electricity and salaries, and other inputs such as the increase in fuel prices, as well as violent strikes, all three companies initiated retrenchments to become profitable again (Genc and Jerome, 2013). According to the National Union of Mineworkers (NUM) national executive committee meeting (2014) held on 24 February 2014, the after effects of major restructuring caused retrenchments of 7 450 workers at Amplats, 5 210 jobs at Implats and an estimated 3 000 jobs at Lonmin, totalling 16 660 during 2013. This was one of the expected outcomes of the 2012 strikes in the platinum belt. As the five month long strike had just ended, the consequences of the longest strike in SA's history is difficult to predict, but, similar to what followed the 2012 strike as mentioned earlier would be the most probable outcome. Figure 2 shows the strike effects on production in Lonmin's Marikana mine.

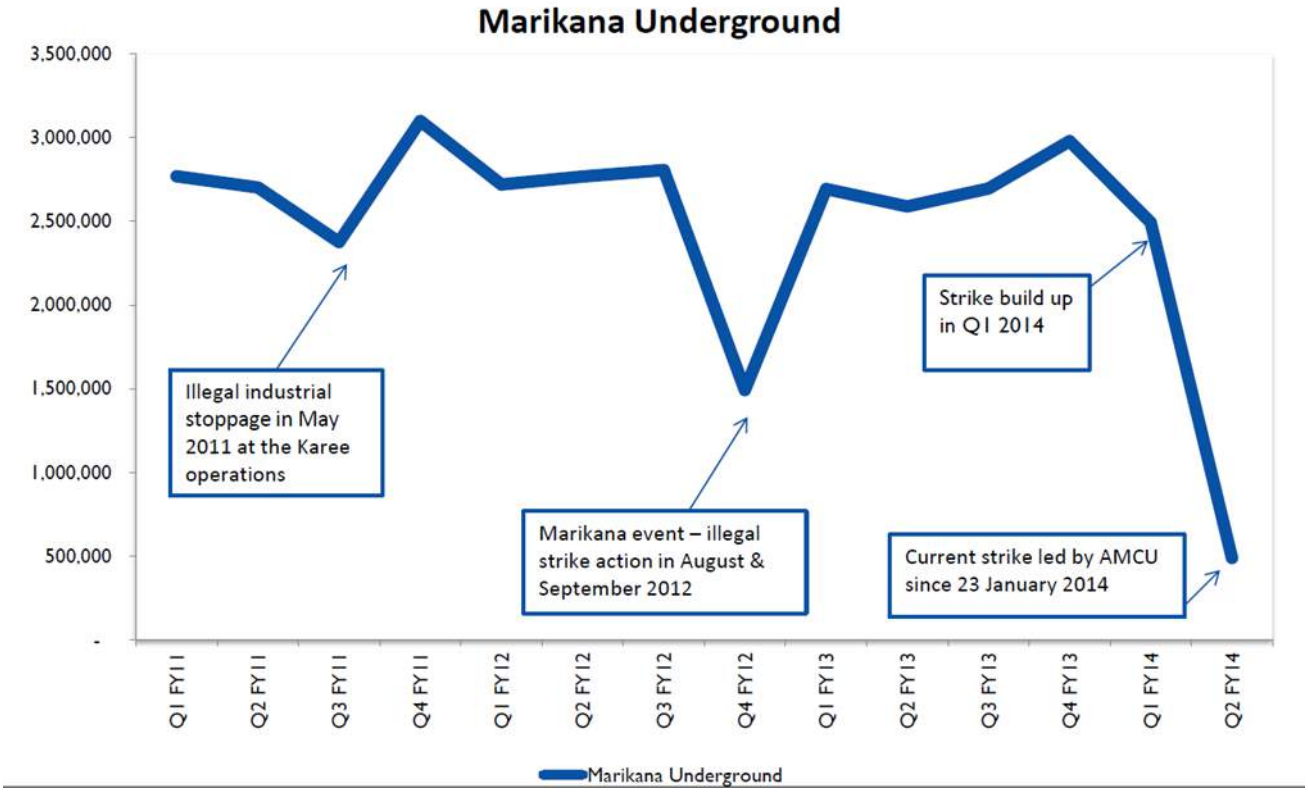

Figure 2. Strike effects in Lonmin's Marikana operations (after Magara, 2014)

The fact is that the platinum sector is in crisis as the platinum price had declined by 31% over the past five years, between 2010 and 2014. Although, at the same time, the ZAR depreciated by almost 50% against the USD, this depreciation was almost wiped away by not only the operational costs which have risen by 18%, but also above-inflation increases in fuel and electricity and annual wage increases higher than the inflation rate. One of the outcomes of the five months long strike has been the platinum price remained unchanged. The platinum price averaged at USD 1 440 during the first six months of 2014 while the strike was ongoing. Although the five months old strike was expected to have caused some platinum deficit in the market, according to World Platinum Investment Council (2014), which was established by the platinum producing companies', there are over 2.56 million ounces of platinum stockpiles at the end of the year 2014 which off-sets the supply concerns in the market. This is the reason

why the current level of platinum price is around USD 1 200 an ounce at the end of the year, 2014. In this light, it is also important to look at the financial performance of the top platinum producers.

5 FINANCIAL PERFORMANCE OF THE TOP THREE PRODUCERS IN THE PLATINUM SECTOR

In this section, the financial performance of the top three platinum producers are outlined. The financial comparisons were made using four key indicators, namely:

- Refined platinum production
- Headline earnings per share profile
- Operating profit and
- Headline profit.

The following tables (Table 1, 2, 3 and 4) show the top three platinum producers' financial performances between 2009 and 2013. As Lonmin reported its financial results in USD, an exchange rate of 7.47, 7.10, 7.36, 8.23 and 9.91 average ZAR values are used to convert the results to ZAR equivalent values, respectively.

Similar to any other business model, platinum miners also have to stay profitable to continue their core mining operations. Unforeseen circumstances such as illegal and lengthy legal industrial actions can affect profitability in a negative way. For example, the main reason behind the huge financial losses that Amplats suffered in 2012, were those illegal strikes. Figure 2 shows production related losses where the 2012 strike had a clear impact on.

Volatility in the mining industry is a well-known fact. For instance, Amplats's operating loss in the 2012 financial year amounted to ZAR 6.33 billion but in the next year, Amplats managed to turn into profit and declared ZAR 1.97 billion profit for the 2013 financial year. Similarly, Lonmin also made profit in 2013 after making a huge loss in 2012. This is a clear indication of volatility within the platinum sector. Headline earnings per share profile, operating profit and headline profit results were shown in Table 2, 3 and 4 respectively, clearly indicate the impact of the 2012 strike, hence the volatility within the platinum mining sector.

Table 1. Refined platinum production (000's) ounces

	2009	2010	2011	2012	2013
Amplats	2 464	2 484	2 410	2 219	2 320
Implats	1 704	1 741	1 836	1 448	1 582
Lonmin	683	706	720	701	751

Table 2. Headline earnings per share profile

	2009	2010	2011	2012	2013
Amplats	ZAR 2.89	ZAR 19.35	ZAR 13.65	ZAR -5.62	ZAR 5.56
Implats	ZAR 10.01	ZAR 7.86	ZAR 11.05	ZAR 6.85	ZAR 3.30
Lonmin	ZAR -10,38	ZAR 4,40	ZAR 9,99	ZAR -8,86	ZAR 3,09

Table 3. Operating profit (000 000's)

	2009	2010	2011	2012	2013
Amplats	ZAR 921	ZAR 7 253	ZAR 7 965	ZAR -6 334	ZAR 1 968
Implats	ZAR 8 823	ZAR 7 031	ZAR 10 193	ZAR 5 703	ZAR 2 376
Lonmin	ZAR -1 061	ZAR 1 441	ZAR 2 260	ZAR -5 777	ZAR 1 457

Table 4. Headline profit (000 000's)

	2009	2010	2011	2012	2013
Amplats	ZAR 705	ZAR 4 931	ZAR 3 566	ZAR -1 468	ZAR 1 451
Implats	ZAR 6 015	ZAR 4 718	ZAR 6 639	ZAR 4 151	ZAR 2 001
Lonmin	ZAR –1 808	ZAR 866	ZAR 2 009	ZAR -3 374	ZAR 1 695

When compared Table 1, 2, 3 and 4 all show that the companies' selected financial indicators were the lowest in 2012 due to the illegal strikes. Since then the metal price has not fluctuated much and the last five years (2010 to 2014) average metal price was around USD 1 554. The drop in the platinum price also affected operating profit (Table 3) negatively over the last five years. The full year earnings for all the three producers for the year 2014 is expected to be lower than the 2013 levels.

6 CONCLUSION

The post 2012 affects in the platinum sector is outlined in this paper. The platinum sector in South Africa is facing extreme pressure on the profit margins. The fact is that the platinum sector is in crisis as the platinum price has declined by 31% over the past five years. Although at the same time ZAR depreciated almost 50% against USD, this depreciation was wiped away by not only the rising operational costs by 18%, but also above-inflation increases in fuel and electricity prices and the annual wage increases higher than the inflation rate. One outstanding fact is that, although there was a five months long strike in the platinum belt in 2014, the price of platinum has not improved and ended the year 2014 at USD 1 200 level, the lowest level over the five years. As long as the current high level of stockpiles exist, the platinum prices will not improve.

The wage negotiations are a very complex and sensitive topic. While investors are always on the lookout to find better returns, on the other hand employees demand for better wages and improved working conditions needs to be addressed. This is essential to create not only a positive work environment and right balance between the employers and the mineworkers demand but also to establish the trust between the parties involved. As long as legacy issues are not resolved, there will be a possibility for even longer strikes. One of the important facts behind the 5 months long strike was that companies' revenues lost amounted to ZAR 24.1 billion while employees' earnings loss was around ZAR 10.7 billion. To avoid future confrontations, it will be in everybody's interest to find common ground to avoid long lasting strikes through dialogue and mutual understanding.

7 RECOMMENDATIONS

It is recommended that the salary negations need to continue in good faith by considering all the facts, including legacy issues. To avoid long lasting and potentially damaging impacts of the strikes, not only employers and mineworkers need to work together to resolve burning issues, but also government as a custodian of the mineral wealth of the country needs to get involved ideally before strike action becomes imminent to find solutions. Although there is no quick fix to the current labour related problems in South Africa, nevertheless it is crucial that involved parties show good leadership during the negotiations.

Estimating the Energy Costs of Mine Equipment Using an Information System

A. R. Sayadi, J. Khademi

Tarbiat Modares University, Theran, Iran

M. A. Rahimi,

Msc Student, Tehran University, Iran

ABSTRACT The energy cost has a significant share in the total costs of mineral production. Estimation and improving the energy costs require access to the costs of all equipments used in mining production including exploitation, transportation and mineral processing. Considering the variety and wide range of equipment in this business, to figure out the costs of energy is only possible through designing and building databases for technical and economical specifications of such equipment. In the course of this research a comprehensive database has been developed that stores various specs of these equipments, particularly the equipment powers and energy costs. With the help of such data the energy cost functions of equipment are calculated. These data can be used in estimation of energy costs, selection and improvement of equipment in mining projects. Energy requirements vary considerably for any equipment and they depend on the type and the size of equipment being operated, whether it is underground or surface. The amount of energy consumption is mainly a nonlinear function of the capacity of a machine and the amount and type of the function depend on the type of the machine. For example, the energy costs for one hour work of a loading machine in open-pit mines (shovel) is a nonlinear function of the volume of the bucket, and in cable and hydraulic shovels the power would be 0.98 and 0.60 respectively.

Keywords Energy costs, equipment, mine, mill, database

1. INTRODUCTION

Energy costs represent a significant component of the total costs of operations for mining sector. The energy use in the mining sector is also a significant contributor to the world's greenhouse gas emission. Improving energy efficiency reduces greenhouse gas emission that contributes to climate changes. There are, therefore, compelling economic and environmental reasons for mining and milling operations to examine their energy consumption and costs comprehensively.

Main part of the energy in mining sector is used for exploitation and mineral processing. Studying the amount of energy consumption and its costs requires studying and reviewing the total energy consumed by various equipment used in mines and processing factories. The main subject and target of this research paper is to study the power and energy costs of various equipment used in mining and processing operations concerning their technical specs such as capacity, power, and some other technical specs. To achieve this goal and considering the variety and wide range of capacity and the large volume of technical and economical data for mining and processing equipment, a comprehensive information system, including a database and a software package, has been developed for easy and efficient application and management of this database. This database provides the opportunity to analyze the costs of energy consumed by equipment. This paper introduces this software, and presents the some functions for estimation and prediction of the amount of energy costs.

2. THE POSITION OF ENERGY IN MINING

Energy used in mining operations accounted for approximately 3.3 percent of total industrial energy use in the U.S. in 2000. The U.S. Department of Commerce reports total energy consumption in mining to be 491 trillion Btu; however, this does not include data withheld. The US Department of Energy, Office of Industrial Technologies has estimated total industry energy consumption including data withheld to be 753 trillion Btu (US. Department of Energy, 2000). This total is reported about 1,246 Trillion Btu/year in 2007 (BCS, 2007).

Equipment-level and process-level energy consumption estimates are needed because improvements in energy efficiency will be driven by improvements in mining processes and technologies.

Extraction, materials handling and beneficiation– processing can be represent as the three main stages in mining process. As shown in Figure 1 materials handling accounts for 42 percent of the energy consumed. Diesel equipment accounts for 87 percent of energy used in materials handling. Beneficiation and processing consume 39 percent of the energy in mining. Crushing and grinding activities account for 75 percent of the energy used in beneficiation and processing. The remaining 19 percent of energy in mining is consumed by extraction activities. Pumps account for 41 percent of the energy in extraction (Mining Overview, 2010).

Surface mining may extend to depths as much as 500 m. The energy used and the cost of hauling rock from such depths become important limiting factors. The five principal energy-using units in mining are drilling, blasting, loading, hauling, and ancillary processes.

The share of hauling is important, for example, for copper, hauling by truck consumes more than 54% of the total energy required in mining (IPT Mining, 2002).

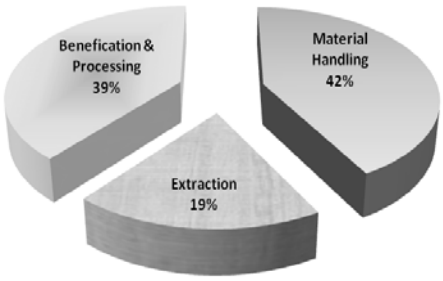

Figure 1. Estimated energy consumption by stage (percent of total energy requirements)

The total energy costs for open-pit mining for the nine operations in Canada vary from $170 per kiloton of ore mined to $3,120 per kiloton (Tab. 1) (NRC, 2005). The total cost covers drilling, blasting, excavating, hauling, pit dewatering, and mine support equipment, road maintenance and service equipment. Any in-pit crushing or re-handling of ore from stockpiles is excluded.

Table 1. The range of energy cost and efficiencies for open-pit mining in Canada

	Range High: Low
Energy cost ($/kiloton of ore mined)	3 120 : 170
Energy consumption (kWh_e/kiloton of ore mined)	42 474 : 7 006
Unit energy cost ($/$kWh_e$)	0.073 : 0.022

In processing plants, 50-70% of the energy is typically used for communication. In processing for copper, grinding and concentration consume about 45 percent of the energy used, with grinding accounting for the majority of the energy consumed.

The total energy costs for open-pit mining-Mill/Concentrator operations for seven operations in Canada vary from $105 per kiloton of ore processed to $2,367 per kiloton (Tab. 2). The total costs cover crushing, grinding, all other concentration, extraction and recovery operations, tailings treatment, process water supply, and other plant energy. Any in-pit crushing has been included with the primary crushing operations at the mill.

Table 2. The range of open-pit mining-Mill/Concentrator in Canada

	Range High : Low
Energy cost ($/kilotonne of ore processed)	2 367 : 105
Energy consumption (kWhe/kilotonne of ore processed)	35 701 : 13 144
Unit energy cost ($/kWhe)	0.083 : 0.005

Because of globalization and international competition, mineral processing plant managers seek at reducing production costs. These plants are major energy consumers and therefore energy efficiency is becoming an important objective. Other incentives are the energy cost that will probably continue to rise and the environmental and social pressures for reducing energy consumption. Using more energy efficient equipment is a first approach.

There are some general estimates of potential energy savings from attaining the performance of the most energy-efficient operations. After Natural Resource of Canada (NRC), potential annual energy savings identified with the most efficient operation for each production stage can be about one third of total energy costs. It should point out that these savings are hypothetical and may not be achievable owing to circumstances faced by each mine, i.e. the nature of the ore body, technology employed, long-term contractual obligations, etc.

In this study a database of mining and milling equipments is developed. The focus is a detailed comparison of the energy costs for open-pit mining and concentration equipments.

3. DESIGNING THE DATABASE AND SOFTWARE

Information systems and databases provide easy method for data analysis and pattern recognition. In this regard, a database related to technical and economical specs of common equipment used in mining and mineral processing along with a software package for managing this database has been designed and developed. It's needed to mention that in order to improve this software's efficiency and applicability, in addition to the costs of energy consumed by these equipment, other capital and operating costs have been taken into account as well but they are out of the framework of this paper as the main focus here is on the energy and fuel costs.

Databases are designed to support the data storage, processing, and retrieval activities related to data management in information systems (Zongin, 2006). A database is a set of files that are interrelated. It is not just a collection of files and the word "interrelated" is the keyword as these files need to be able to relate and connect to other files in the database (Whitten and Bentley, 2008). In the other word a database is an organized collection of information called data. Data are the raw numbers or basic information collected from the appropriate sources at the proper times using the correct methods to answer a question or solve a problem. These data are analyzed numerically, spatially, visually and/or statistically and converted into information (Mclemore et al., 2005). Databases are designed to support the data storage, processing, and retrieval activities related to data management in information systems (Zongin, 2006). A more rigorous definition of a database is a collection of data organized to serve many applications efficiency by centralizing the data and controlling redundant data. Rather than storing data in separate files for each application, data are stored so as to appear to users as being stored in only one location. A single database services multiple applications (Laudon and Laudon P., 2006).

Databases are handled by database management systems (DBMS) (Laudon and Laudon P., 2006). Database management systems form the foundation of most information systems. A database management is a complex multi-attribute tool that supports many types of business applications (Post and Kagan, 2001). A DBMS is simply the software that permits an organization to centralize data, manage them efficiency, and provide access to the stored data by application programs (Laudon K. and Laudon P., 2006). It is specialized computer software,

available from computer vendors, that is used to create, access, control, and manage the database. The core of the DBMS is often called database engine. The engine responds to specific commands to create database structures and then to create, read, update, and delete records in the database (Whitten and Bentley, 2008).

3.1. The Specification of Mining Equipment Database

Every database is built based on a data model. A data model is a set of tools that describe data, relations between data and meaning of data and finally is a way to describe the stages of designing the database (Silberschatz, 2006). Unified Modeling language (UML) is used to design this database. The UML Data Modeling Profile was proposed by Rational Software from IBM (Song et al.). The Unified Modeling Language has quickly become the standard language used for modeling business and software application needs (Naiburg and Maksimchuk, 2001).

Relational model is the most used data model and the most of database systems are base on this model (Silberschatz, 2006) and here in this case the relational model has been selected and considered to design this database. The equipment in this database has been categorized into four categories of surface, underground, processing and miscellaneous. In general, for each of these categories a number of technical specs are taken into account, which based on these specs the capital and operating costs data would be entered into this database. One the most important costs considered for each machine in this database is the energy and fuel costs, which based on the type of the equipment; it can be the costs of diesel, gasoline, natural gas or electricity calculated by dollar per hour of operation. Please note that a separate table is allocated for each equipment group, and a total of 309 equipment groups have been fallen into four categories mentioned above (e.g. cable shovels). Later on the expenditure data related to each type of this equipment is entered in this database. Table 3 shows a summary of the status of these groups and equipment in this database broken down by surface, underground, processing and miscellaneous. Figure 2 also shows the number of the records in each of these four categories in this database. Tables 4 and 5 display more detailed information about descriptive and expenditure data in this database.

Table 3. A summary of the status of these groups, and the types of the equipment in this database

Category	Number of Tables (Equipment Groups)	Number of Records (Equipment Types)	Number of Appendix Tables	Number of Cost Items	Number of Descriptive Items
Surface	54	349	4	4188	1396
Underground	73	503	13	6036	2012
Mineral Processing	94	1648	19	19776	6592
Miscellaneous	78	883	1	10596	3532
Total	309	3383	37	40596	13532

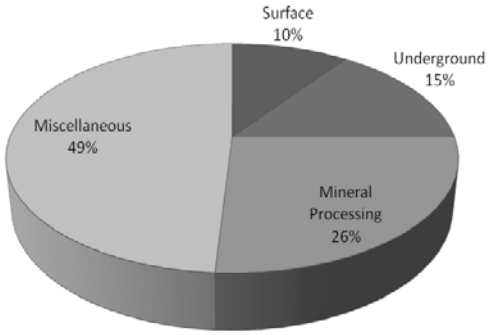

Figure 2. The number of records in each of these four categories

Table 4. Descriptive data of database

Table Names	Su_desc	Ug-desc	Milling_desc	Misc_desc
Goal	Saving Descriptive Information of Surface Equipment	Saving Descriptive Information of Underground Equipment	Saving Descriptive Information of Milling Equipment	Saving Descriptive Information of Miscellaneous Equipment
Number of Records	349	503	1648	883
Number of Fields (Column)	23	23	23	23

Table 5. Cost data of database

Table Names	Su_desc	Ug-desc	Milling_desc	Misc_desc
Goal	Saving Cost Information of Surface Equipment	Saving Cost Information of Underground Equipment	Saving Cost Information of Milling Equipment	Saving Cost Information of Miscellaneous Equipment
Number of Records	349	503	1648	883
Number of Fields (Columns)	13	13	13	13

Once the data modeling is completed and the specification of the database is defined and determined, a SQL Server platform has been used to implement the Database Management System (DBMS). Figure 3 displays a summary of the status and situation of the main tables as implemented within SQL Server.

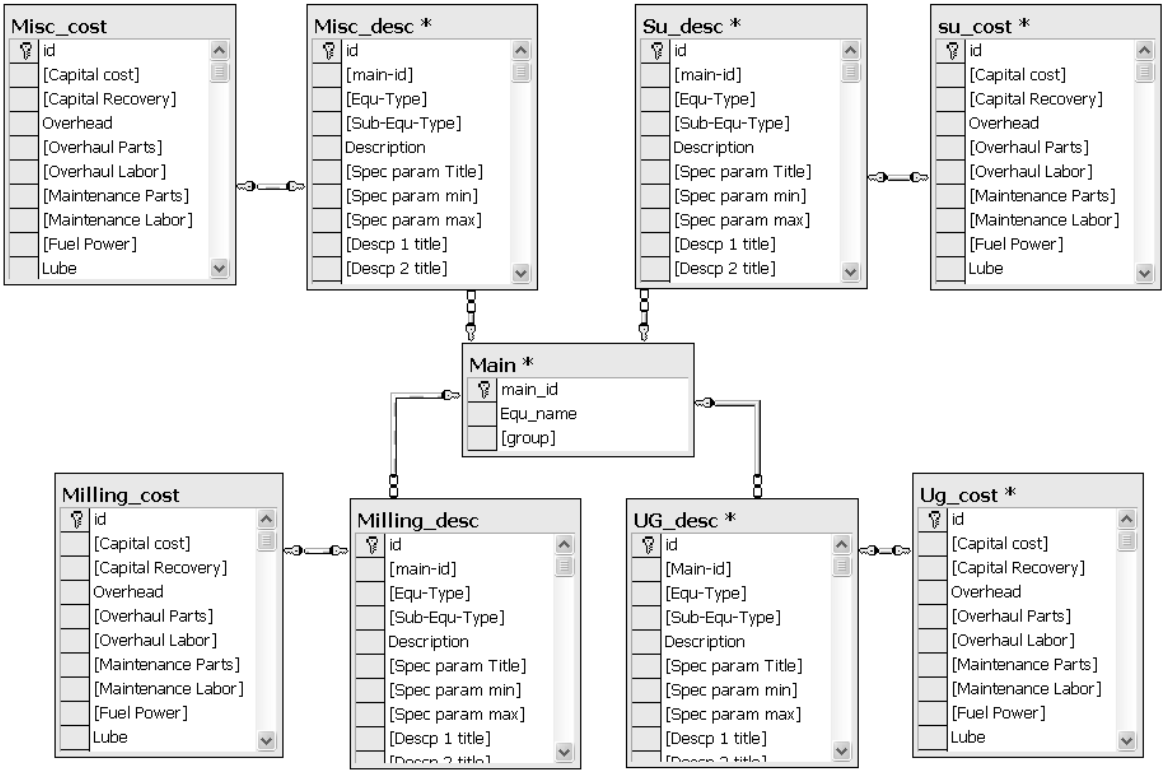

Figure 3. The relationship between the main tables in the database implemented in SQL Server

3.2. The Specification of the Cost Estimating Software

In order to improve the efficiency and capabilities of this database, an applied software package called EquipMine has been designed and installed as the front-end on the top of this database.

EquipMine is a software tool that processes, manages and provides the capital and operating costs of mining and processing equipment including the energy and fuel costs during mining operations. There are two important strong points for this front-end tool; first strong point is the great effort made in understanding the conceptual and logical models on technical and scientific basis during the course of implementation of this software, and the second one is the fact that the software has been built and implemented as simple, attractive and user-friendly as possible, and it's application is very easy yet very efficient. This software has been developed with .NET technology and the standard features in developing applied business application have also been considered in its design and implementation.

This software is designed based on 3-tiered model, which includes application layer, classes' layer and database layer. Figure 4 shows a schematic view of this model.

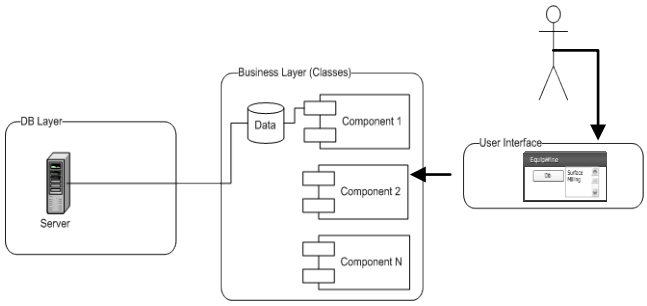

Figure 4. Architecture of EquipMine

With use and help of this software, we can assess and calculate the capital and operating costs related to each type of equipments with regards to its technical specs and data in the database. Therefore, it is possible to estimate the energy and fuel costs for all equipment working in a given mine based on dollar per hour. Figure 5 displays a sample report generated by this software in which the capital, energy and

fuel costs are displayed for selected equipment. Figure 6 also shows a sample graph created by the software in which the trend of changes in the energy and fuel costs is displayed for mill type machines based on the changes in the mill radius.

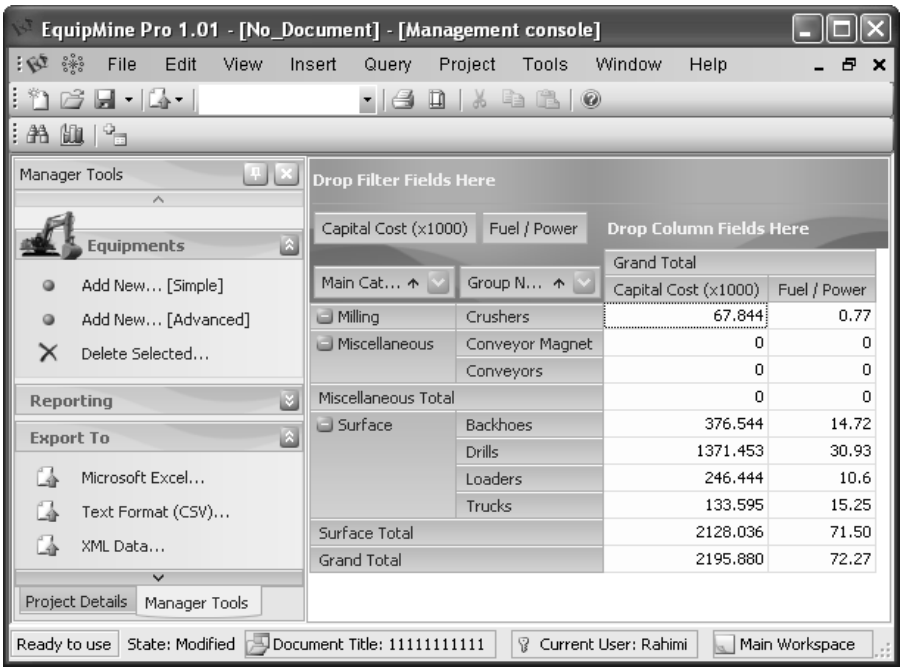

Figure 5. Sample report generated by the software

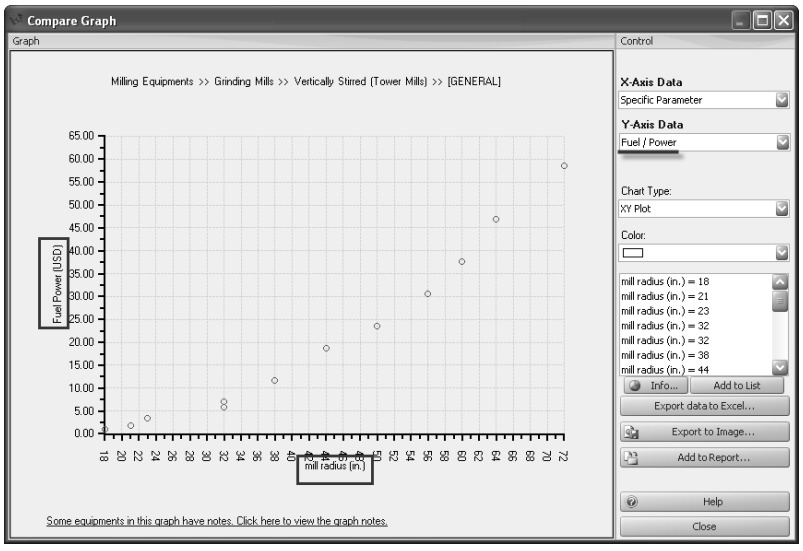

Figure 6. Sample graph created by the software (changes of hourly energy/fuel costs based on the radius of the mill)

Below is a summary of the benefits of having such software:

- Covers a wide range of mining equipment
- Few software packages exist in this area of expertise
- Multi-user capability
- Ability to adjust to the condition(s) of the country hosting the project
- Ability to update the costs using the cost indexes
- Ability to add new equipment data
- Ability to generate graphs and reports in various formats

Figure 7 also shows a summary of the main components of this software.

4. DATA ANALYZING SAMPLES

Considering the variety and multiplicity of the equipment, the energy costs for a selection of mining and processing equipment are being analyzed in this section.

4.1. Mining Equipment Shovels:

Figure 8 shows the variation of energy cost ($/h) for shovels based on the volume of their buckets broken down by cable and hydraulic shovels.

The energy cost is a nonlinear function of volume of the bucket; in cable and hydraulic shovels it would be around 0.98 and 0.60, respectively. It should be noted that the effect of rock formation property has not been considered.

Trucks:

A variety of trucks using in surface mining such as bottom-dump (mechanical), rear-dump (articulated), and read-dump (rigid frame) have been studied. The function of energy costs for rear-dump (articulated) turned out to be exponential and different from the other two (Fig. 9). Trucks using in underground mines have also been studied (Fig. 10). The energy cost is a nonlinear function of the capacity of the truck per ton and the power of 0.73.

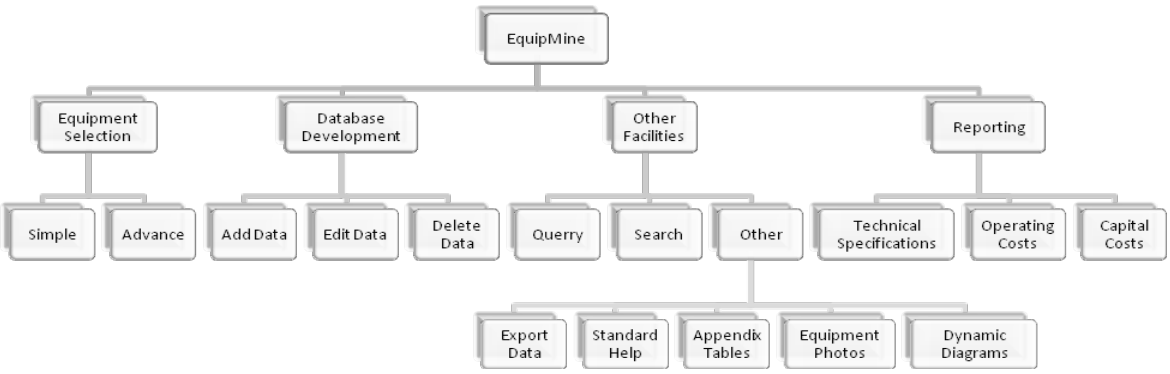

Figure 7. A schema of the main components of EquipMine software

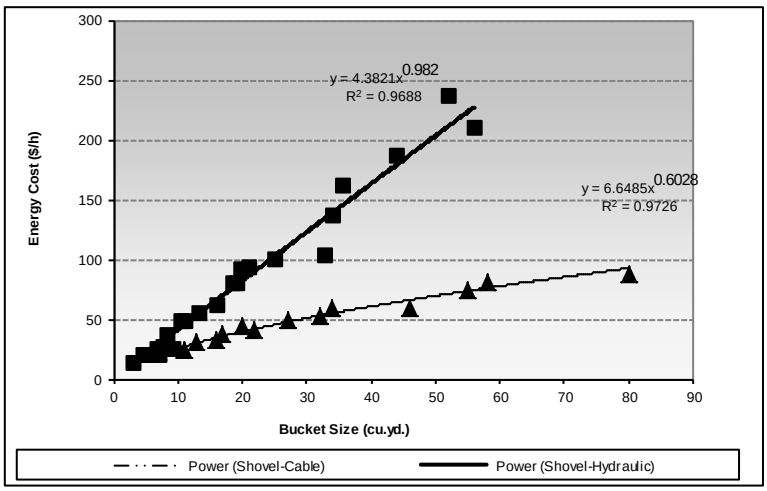

Figure 8. Energy cost vs. shovels bucket volume (cu.y.)

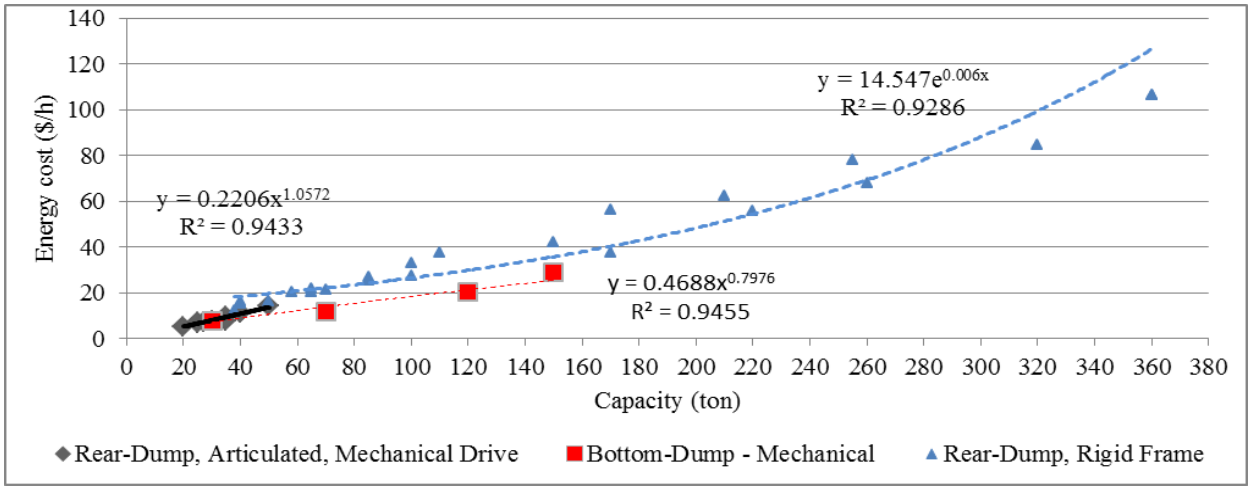

Figure 9. Energy cost vs. trucks capacity (surface mining)

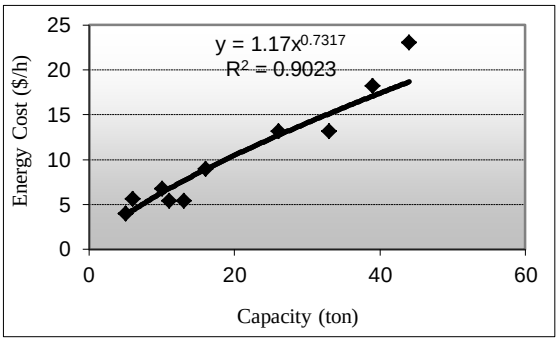

Figure10. Energy costs vs. capacity of read-dump (articulated) trucks (underground mining)

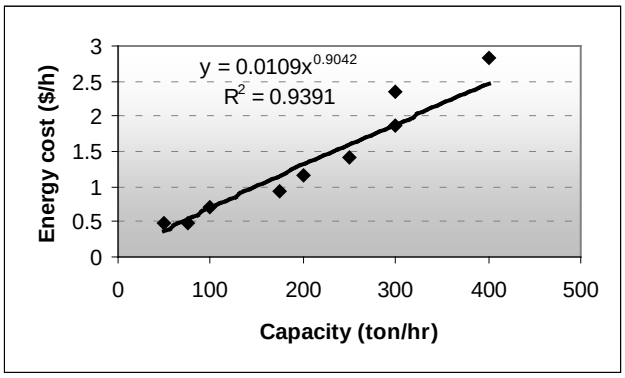

Figure 11. Energy cost vs. capacity of classifiers

4.2. The Processing Equipment

There are various and numerous equipment being used in mineral enriching processes. The energy costs of classifiers are function of their capacity (tons per hour), and it is a nonlinear function with power of 0.9 (Fig. 11). The energy costs of grinding-mill vertical machines are a function with the power of 2.8 relative to the radius of the mill (Fig. 12).

5. CONCLUSIONS

Information systems can be used as a very helpful tool in analyzing and estimating the energy costs of mining equipment. In this regard, a comprehensive database and a front-end tool have been designed and developed for technical and economical specs of mining equipment, and some functions been presented for estimation and analysis of the equipment energy costs in mining projects.

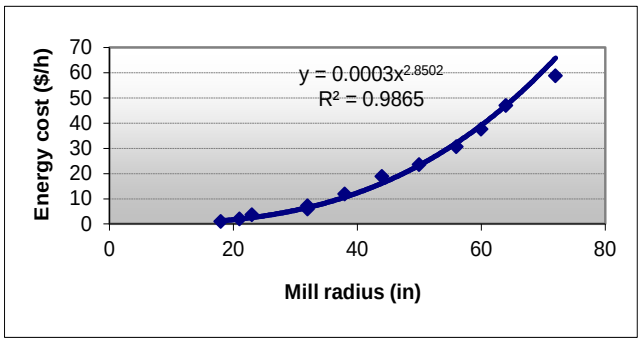

Figure 12. Energy costs vs. radius of grinding-mill vertical machines

In addition to that, this software can also be used to improve the equipment expenditures from the costs of energy point of view. The results from this study indicate that the energy costs of different equipment in relation to their capacity would show different pattern and behavior, and the cost functions clearly explain such behavior.

In this research the costs of equipment has been studied individually but it is needed to develop this software to the extent that it provides the opportunity to assess and improve the energy costs for the whole fleet of such equipment.

Indonesian Low Rank Coal Regulation: Economic Approach

T. Winarno
Ministry of Energy and Mineral Resources of The Republic of Indonesia

C. Drebenstedt
TU Bergakademie Freiberg, Sachsen, Germany

ABSTRACT The Gross Domestic Product (GDP) of Indonesia growth in the last 5 years rose to on average of 5.5 %/y, with final energy consumption grows on an average of 2.91 % per year. Moreover, the GDP growth target of more than 6 %/y, estimated energy needs in Indonesia have significantly increased. In the last forty years, Indonesian energy consumption has been heavily depended on oil fuel, and currently, Indonesia is trying to diversify energy.

One of the energy resources that can be utilized to diversify is the Low Rank Coal (LRC). Utilizations are limited due to its low heating value and spontaneous combustibility, but has low sulfur/ash content. Solution of the LRC utilization is by value-added. The value added can be done by mixing/blending, upgrading, coal gasification, coal water mix/fuel and even by coal liquefaction. So far, the value added of LRC is limited only blending/mixing to improve market demand. However, the use of the LRC relies primarily on economic and technological considerations. This paper will discuss the economics of LRC utilization based on regulation of the Indonesian government, so as to provide an overview LRC utilization opportunities in Indonesia.

Keywords: LRC, market, economic analysis

1 INTRODUCTION

Coal is a major mining commodities Indonesia. In 2013, production reached 426 million tons, or increased three times compared to 2004 (131 Million tons). More than 70% of coal production was exported, and Indonesia became the biggest steam coal exporter in the world (worldcoal, 2014). Unfortunately, the production and utilization of the LRC was not optimal yet.

LRC Classification sometimes cause confusion/trouble. Each country with a coal industry has tended to develop its own criteria in order to classify its domestic coals, often for a particular application. These classification parameters were often chosen for historical reasons (Carpenter, 1988). In Indonesia, the LRC is intended to caloric value <5,100 kcal/kg (adb). The combination of the high moisture content and high reactivity of LRC necessitate their utilization close to the mine, unless by upgraded to value-added products to improved transport safety and economics (Allardice, 2001).

Currently, the value added is a major issue in Indonesia, as contained in the Law 4 of 2009 on Mineral and Coal Mining. This means that the mineral and coal can be more beneficial for economic growth in Indonesia. For coal especially the LRC, the government will require companies doing the added value before using, with the main target for domestic needs. Some of the reasons for the needs to improve the added value are : optimizing the use of coal (conservation), meet domestic raw materials industry, improve the national economy, lead to the development of downstream industries.

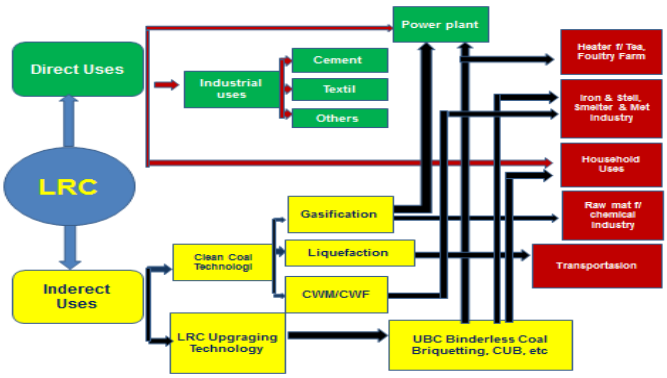

Figure 1. Indonesia LRC Management (Sihite, 2012)

In each country, the present status is that the LRC utilization technology is under development according to the situation in each country and the expected utilization in the future of low rank coal (METI, 2012). In Indonesia, LRC be used directly for the industry, cement and textile, (with or without blending), and attempted to be used indirectly as Clean Coal Technology (Gasification, Liquefaction and CWM/CWF) and LRC Upgrading or quality improvement with UBC (Upgrading Brown Coal) or CUB (Coal Upgrading Briquette Technology). The most important issue of LRC utilization in Indonesia are the economical and technology aspect itself.

With a GDP growth target of more than 6%/year, estimated energy needs in Indonesia have significantly increased and expected LRC can contribute. In order to utilize, economic calculation must be performed to assess the feasibility of the value added. Analysis and determination of the economic analysis/feasibility are done by using the criteria : *Net Present Value* (NPV), *Internal Rate of Return* (IRR), *Profitability Index* (PI), and *Discounted Pay Back Period* (PBP).

2 DOMESTIC MARKET OF THE LRC

Indonesian energy consumption increased from 764 million Barrels Oil Equivalent (BOE) in 2000 to 1,079 million BOE in 2012, a rose of an average 2.9%/y. The largest share of energy demand are industry sector (34.8%) followed by the household (30.7%), transportation (28.8%), commercial (3.3%), and other sector (2.4 %) (BPPT, 2014). While the type of energy used, the oil fuel is still dominated by 38.86%, coal 22.44%, biomass 18.36%, gas 16.87%, hydropower 2.1%, Geothermal 1.08%, and biofuel 0.29% (EMR, 2013). Expected in the future, the role of coal and gas are increasing, while the role of oil fuel decreases, as according by Presidential Instruction No. 5 of 2006 on the Energy Mix.

2.1 Direct Uses

2.1.1 Power plant

Coal is one of the primary energy for power plants. In Indonesia (2013), 52 % of the power plants using coal or about 65 million metric ton of coal burned. Coal used consist of 9 million metric tons of High Rank Coal (HRC), 31 million metric tons of Medium Rank Coal (MRC) and 25 million metric tons of LRC (3800-4500 kcal/kg GAR). Currently, the electrification ratio around 79 % or only 680 kWh/capita and Indonesia will add 60 GW additional capacity period of 2013-2022, consist of 38 GW coal fired (Nasri, 2014).

2.1.2 Cement, textile and others industries

The industrial sector is the largest energy user in Indonesia in 2012, and shows the numbers continue to rise. All industries showed a significant increase in production, although coal has not been widely used. The main industries that use coal is cement. With a production of 60 million metric tons of cement, requires about 7.8 million metric tons of coal per year, consisting of 0.55 million metric tons of HRC, 5.2 million metric tons of MRC and 2.05 million metric tons of LRC. In the last 10 years (2002-2012), the industry grows by 6%/y (Indusrty,

2012). Other industries have not used the LRC for its energy supply.

2.2 Indirect Uses

2.2.1 Upgrading

Coal upgrading technology (UBC/CUB) is one option for the utilization of LRC by reducing the moisture content so that it will directly increase the calorific value of the coal. With higher caloric value of the coal can respond to market needs, especially power plants that already exist, and others industrial sector. With growth in all industries, LRC has high utilization opportunities and coal mining industries in Indonesia will continue to grow and can be contribute as an energy supplier for the country and increase the exports in the future.

Briquetting is another option of coal upgrading. Briquetting make coal an attractive substitute fuel by converting it into compact, stable and inexpensive coal (Glenn et al, 1989). Briquettes can be substituted for firewood, even kerosene and LPG. Briquettes can be used for small industry and households, poultry farm, restaurant and others.

2.2.2 Clean coal technology

2.2.2.1 Gasification

Coal gasification is the technology for high-efficient conversion and utilization of coal (Yiman, et.al, 2013). The methods for producing gas from coal are numerous (James, et.al, 1984). Gas production in Indonesia (2012) has reached of 3,087 Billion Standard Cubic Feet (BSCF) with consumption of 1,329 BSCF (EIA, 2014). Gas distribution infrastructure constraint in Indonesia, so that utilization is not optimal yet. In general, the gasification of the LRC is not needed at this time in Indonesia

2.2.2.2 Liquefaction

The process of coal liquefaction is the process of converting coal into oil such as gasoline or diesel. This process is often termed as coal liquefaction or coal-to-liquids (CTL). There are two ways to produce oil from coal is through direct coal liquefaction (DCL) and indirect coal liquefaction (ICL), each of which has advantages and disadvantages. The results of this liquefaction process can be used as a fuel for transportation and industry. Indonesia has been cooperating with Japan in LRC liquefaction, namely Brown Coal Liquefaction.

Currently (2012), oil production amounted to 989,000 barrels oil per day (bopd), with consumption of 1,610,000 bopd. Import of oil is expected to continue to increase. Anyway, with oil production steadily declining since 2004, expected that BCL (Brown Coal Liquefaction) technology can be operated in Indonesia.

2.2.2.3 Coal water mix/coal water fuel (CWM/CWF)

CWF is a homogeneous mixture consisting of coal, water and additives, which form a slurry. CWF can not be used directly as fuel and have the nature of non-flammable, but have a flow properties such as fuel. When it will be used as a fuel must go through by another heating media (furnace). Combustion is done by using a pump to spraying the CWF furnace which has been preheated (injection system). Combustion efficiency depends on the degree of atomization of the CWF and the type used of atomization (Wall, 1987). CWM/CWF can be used as energy in several industries and even as a fuel for large ships.

Paragraph starts immediately after a heading or a gap.

3 ECONOMIC ANALYSIS

There are several models that can be used to analyze a project, e.g. the net present value, internal rate of return, profitability index and the discount payback period (Shapiro, 2005).

3.1 Net Present Value (NPV)

Net Present Value (NPV) is a method of investment appraisal, which is the present value of cash flows in the future, discounted at an appropriate cost of capital, reduced by investment cost. If there are mutually exclusive projects, the higher NPV will be accepted.

$$NPV = -Io + \sum_{t=1}^{n} \frac{CFt}{(1+r)^t} \quad (1)$$

NPV = Net Present Value
Io = investment cost
CFt = Cash flow at t period
t = the time of the cash flow
r = discount rate
n = total number of periods
Assessment Criteria :
- If NPV ≥ 0, then the project is accepted
- If NPV < 0, then the project is rejected

3.2 Internal Rate of Return (IRR)

IRR is the discount rate that results in NPV to zero or that makes the net present value of all cash flows from a particular project equal to zero.

$$0 = -Io + \sum_{t=1}^{n} \frac{CFt}{(1+IRR)^t} \quad (2)$$

Assessment Criteria :
- If the IRR is greater than the capital costs, the project is accepted.
- If the IRR is less than the capital cost, the project is rejected.

3.3 Profitability Index (PI)

Profitability Index or cost-benefit ratio is an investment appraisal technique by dividing present value of future cash flows by initial investment cost.
Assessment Criteria :
A profitability index equal to or greater than 1 is considered good. It means that the project is worth executing.

3.4 Discounted Payback Period (DPP)

The discounted payback period is the amount of time to return the initial investment cost in the form of cash flow based on total revenue minus all cost except depreciation cost.
Assessment Criteria :
If the DPP is smaller than the specified economic life of the project, the investment of the project is acceptable.

4 DISCUSSION

4.1 Coal Upgrading

With assumption of coal price US $ 24.7, investment cost US $ 133.1 million, capacity 5000 t/d, 8% of interest, operation cost US $ 10.71/t, and price of product US $ 65.7, then the economic analysis result:

No	Parameter	Result	Criteria	Decision
1	NPV	US$ 64,106,558.73	NPV > 0	Feasible
2	IRR	14.64%	IRR > 8 %	Feasible
3	PI	1.48	PI > 1	Feasible
4	DPP	8 year 10 month	DPP<15 year	Feasible

4.2 Coal Briquetting

With assumption of coal price US $ 24.7, investment cost US $ 3,125,000 million, capacity 60,000 t/d (prod : 45000 t/d) , 8% of interest,operation cost US $ 1,527,566.67, and price of product US $ 166.67/ton, then the economic analysis result:

No	Parameter	Result	Criteria	Decision
1	NPV	US$ 8,502,798.23	NPV > 0	Feasible
2	IRR	69.04%	IRR > 8 %	Feasible
3	PI	3.7	PI > 1	Feasible
4	DPP	1 year 7 month	DPP<10 year	Feasible

4.3 Coal Liquefaction

Assumption of, investment cost US $ 2,334 million, capacity 6000 t/d, 8% of interest, operation cost US $ 30.75/t (Anonymous, 2008), coal price US $ 24.7, oil price US $ 70/barrel and price of product US $ 2,122,498 (26,905 bbl/d, 234 t/d of LPG, 10 t/d of sulphur, 1.2t/d of phenol and 49 t/d ammonia) then the economic analysis result:

No	Parameter	Result	Criteria	Decision
1	NPV	US$ 1,066,677,052	NPV > 0	Feasible
2	IRR	12.48 %	IRR > 8 %	Feasible
3	PI	1.45	PI > 1	Feasible
4	DPP	13 years 1 month	DPP<25 year	Feasible

4.4 CWM/CWF

With assumption of, investment cost US $ 250 million, capacity 1,000,000 t/y, 8% of interest, price of product US $ 250 (Dedy Y, et al, 2012), operation cost US $ 65/t, and coal price US $ 24.7, then the economic analysis result :

No	Parameter	Result	Criteria	Decision
1	NPV	US$ 760,107,350.63	NPV > 0	Feasible
2	IRR	50.12 %	IRR > 8 %	Feasible
3	PI	4.04	PI > 1	Feasible
4	DPP	2 years 4 month	DPP<15 year	Feasible

5 CONCLUSION

All of increases in added value of the LRC are feasible from the results of the economic calculation. With the growth in all industries, population, and GDP growth target, making the market to increase the added value of coal is very open. However, because it involves investment and certainty of capital return, require assurance from the government to support, especially regarding the royalties (before/after the value added), market, distribution (for BCL because oil distribution is a government monopoly) and subsidies (LPG subsidies for households and small industries make briquettes difficult to growing).

A Case Study: Incongruity In Mining Laws In India

P. Kumar
Director, Ministry of Mines, Government of India

ABSTRACT The regulation of mines in India, through policy & legislation, is under a federal setup. The Constitution of India empowers the Union Government for regulation of mines and development of minerals by enacting laws expedient in the public interest. The State Governments, on the other hand, have been given powers, subject to control of the Union. Union Government has enacted the Mines and Mineral (Development & Regulation) Act, 1957 and rules thereunder, to provide for the regulation of mines and development of minerals under control of the Union. They constitute the basic laws governing the mining sector in India. The State Government has been conferred full legislative powers with regard to the minor minerals.

The mining sector in India is also required to comply with the various laws & regulations in regard to forest, environment, labour, mine safety, etc., each of them are administered by separate government agencies at Union and State level, leads to infringements, gaps, overlaps and even incongruities, in the comprehensive regulation of the mining activity.

The case study of operation of a mining lease of iron ore mines, located in the mineral rich Barbil-Barajamda belt in the Keonjhar and Sundergarh districts of the State of Odisha, will be presented to depict the interwoven laws. The case captures the interaction of the forest laws with the mining laws. The mining lease area is mostly spread over the forest, requiring the forest clearances and diversion of forest land, for the purpose of carrying out mining in the forest area.

The diversion of forest lands in India, for the non-forestry purposes (including mining), is regulated by the Union Government through the Forest (Conservation) Act, 1980, (Ministry of Environment, Forests & Climate Change), in the national interest and in the interest of future generations.

The case traverses the life cycle of the mining lease and its renewals through the various amendments in the mining laws and its incompatibilities with the compliance of the existing forest laws. The requirement of clearances and proscriptions in the mining laws lead to the impasse in mine operations.

The paper explains the problem with the help of the above case study and identifies specific points of discord. It then analytically delves to find plausible solutions by harmonizing the laws inter-se and with their field implementation.

Keywords: Mining laws, India, Concession regulations

1 INTRODUCTION

1.1 Indian Mineral Scenario

Minerals are vital raw material for development of infrastructure, capital goods and basic industries in any country. India is fortunate that it is blessed with ample resources of a number of minerals. It is globally well accepted amongst the geologists that India has the geological environment for discovery of many deep seated precious minerals. This premise is based on the assumption that India belongs to an ancient land-mass which gave many resource-rich countries like Australia, South Africa and Latin America.

1.2 Grant Of Mineral Concession And Its Regulation In India

The regulation of mines and development of minerals is undertaken in terms of the Mines and Minerals (Development and Regulation)(MMDR) Act, 1957. The MMDR Act 1957 has laid down the framework for grant of mineral concessions (Table 1, Figure 1) which have been supported by the Mineral Concessions Rules, 1960 (MCR) and Mineral Conservation and Development Rules, 1988 (MCDR), elaborating the grant procedures and the regulation of the mineral concessions

In the federal structure of India, the State Governments grant the mineral concessions for all minerals under the provisions of the MMDR Act, 1957. All minerals other than those specified in Parts 'B' and 'C' of the First Schedule to the Act are under the exclusive control of the State Governments and Ministry of Mines has no role in their grant. It is only for The 11 Atomic Minerals listed in Part 'B' and 10 Metallic and Non-Metallic Minerals listed in Part 'C' of the First Schedule to the MMDR Act (hereinafter refereed as 1st Schedule Minerals) that the State Governments require prior approval of the Central Government under Section 5 (1) of the Act for grant of mineral concession.

Table 1: Types of Mineral Concessions as per the MMDR Act, 1957

Types of Mineral Concession	Purpose
Reconnaissance Permit (RP)	For undertaking any operations for preliminary prospecting of a mineral
Prospecting License (PL)	For undertaking prospecting operations for locating or proving mineral deposit to take up mining
Mining Lease (ML)	For mining the mineral

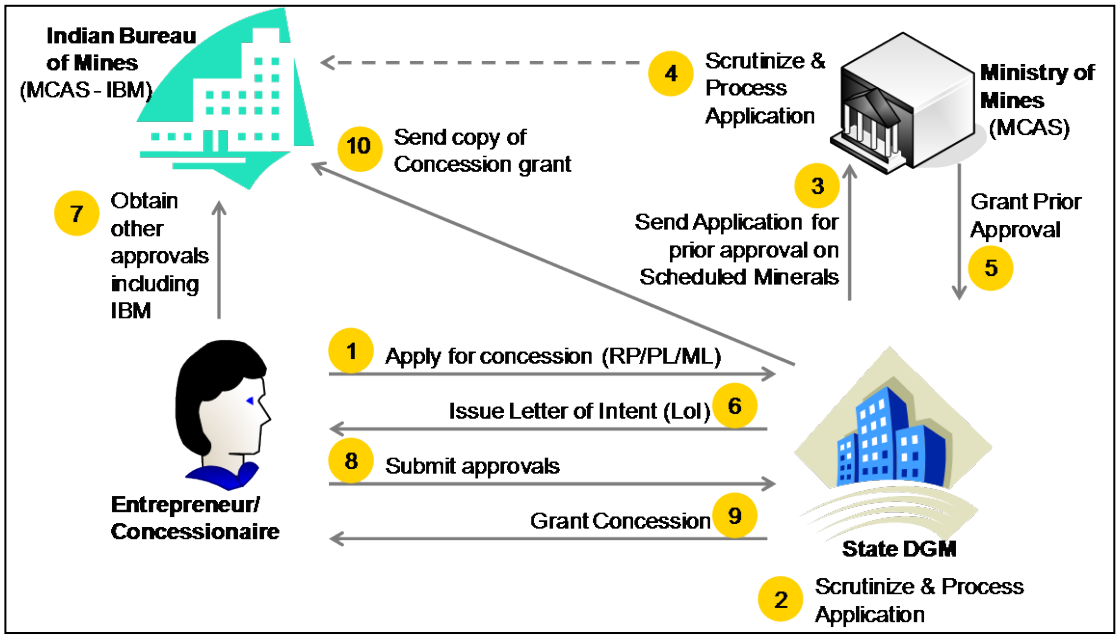

Figure 1: Process Workflow of the Grant of Mineral Concession (1st Schedule Minerals) in India

Subsequent to the prior approval of the Central Government, the State Governments grant the mineral concession, after the prospective permit holder/license/lessee has obtained necessary statutory approvals and clearances such as

- Forest Clearances, Environment Clearances, Wildlife Clearances – from the Ministry of Environment, Forest & Climate Change, Government of India governed by their respective Act and Rules.

► Approvals / clearances from other agencies like Pollution Control Board etc

1.3 CHANGES IN MINERAL CONCESSION REGULATIONS

The mineral concessions tenures are by nature have long tenures which are subject to the changing laws and legislations, governing them, in the country. The MMDR Act of 1957 has undergone several amendments, passed by the Parliament of India, of which the last one being on 12th January, 2015. The subordinate legislations - Mineral Concessions Rules, 1960 (MCR) and Mineral Conservation and Development Rules, 1988 (MCDR), are subject to continuing amendments by the Central Government from time to time, suiting the requirements for better regulation, conservation & development of the mineral sector in the country.

The changes in Mining regulations mentioned above are also subject to the associated regulations of the environment, forest, etc. as the mining sector in India is also required to comply with the various laws & regulations in regard to forest, environment, labour, mine safety, etc., each of them are administered by separate government agencies at Union and State level, leads to infringements, gaps, overlaps and even incongruities, in the comprehensive regulation of the mining activity.

The case study of operation of a mining lease of iron ore mines, located in the mineral rich Barbil-Barajamda belt in the Keonjhar and Sundergarh districts of the State of Odisha, will be presented to depict the interwoven laws. The case captures the interaction of the forest laws with the mining laws. The mining lease area is mostly spread over the forest, requiring the forest clearances and diversion of forest land, for the purpose of carrying out mining in the forest area.

The diversion of forest lands in India, for the non-forestry purposes (including mining), is regulated by the Union Government through the Forest (Conservation) Act, 1980, (Ministry of Environment, Forests & Climate Change), in the national interest and in the interest of future generations.

The case traverses the life cycle of the mining lease and its renewals through the various amendments in the mining laws and its incompatibilities with the compliance of the existing forest laws. The requirement of clearances and proscriptions in the mining laws lead to the impasse in mine operations.

The paper explains the problem with the help of the above case study and identifies specific points of discord. It then analytically delves to find plausible solutions by harmonizing the laws inter-se and with their field implementation. The problems being faced by the mining industry due the changes in

2 CASE STUDY: KASIA IRON DOLOMITE MINE

2.1 General Information

- Mine Name : KASIA
- Lessee : ESSEL MINING & INDUSTRIES LTD.
- Address : KASIA IRON DOLOMITE MINE, PO-KASIA DIST-KEONJHAR,PIN-758035, ODISHA, INDIA.
- Category : Mechanized
- Type of Working : Opencast
- First opening date : 14/09/1955
- Mineral worked : IRON ORE, DOLOMITE
- Lease area : 134.73
- Indian Bureau Of Mines, Mines Control And Conservation Of Mineral Division inspected mine on 26th July, 2011.
- IRON ORE Production in 2011: 556659 TON

2.2 Fact Sheet of Kasia Iron And Dolomite Mines

1. Original Mining Lease was granted and executed over an area of 297.444 Ha on 14.09.1955 for a period of 30 years (1955-85).

2. 1st renewal of Mining Lease application was filed on 25.07.1984 (One year prior to the expiry of the lease as prescribed by the then rules) over a reduced area of 194.196 Ha (173.039 Ha forest land + 21.157 Ha Non Forest Land) which was a part of the original lease area.
3. State Government took possession of the balance 103.248 Ha on 26.06.1986, which was not applied for renewal.
4. Ministry of Mines accorded approval on 26.10.1987 under section 8(2) of MMDR Act for grant of lease over an area of 194.196 Ha based on the recommendation of the State Government for a period of ten years (85-95).
5. State Government issued terms and conditions for grant of Mining Lease over 194.196 ha area as per approval accorded by Ministry of Mines on 16.05.1988 and Lessee accepted the same.
6. Forest Diversion proposal was applied in 1988 and recommended by State Government for diversion of total forest area of 152.229 Ha excluding the safety zone area of 20.810 ha (7.5 mtrs along the periphery of the lease which is not to be diverted as per the Forest Conservation Act Guidelines)
7. Section 8(2) of MMDR Act got amended on 25.01.1994 revising the provision of 1st renewal from two periods of ten years each to twenty years.
8. Pursuant to the revision, the Lessee applied to the State Government on 16.02.1995 prior to the expiry of the approved period of 1st renewal of Mining Lease to extend the period of renewal from 10 years to 20 years.
9. State Government recommended the request of the Lessee in October 1995 to the Government of India with a request to extend the approved lease period from 10 to 20 years.
10. Government of India in Feb 1997 returned back the proposal to State Government asking them to take action in line with the amended provisions vide notification dated 30.01.1997 authorising the State Government to grant the 1st renewal.
11. MINISTRY OF ENVIRONMENT, FOREST & CLIMATE CHANGE accorded approval over 83.88 ha of broken forest on 22.01.1998 against the approval sought over an area of 152.229 ha. On further correspondence by the State Government, the MINISTRY OF ENVIRONMENT, FOREST & CLIMATE CHANGE revised their above final approval order on 27/28.05.2004 and accorded final clearance for 83.88 ha of broken forest land and additional 30 ha of virgin forest land (total 113.88 Ha) during the 1st period.
12. The additional 30 ha land was granted considering the production rate and the balance lease period.
13. State Government issued another Terms and Conditions on 20.08.2002 for grant of Mining Lease over an area of 134.733 ha (113.88 ha forest land +20.853 ha Non forest land) which was accepted by the Lessee
14. State Government passed grant order on 09.09.2002 for grant of Mining Lease over an area of 134.733 ha. No opportunity for hearing under Rule 26(1) was given before reduction of the area.
15. The state Government also did not take over the balance area nor the lessee was asked to surrender the balance area.
16. The lessee deposited the fees for survey and demarcation of the approved area.
17. Further the lessee requested the State Government for grant of the balance area of 59.463 ha of the ML on 22.02.2003.
18. Lease Deed could not be executed during the 1st period and the Lessee continued the operations as per provision of 24 A(6) of Mineral Conservation Rules.
19. Lessee applied for diversion of forest land over entire forest area on 07.09.2004 (one

year prior to the expiry of the lease.) for the 2nd lease period.

20. Lessee has got the final Mining Plan approved over an area of 194.196 Ha area.
21. Ministry of Environment, Forest & Climate Change accorded final clearance on 18.11.2011 over the entire forest land of 173.039 ha on the recommendation of the state Government.
22. Lessee also obtained the environmental clearance for the project in March 2006 and November 2010.
23. Lessee has obtained valid consent to operate valid upto 31.03.2016.

Table 2: Chronology Of 'Mining Lease' (ML)

Date	**Activity**
14-09-55	Original ML period
19-02-83	Dolomite added over Iron Ore for the same validity of Original ML
25-07-84	Application for 1st Renewal of ML (RML) under 24(A)(1)
25-07-84	State Government (SG) forwarded to Central Government (CG) for renewal
26-06-86	SG took possession of the Lessee surrendered 103.248 ha
26-10-87	CG gave prior approval for entire area and not the reduced area but for 10 years for iron, limestone & dolomite
16-05-88	SG granted the approval area for 10 years, subject to the approval of MoEFCC (Ministry of Environment, Forest & Climate Change) for diversion of forest land
23-10-90	Company got its name changed from M/s Lal & Co to Essel Mining & Industries Ltd
18-12-94	Lessee working on the strength of SG of Odisha working permission on the forest area broken prior to 25.10.1980
25-01-94	Amendment of Section 8 read with Section 16
20-07-95	Decided to revise period of grant of 1st RML from 10 to 20 years with approval of CG
22-01-98	MoEFCC accorded final approval for mining on pre-1980 broken up forest land
17-06-99	Approval for Virgin Forest by MoEFCC
09-09-02	SG granted reduced area for for 1st RML period on the broken up forest land by MoEF and Forest Land approved by MoEFCC
13-12-02	Reduced area sent for Survey & Demarcation to Local District government unit
22-02-03	Lessee demanded for grant of entire area than the reduced area
27-02-03	Local District government unit asked for RoR & village map, which were not submitted, so the work of survey and demarcation could not be completed by the end of 1RML period, meanwhile lessee filed for 2nd RML

Table 2 (cont'd): Chronology Of 'Mining Lease' (ML)

02-09-04	Applied for 2nd RML
	Forest Land broken up in the 1st RML duration including 83.88 pre-1980 broken up forest land
02-06-08	MoEFCC granted temporary working permission on 83.88 ha for 1 year subject to 8 conditions and extended by 3 months
18-11-11	MoEFCC granted Stage II FC coterminous with the RML period
16-02-13	State DMG (Department of Mining and Geology) prepared precise area map to complete the process of 1st RML
06-09-13	State Forest Dept wrote to MoEFCC for withdrawal of FC dt. 18.11.11 & cancellation of lease as it had produced incorrect records for processing of forest diversion
10-12-13	State DMG gave memo to F&E Dept. communicating information regarding 2nd RML
28-12-13	SG wrote to MoEFCC intimated facts and asked to take necessary acion
25-01-14	SG again wrote in ref to its earlier letter to take up steps for revocation of FC
03-02-14	MoEFCC letter to SG for Map of 134.733 ha area and action taken against officials taking prior approval of 173.039 hs of forest land from GOI

3 HISTORY OF RENEWAL OF MINING LEASE REGULATIONS

The Mineral Concession Rules, 1960 which was notified vide GSR 1398 dated 11.11.1960, contained laws governing the renewal of Mining Leases, but originally did not have the provision of deemed extension. **MCR 1960 was amended on 6.5.1962** which was notified in the Gazette vide notification No. MII – 169(44)/61 dated 6.5.1963. By this amendment sub-rule (6) was inserted under Rule 28 whereby a provision of deemed extension for a period of six months was introduced. The provisions spelling out the renewal / deemed renewal status have been chronologically tabulated below-

Table 3: Chronology of Renewal / Deemed Renewal Legislations of Mining Leases

Date	**Renewal / Deemed Renewal Status**
11.11.1960	No deemed renewal
6.5.1963	sub-rule (6) was inserted under Rule 28 whereby a provision of deemed extension for a period of six months was introduced

Table 3(cont'd): Chronology of Renewal / Deemed Renewal Legislations of Mining Leases

10.2.1987	The provisions relating to renewal of mining lease which were hitherto under Rule 28 were now inserted under Rule 24A. *"… (6) If an application for first renewal of a mining lease made within the time referred to in sub rule (1) is not disposed of by the State Government before the date of expiry of the lease, the period of that lease shall be deemed to have been extended by a further period of one year or end with the date of receipt of the orders of the State Government thereon, whichever is shorter...."*
1.4.1991	The words "If an application for 1st renewal" in sub rule (6), the words "Notwithstanding the provisions of sub-rule (5), if an application for renewal" were substituted
7.01.1993	sub-rules (4) and (5) of rule 24A were omitted. This amendment also omitted the words "notwithstanding the provisions of sub-rule (5)," occurring in sub-rule (6) of the rule 24A.
27.9.1994	Amended the Sub-Rule (6) - "*(6) If an application for renewal of a mining lease made within the time referred to in sub-rule (1) is not disposed of by the State Government before the date of expiry of the lease, the period of that lease shall be deemed to have been extended by a further period till the State Government passes order thereon"* **Now provision given for Unlimited deemed renewal**
17.1.2000	The renewal of Mining Lease in Part 'C' of 1st Schedule can now be done by the state governments without prior approval of Central Government. The amendments read as *"(2) The renewal or renewals of a mining lease granted in respect of a mineral specified in Part 'A' and Part 'B' of the First Schedule to the Act may be granted by the State Government with the previous approval of the Central Government.* *(3) The renewal or renewal of a mining lease granted in respect of a mineral not specified in Part 'A' and Part 'B' of the First Schedule to the Act may be granted by the State Government."*
11.1.2002	By this amendment a proviso was inserted in sub-rule (3) which read as follows: "*Provided that before granting approval for second or subsequent renewal of a mining lease, the State Government shall seek a report from the Controller General, Indian Bureau of Mines, as to whether it would be in the interest of mineral development to grant the renewal of the mining lease.* *Provided further that in case a report is not received from Controller General, Indian Bureau of Mines in a period of three months of receipt of the communication from the State Government, it would be deemed that the Indian Bureau of Mines has no adverse comments to offer regarding the grant of the renewal of mining lease."*
18.7.2014	Rule 24A was further amended on 18.7.2014 to the effect that the provision of deemed was : (i) limited to a period of two years; and (ii) was applicable only to cases of first renewal and not to cases of second and subsequent renewal as provided for u/s 8(3) of MMDR Act.-

4 CONCLUSION

It is evident from the above discussion that the discrepancy between the area in regard to which the renewal must be granted has arisen due to incongruity of different mining laws.

Under these conditions, the lessee was claiming that taking into consideration the statutory rights of the lessee over the 1st of 194.196 ha as per the revision of the lease period from 10 to 20 years and non observance of the provisions of MINERAL CONSERVATION RULES 26 (1) while reducing the area, nor passing a reasoned order for reduction in granted area, neither taking over possession of the balance area nor asking the lessee for surrender of the balance area, the 1st period will be considered as 194.196 ha area for 20 years wef 1985 till 2005 and the Lessee is entitled to seek clearances over an area of 194.196 ha during the 2nd period.

The Rule 24A of the MCR, was further amended on 18.7.2014 to the effect that the provision of deemed was : (i) limited to a period of two years; and (ii) was applicable only to cases of first renewal and not to cases of second and subsequent renewal as provided for u/s 8(3) of MMDR Act. Thus, taking away the right of any further second renewal from the Lessee.

The Ordinance for amendment of the MMDR Act 1957 promulgated on 12th January, 2015, provides by way of its Sub-Section 5 and 6 of Section 8(a) that the Mining Leases would be deemed to be extended from the date of their last renewal to 31st March, 2030 (in the captive miners) and till 31st March, 2020 (for the merchant miners) or till the completion of the renewal already granted, if any, whichever is later. Thus, no Mining Lease holder is likely to be put into any disadvantaged condition. It is expected that this would immediately permit such closed mines to start their operations, of course, subject to the necessary clearances like forest and environment.

Coal Cities: Characteristics, change and forms of intervention
Kömür Kentleri: Karakteristikler, değişim ve müdahale biçimleri

Ş. Işın
Bülent Ecevit Üniversitesi, Siyaset Bilimi ve Kamu Yönetimi Bölümü, Kentleşme ve Çevre Sorunları Anabilim Dalı, Zonguldak

ABSTRACT Coal cities comprise characteristic urban context mainly based on the relationship between production and urbanization. Apart from taking into consideration of local, geographical and social idiosyncracies, studies on coal cities bring forth some common characteristics in terms of demographic characteristics, economic characteristics, production culture, solidarity networks, social identity, all inscribed in urban space socio-spatially. Hence, coal cities remain as a subject for interdiciplinary research.

Coal cities and coal mining regions, as old industrial regions, have experienced dramatic urban and regional change due to changes in terms of production process, introduction of new technologies and new environmental legislation related to coal and also introduction of new energy sources. This conceptual paper will study the main characteristics of coal cities, the impacts of change on coal cities socio-spatially and main forms of intervention to coal cities as part of urban and regional restructuring as responses relying on an in-depth literature review.

Keywords: Coal cities, Zonguldak, socio-spatial

ÖZET Kömür kentleri temel olarak üretim ve kentleşme arasındaki ilişkiye dayalı olarak karakteristik bir kentsel bağlam içerirler. Yerel, coğrafik ve sosyal kendine özgülükler dışında, kömür kentleri üzerine olan çalışmalar, tümü sosyo-mekânsal olarak kentsel mekân içerisine kazılı olan demografik karakteristikler, ekonomik karakteristikler, üretim kültürü, dayanışma ağları, sosyal kimlik gibi bazı ortak karakteristikleri öne çıkarırlar. Dolayısıyla, kömür kentleri, disiplinler arası araştırmaya konu oluştururlar.

Kömür kentleri ve eski endüstriyel bölgeler olarak kömür madenciliğinin yapıldığı bölgeler, üretim süreci, yeni teknolojilerin ve kömüre ilişkin yeni çevresel mevzuatın ortaya çıkışı ve yeni enerji kaynaklarının da bulunması açısından ortaya çıkan değişimler nedeniyle çarpıcı kentsel ve bölgesel değişimler geçirmişlerdir. Bu kuramsal çalışma, kömür kentlerinin temel karakteristiklerini, sosyo-mekânsal olarak değişimin kömür kentleri üzerine olan etkilerini ve değişime verilen karşılıklar olarak kentsel ve bölgesel yeniden yapılanmanın bir parçası olması açısından kömür kentlerine olan temel müdahale biçimlerini derinlemesine literatür taramasına dayalı olarak inceleyecektir.

Anahtar Kelimeler: Kömür kentleri, Zonguldak, sosyo-mekân

1 SOCIO-SPATIAL CHARACTERISTICS OF COAL CITIES

Production, working practices, coal reserve or basin as resource play preliminary roles in emergence of urban set-up and urbanization process in coal cities. Coal cities or coal mining regions define an employment structure mainly based on coal mining and complementary economic activities.

The spatial division of labor and industrial production characterize the socio-spatial pattern of coal mining cities. Coal mining towns embody characteristic socio-spatial

structures in close relation to industrial production and production culture. The social structure of mining communities, excluding context-dependent and place-specific differences, comprises strong binds, an understanding of solidarity and social identity in relation with hard working conditions, labor class consciousness and trade union tradition (Massey 1984, Işın 2009).

Coal mining remained and was perceived as one of the main engines for national economic growth. It generally integrates with heavy industry, particularly iron and steel manufacturing industry and energy production via coal burned thermal power stations. Thus, the spatial and employment structure at the urban and regional scales is dominated by the main industry, such as coal mining industry and directly related complementary industries (Massey 1984, Işın 2009).

Specific structures based on economic and social relations characterize the coal mining areas and they reveal spatial division of labor (Massey 1984). Massey (1984) discusses specific social and economic structures and their characteristics on South Wales Case, in the UK. Self-conception and identification with working practices have remained characteristic to coal mining areas and they are associated with specific social relations brought by working practices (Massey 1984). Toughness of the work, masculinity, collectiveness as a basis for labour movement, labour power and solidarity have been emphasized as some of those social relations embedding in working practices.

Especially in coal mining towns where the preeminence of a single industry is evident, domination of male labor prevails (Massey 1984) and consequently, there remains shortage of both job opportunities for female labour and alternative jobs for male labour as well as the deficient number of local small firms (Massey 1984). Poor housing and lack of higher ordered services are also mentioned as other common characteristics of some coal mining localities (Spooner 1991).

As specific cases, coal-mining towns characterize social and economic insularity (Turner 2000) within a not much diversified regional economic base.

Old coal mining regions carry characteristics of nineteenth century industrial production associated with specific socio-spatial characteristics. Accordingly, spatial division of labor, relationships between industrial production and the spatial pattern exhibit the specific spatial characteristics of these localities. This type of industry shapes socio-spatial structure with respect to urban macro form, transportation network and urban land regarding industrial production and the resource, coal. Coal mining industry as complementary to iron and steel industry embeds in a relatively isolated socio-spatial structure. The citizens are miners and their families at the origin of urbanization and urban form. Therefore, changes in employment structure and also in the local economic base reveal chances to observe spatial change consistently (Işın 2009).

As engines of national growth, coal mining and complementary industries once acted as the prominent industrial activities in industrial development. Development economics and interventionist developmental states have reinforced externally driven expectations of both the local institutions and local community (Işın 2009).

In cases of coal cities, dominance of a single industry has brought forth a particular kind of social, political and community culture insular in characteristics and including a sense of community in coal mining localities within a mono structural economy (Turner 2000).

2 CHANGE IN COAL CITIES: DEINDUSTRIALIZATION AND SOCIO-SPATIAL RESTRUCTURING

Change in coal cities can be mainly discussed on the relational context of deindustrialization and socio-spatial restructuring.

Industrial change in the coal mining sector offers an opportunity to observe disintegration tendencies among geographical production clusters composed of complementary industries to coal mining industry.

Industrial change which brings socio-economic and socio-spatial change in coal mining localities have revealed impacts and responses related to their characteristics. Local restructuring in the economic, institutional and spatial dimensions interrelate with response capacity and intervention strategies which both affect and are affected by the former characteristics of old coal mining regions. A common ground to search for these impacts may show their experience of change and response capacity (Işın 2009).

Change in coal mining cities including specific socio-spatial characteristics, based on working practices and the existence of coal can bring forth deindustrialization, decline and restructuring as socio-spatial phenomena. Deindustrialization process is simply defined as the change in economic base involving decline in industrial production, hence manufacturing industry and transition to service sector with alternatives to also different forms of industrialization. Işın (2009) points out that industrial decline, deindustrialization and restructuring are interrelated and defines deindustrialization as a process of socio-economic and socio-spatial decline based on industrial decline comprising changes in local socio-spatial pattern and in old forms of development. Hence, apart from impacts of change, responses to change are also evident within deindustrialization process (Işın 2009).

2.1. Dynamics Behind Change in Coal Cities or Coal Mining Regions

As a process embodying interrelated causal processes (John and Wild 1991), deindustrialization can be examined via global economic restructuring, its repercussions at multi dimension revealing local and regional restructuring and structural changes at the national level (Işın 2009). Consistently, the dynamics behind deindustrialization can be searched through economic, social and institutional restructuring within a relational context (Castells 2005).

Old industrial regions, mainly based on traditional industries, such as coal mining, textiles, iron and steel manufacturing, vice versa witnessed industrial decline and deindustrialization and generated diverse responses to change through restructuring (Işın 2009). For the coal cities or coal mining regions, in particular, regulational change via coal content in terms of new legislation and introduction of new clean technologies, together with the rise of low carbon economies remain as evident complementary factors in their deindustrialization and restructuring processes.

2.1.1 Global economic restructuring and its repercussions: National, regional and local restructuring

Fluctuational processes within increased mobility particular to global economic restructuring (Wallerstein 1974, Jones and Wild 1991) associated with internationalization of world economy and dispersion of technological innovations (Cheshire and Hay 1989) lay behind deindustrialization process. As inseparable from economic and social restructuring, changing land use patterns and spatial division of labour are major outcomes of spatial restructuring (Massey 1984, Işın 2009). Consistently, urban decline, urban transformation and regeneration can act as components of urban change (Işın 2009). Anderson, Duncan and Hudson (1983) have stated the concept of redundant spaces relating to inner city problems, urban decline and urban decay in relation with industrial decline and deindustrialization (Işın 2009).

Different viewpoints within different theoretical approaches exist in explaining the relational bind of global restructuring with deindustrialization (Jones and Wild 1991, Işın 2009). These are the neo-

Schumpeterian approach focusing on the relationship between technical change and economic growth mainly depending on innovation and entrepreneurial activity; the Neo-Marxist approach focusing on fragmentation in the production process and change in the mode of production, accumulation and regulation and the third viewpoint revealing Castells's (2005) concept of informationalism founding on information economy and its relational context with economic and social restructuring (Jones and Wild 1991, Işın 2009).

Işın (2009) states that economic restructuring is examined in terms of three dominant theoretical frameworks, in particular the economic restructuring process in Western Europe referring to Jones and Wild (1991) and Keeble (1991). These theoretical frameworks of Neo-Schumpeterian, Neo-Marxist approaches and the one based on information economy, introduce different dimensions in evaluating deindustrialization on different scales dealing with the restructuring process. They further draw attention to the simultaneous facts taking place considering change from diverse perspectives (Işın 2009).

The first is stated to focus on the cyclic mode of industrial restructuring in relation with technical change, technological innovation and entrepreneurial activity to further reflect on either economic growth or stagnation referring to Schumpeter (1939). The second theoretical framework focuses on the mode of production, revealing transition from the Fordist mode of accumulation to the Post-Fordist/flexible mode of accumulation, as the most important dynamic behind industrial restructuring (Mandel 1975, Jones and Wild 1991). The transition has shown a shift from mass production of standardized goods in the media of assembly line and unskilled, unionized labor large in size to flexible production characterized by specialization and highly skilled labor (Jones and Wild 1991, Harvey 1999, Soja 2001). The mass production system of standardized goods and big fixed capital investments within vertically integrated large firms have characterized the Fordist mode of accumulation while collective consumption and social reproduction of labor have indicated the Fordist mode of regulation managed by the Keynesian state (Harvey 1999).

Transition from economies of scale to economies of scope is another description to inform the transition process. This process of transformation has pointed out the emergence of a new division of labor and informed the start for the deunionization process due to requisite flexible labor practices in the new industrial production process. Further, new technologies are introduced and are an important factor in the global change in organization of production and the introduction of a new division of labor (Harvey 1999).

Global change in the organization of production and technological advances have played major roles in shifts in paradigms of development and also on the social transformation process (Işın 2009). The first and second Oil Crises meant a crucial rise in energy cost in production, which could be compensated by a contraction in labor cost with high wages due to organized labor and strong trade unions (especially in the UK and the USA). Soon, low cost East and Japanese goods grounding on low cost labor invaded these markets and the need to decrease production costs as a productivity constraint has formed the main motivation behind peripherization of labor. In addition to rise in prices of energy inputs, labor unrest and wheat shortages are emphasized as other events behind deindustrialization in terms of reorganization of production (Pietrikowsky 1999). Capital has moved to areas where low cost labor is available. These events have informed the reorganization of production and a more flexible, fragmented production process is introduced (Işın 2009).

The transition to the flexible mode of accumulation has re-conceptualized the production process proliferating some sectors such as finance, production services involving insurance, advertisement, etc.,

telecommunication and research sectors while excluding some other. In this sense, traditional industries peculiar to old industrial regions such as coal mining, iron and steel manufacturing, shipbuilding and textile have declined (Castells 2005). The decline of the traditional old industries has been related to their decreasing competitiveness and the emerging new paths for competitiveness (Cooke 1995).

The third theoretical framework on the relationship between deindustrialization and restructuring is based on information economy (Jones and Wild 1991). Castells (2005) emphasizes the introduction of the universal communication system and the direct effect of information on productivity. Information, as an asset in the production process has revealed certain breaking points brought by capitalism, such as flexible management, network of firms, individualization and variety in working relations, empowerment of capital over labor--hence decline in labor movements--restructuring in global economic competitiveness in terms of capital accumulation, and management and integration of financial markets. Following these developments, he further notes that the characteristics of the new type of production are mainly based on communication and innovation transformed to a single operating system in the form of mutual dependence (Işın 2009).

Consolidations and integrations between firms are observed to act around the globe, often making investments in multi-sector business activities. Outsourcing and subcontracting type operational constraints have introduced vertical disintegration. Minimizing transaction costs has become a crucial constraint within and between firms, again referring to vertical and horizontal disintegration for further re-integration, often laying the relation of reason in formation of geographical clusters of new industrial production motivated by innovation, research and development (Scott 1986, Işın 2009).

Changes in both social organization of labour and social structure of employment are put forward in parallel to changing working process and practices as part of social restructuring. Accordingly, Castells (2005) stresses the central role of the working process for the social structure. He puts forward components of social restructuring in relation with changing working practices as the change in capability and productivity introduced by the new division of labor together with occupational variety. He further emphasizes the change in working practices and in labor beside sectoral shifts within economy in explaining social restructuring in relation to economic restructuring. Massey (1984) points out that the social composition of the workforce has changed with a tendency of increasing female labor while its distribution has preserved its importance in the changing social structure of employment (Işın 2009).

Structural changes have impacted localities in terms of their economic, social, institutional restructuring processes. In that sense, national economic restructuring and its repercussions in old industrial regions have revealed a meso-level investigation of deindustrialization and its decline impacts on the locality. On a wider scale, the repercussions of global economic restructuring have reflected on national economies as changing development policies in the context of the structural adjustment process (Işın 2009).

What has altered in national systems through transforming paths in development is a question behind the changing modes of accumulation and regulation, in particular to the role of the state in these processes. Accordingly, Castells (2005) points out the changing roles of the state in the Fordist and Post-Fordist eras through stressing that industrialization relies on a statist type of production where the state owns the surplus and aims to maximize state power while post-industrialization relies on a capitalist type of production with the aim of profit maximization. Therefore, he stresses that industrialization as a development type aims maximum industrial output and hence economic growth, and states that the main objective in industrial society is the

production and distribution of energy while for post-industrial society, it is stated to be information and information technologies in improving productivity as new dynamics.

The industrial era is pointed out to be based on the link between mass consumption and mass production and this link is outlaid by the close relationship between productivity growth and real wage income referring to Fordist mass production and the relations between capital, unions and the state referring to Fordist mass consumption (Bowles, Gordon and Weisskopf 1983, Pietrikowsky 1999 and Piore and Sabel, 1984). The weakening of the developmentalist state, hence statism, and its regulational role are stated to be undermined within an integration process with global capitalism (Castells 2005). The role of the state as the entrepreneur and the investor in industrial development has in a way come to an end (Işın 2009).

Winterton (2003) has characterized the 1980s by a period of deregulation informing the fall of the Keynesian state and its failure in managing crisis together with a crisis of investment leading to stagnating productivity in manufacturing industry in the 1980s accompanying a dominancy of neoliberal policies. The restructuring process brought by economic globalization is on the agenda since the 1980s through the changing national economic systems, organizational structure of production process, changing capacities and capabilities as well as changing tools and intervention areas for development. The extent of response to this restructuring process has remarked the existence of localities/regions/nations in the network constructing the global capitalist economy (Işın 2009).

Deindustrialization, with its relation to disinvestment and also deunionization has formed complementary developments within the national economic restructuring process. Deregulation remains as an evident part of this process in the neo-liberal climate. Transition from import substitution to export led development strategies has marked changing economic and development models especially starting with the 1980s under the influence of the neo-liberal wave. Deregulation, deindustrialization and privatization have dominated the agenda that changed regulational constraints on subsidy transfers, public spending and investment structures. Apart from distributional constraints, a decline discourse has started to be coded on old industrial regions with high production costs and organized labor, which leads to deindustrialization, disinvestment and deunionization processes (Işın 2009).

Işın (2009) denotes that deindustrialization is complementary to processes of deunionization and disinvestment at the meso-level related to impacts of global change in organization of production, the preferences of flowing capital in form of foreign direct investment and multi-national investment on national economic systems and policies. This explanation shows the impact of globalization on national economies and further provides insight into the relationship between restructuring national economies and industrial production. This relation reveals changes in the investment and subsidy structures concerning especially the public sector in industrial production. Following the dominancy of neoliberal policies in national economies, and hence deregulation, such effects like disinvestment and deunionization are evident within national industries. In addition, the downsizing, privatization, contraction in labor force or weakening of the trade unions all provide insight on such repercussions of global economic restructuring on national industries/economies and industrial production in general (Işın 2009).

Townsend (1983) sees disinvestment as one of the dynamics behind the deindustrialization process in relation with financial circumstances and national decline in competitiveness. Also, Anderson, Duncan and Hudson (1983) relate decline in both investment and profit rates with declining employment and production in manufacturing.

The free flow of capital led by deregulation in the finance system and trade has changed investment structures of

national systems. The transnational institutions like the WB and IMF are introduced to manage free flow of capital by changing and orienting weakened developmental states to adapt to this process in terms of fiscal, monetary and distributional means in national systems. Transnational capital investments and foreign direct investments have chosen geographies of low cost labor, catalyzing fragmentation in organized labor and the deunionization process in localities (Işın 2009).

Cooke (1995) comments that the multinational investments and their locational decisions have played important roles in weakening the control of the nation-states on national economies. Global localization is used to define the activities of multinational investments in localities though investing mostly in research and design both at the micro and macro regional levels (Cooke 1995).

State-owned enterprises might be pointed out as the components in industrialization that are affected most severely. Liberalization, by means of availability of cheap imported inputs, outsourcing, and possible technology transfers by partnerships with transnational firms, have disintegrated domestic industrial regions to sustain export capacity beside upcoming new regulations on product content and quality in the global market. Participating in the global commodity chain has become a constraint for firms to be included in the global market network, especially in developing countries (Işın 2009).

Deunionization remains to be a major change as part of the social restructuring process. The deunionization process is emphasized due to its complementary consequences of fragmentation, decrease in bargaining and mobilization power and exclusion of the unions from regulations related to employment (Smith 2001) . Smith stresses that the most prominent events beneath these consequences have comprised free capital flows and changing employment relations, such as sub-contracting, as well as restructuring in legislation on employment. One other consequence is stated to be the decrease in union membership accompanied by a loss of identity. Likewise, Wallerstein and Western (2001) point out degradation of union organization and strength in relation with declining centralized wage setting practices especially after 1980 in advanced industrial societies.

Wallerstein and Western (2000) put forward demolition of centralized systems of wage-setting and labor experiencing high unemployment in Europe and highlight labor market inflexibilities contra capital flight and global competition.

Işın (2009) synthesizes that deindustrialization is discussed with reference to multi-dimensional and multi-perspective criteria and is evident to have impacts at diverse levels that concern globalization of capital emphasizing free flow of capital and changing investment structures through accelerated foreign direct investment and multi-national investment in addition to the global change in organization of production and new technologies. Accordingly, the impact of globalization on national economic systems and policies via changing national investment and subsidy policies together with deregulation process are discussed. The impacts of national economic restructuring on unionized industrial workers, hence deunionization and disinvestment at the regional and local levels are emphasized in relation with deindustrialization. Furthermore, regional impacts concerning disintegration in old industrial clusters in terms of outsourcing or use of imported raw material and changing property schemes via privatization are pointed out. These evaluations have considered macro and meso levels of change and restructuring. On micro scale, impacts on locality via local population/community, local economy and local socio-spatial characteristics acting on the whole urban set-up remain.

With regard to relational context covering socio spatial restructuring at the regional and local levels and deindustrialization, Işın (2009) highlights that socio economic and socio spatial restructuring at the local and

regional levels concern local specific characteristics having impacts on how the change is experienced, on response capacity to change and restructuring on wider scales. Characteristics of urban set-up, local economy and local population, especially local labor market have been taken into consideration as major references. The impacts of change and restructuring on the local labor market, on major economic sectors, on firms and on spatial pattern reveal the change in locality and further reveal outcomes of change and bring the response problem to change. Different experiences of several cases of deindustrialization and industrial decline serve as a common ground to reveal indicators of change defined by deindustrialization and industrial decline through impacts, outcomes, phases of transformation and response capacity (Işın 2009).

The mutual relationship between socio-economic change and spatial change gives insights to industrial and spatial restructuring processes. The impacts of deindustrialization have mainly concentrated on local economy, local population in particular to local labor market and local socio-spatiality (Işın 2009).

2.1.2. Changing regulations on coal content and its polluting effects and changing technologies

The globalization process has affected coal mining industry directly through reorganization in the production process in this sector by bringing technological changes and changing market constraints on putting new content-related regulations on coal in relation with global climate change (Işın 2009). Globalization has also had impacts on the coal mining sector through introduction of the liberalization process in energy sector, on changing state policies related to (state owned) enterprises associated with their subsidy and tax systems, and on the introduction of new capacities and capabilities, thus capital for development (Işın 2009).

Global changes concerning technological changes in the coal production process accompanied by changing legislative constraints on coal content and market changes in coal exportation are crucial in restructuring of coal production and coal mining industry (Işın 2009).

Tamzok (2007) has stressed the impacts of developments and advances in communication, transportation and distribution in the world coal sector by putting forward the impact of liberalization of electricity production on coal production due to the availability of cheap coal in electricity production and the emergence of new actors in coal production, as revealing the change in management of corporations in coal production together with intensified competitiveness in the global market. Especially the liberalization process has played an important role in segregation of domestic regional production in terms of distortion of linkages between the complementary sectors of especially coal mining, iron and steel production and coal burning thermal power stations in the domestic market (Işın, 2009).

Restructuring in coal mining industry has comprised technological change in production process and compensation for new standards for product content in order to adapt to the global coal market to meet environmental concerns on carbon and sulphur emissions (Işın 2009). International and regional environmental conventions such as Kyoto Protocol, United Nations Framework Convention on Climate Change, regional Clean Air Acts as well as introduction of low carbon economics signify regulationary base for such changes. Apart from discussed direct impacts of the globalization process on the sector and on output, globaliation also affected coal mining industry in mediation of changes at the national policy level concerning structural changes in the national system led by supranational institutions such as WB and IMF. These impacts have concerned changes in subsidy structure and changes in economic models that affect trade policies and energy policies as well. On the coal

mining side, changes in investment structure and impacts on state owned enterprises can be primarily specified followed by possible mine closures, as one of the specific outcomes of deindustrialization (Işın 2009).

WEC (2007) discusses coal use and its relational background within energy use, structural changes and environmental constraints, pointing out that relative fuel prices, government policies on fuel diversification, climate change and air pollution, together with developments in clean coal technology in power generation affect the regional coal use to a larger extent.

Early domestic industrial geographical clusters have faced a distortion in their relational context due to restructuring within the coal mining sector, by mediation of liberalization in electricity production, which intensify the use of imported coal in iron and steel manufacturing and thermal power stations.

Işın (2009: 64) synthesizes that impacts of the globalization process on the coal mining sector can be briefly specified in terms of such developments (Tamzok 2007, Yılmaz and Uslu 2007):

• "Increased competitiveness in the global market for coal resulting from the introduction of new partners, such as active multinational firms

• Changes in management and organizational set-up of firms in terms of emerging consolidations, selling, buying and integration of firms by taking advantage of scale economies with an aim to decrease their production costs

• Introduction of new global regulation constraints on coal content to manage carbon and sulphur emissions which act on climate changes and introduction of new content standards for the use and export of coal in global market

• Change in technology of coal production and coal use in other industries on phases of coal excavation, coal cleaning, use of coal in thermal power station by means of modern thermal power systems that increase the productivity of coal use, increasing quality of coal and control of waste management

• Deregulation concerning changes in legislation to include the private sector and proliferating competitiveness in the domestic market

• Changes in investment structure in favor of the private sector and to the disadvantage of state owned enterprises through subsidy cuts, privatization policies accompanied by practices and closures

• Fuel transfers in electricity production through the introduction of new alternative resources to coal"

After mentioning dynamics behind change in coal cities or coal mining regions in relation with old industrial regions, indicators of deindustrialization will be discussed. Restructuring will be taken into consideration via developing response capacity to change.

2.2. Indicators of Deindustrialization and Industrial Decline

The decline impacts of deindustrialization in coal mining regions can be put forward with reference to the intensity of these impacts resulting from the specific characteristics of these regions. The fact that these regions have narrow or single base localities may lead to deeper impacts on local population. Turner (2000) points out those significant changes in local economy, such as pit closures, create demoralizing effects on local workforce; decrease in consumer demand for locally traded goods and services, and an increase in petty crime rates (Işın 2009).

From the vulnerability perspective, change in the nature of the labor process and in work practices; in skill composition of the workforce are emphasized (Massey 1984). Removal of autonomy and individual control over the labor process as major aspects of work, solidarity and organization; increasing difficulties of working class organization by heightening heterogeneity; weakening of the trade union organization by the effect of long-term unemployment are the deficiencies in the labor process and organization of labor in relation with deindustrialization in coal mining regions (Cooke 1981, Friedmann 1977, Massey

1984). Furthermore, the new spatial reorganization of labor has changed social and spatial coherence (Massey 1984). Accordingly, Barchiesi and Kenny (2002) adds that the emergence of new forms of low-wage economy as well as employment, social exclusion, employment uncertainty, vulnerable employment, loss of rights and power are evident disempowering developments, relying on their case, Coal Rim Cluster in Northern KwalaZulu-Natal in South Africa (Işın 2009).

Mine closures, as one of the specific outcomes of deindustrialization in coal mining localities, remain vital. Apart from strikes and political conflict on the labor side, the difficulties in developing ability to take action and respond to mine closures are stated as a major problem (Camagni 1991, Nel, Hill, Aitchison, and Buthelezi 2003).

Turning to a wider frame of general discussion on indicators of deindustrialization, it can be pointed out that freeing capital from space and time has affected industrial regions and their social structures leading to the deindustrialization process. Işın (2009) states that rising unemployment and decreasing real wage on the labor side and closures, privatization experiences on the firm side in an era of increased international competition are the prominent outcomes of the deindustrialization process by referring to Anderson, Duncan and Hudson (1983), Harvey (1999) and Winterton (2003). Introduction of a new division of labor with capabilities to understand, direct and manage new rationality in a complex network of knowledge, innovation and new technologies with high mobility around the globe have defined a privileged group low in numbers with high wages and high living standards (Harvey 1999, Soja 2001) while exclusion of blue-collar labor accompanied the deindustrialization process directing them to generally low cost and non-security service sector jobs, laying a foundation for the emergence of non-capable underclass (Massey 1984, Soja 2001 and Turner 2000). Additionally, Işın (2009) highlights that the feminization of labor, including female labor in temporary low-cost service sector, has come along with the deindustrialization process and the globalization process has further enabled the re-emergence of old type informal work organizations within family production, paternalistic work organization toward informationalization by referring to Soja (2001), Harvey (1999) and Turner (2000).

Işın (2009) reviews indicators of deindustrialization by focusing on impacts and outcomes of change brought by the process. Accordingly, urban economic decline and urban depopulation remain the main indicators to assess local change in terms of deindustrialization. Changes in employment structure and contraction in labor force due to job losses in the manufacturing sector are revealed as the primary impacts of deindustrialization on localities. Thus, the main indicators of deindustrialization emerge as unemployment in relation to job losses in manufacturing employment and consequently, a decline in purchasing power or real incomes (Anderson Duncan and Hudson 1983, Jones and Wild 1991). In addition, stagnation or decline in absolute manufacturing output and dislocation of manufacturing are denoted as evident components in deindustrialization (Townsend 1983). Deindustrialization is stated to also point to a decline in percentages of active workforce and decline in the total economic output of a city in general (Helmut 1991).

The deindustrialization process has revealed decline in terms of urban set-up via urban economic decline and urban depopulation. Closures, massive lay-offs of labor, and early retirement policies remain characteristic to urban economic decline while decreasing population growth rates and increasing out migration rates have indicated urban depopulation (Işın 2009). Consequently, Butzin (1991) highlights that weak endogenous potential is complementary to urban depopulation and urban economic decline due to its relation with loss of human capital and hence poor potential for creativity. He further comments that population losses are indicated to

exceed the regional average. Likewise, Jones and Wild (1991) mention problems on social and economic capital, old infrastructure, environment, and image associated with deindustrialization in old industrial regions. Vulnerable local economy has remained as a consequence of the mentioned outcomes.

Apart from economic and social consequences of deindustrialization, environmental constraints and spatial change are characteristic (Işın 2009). Abandoned industrial buildings, contaminated and derelict physical environment, smokestack landscapes describe the imagery of decline within the context of deindustrialization (Townsend 1983). Environmental deterioration is taken into consideration as an ongoing problem associated with deindustrialization (Cooke 1995) while spatial inequalities characterize declining traditional industries (Jones and Wild 1991). Rust-belt old industrial regions are characterized with limited socio-cultural infrastructure as well as physical infrastructure; outdated housing and polluted environment with complementary social characteristics of homogeneity in terms of working practices within the domination of large industrial firms and strong trade unions (Jones and Wild 1991).

Apart from economic, social, spatial and environmental consequences of decline and deindustrialization, there are psychological consequences. Integrated in its specific social context, an economic activity and the impacts on the local community are related to wider social consequences beyond loss of income and job such as loss of hope for the future, loss of the main assets to develop one's social identity and loss of value on one's capability (Işın 2009). The high levels of disempowerment in communities through discrimination and negated opportunities are remarked within this context (Nel et al. 2003). Likewise, diminishing living standards for the working class are stated as complementary (Anderson, Duncan and Hudson 1983). In addition, diverse forms of exclusion as outcomes of long term structural poverty and unemployment are some of the mentioned results of deindustrialization in the long run (Cooke 1995, Massey 1984, Nel et al. 2003).

Işın (2009) highlights that the spatial transformation, embedded in socio-economic phenomena, hides in itself the landscapes of production that once served as the motors of economic growth with its images on the production culture and the institutional context. In this regard, the dominance of a situation of becoming "out of context" has accompanied some of the old industrial regions.

The local restructuring process is embedded in the experience of consequences of deindustrialization and industrial decline (Işın 2009). Spatial restructuring can be considered as responses to complex and multi-dimensional socio-economic changes. Spatial structures of production are observed as outcomes of integrated capital, technical and organizational characteristics of an industry and change in industrial production in terms of its organization considering technology, working practices, skills, investment and vice versa lays behind changing spatial pattern (Massey 1984).

Mass unemployment, manufacturing job losses, collapsing local economies beside to plant closures, clearance and landscaping problems reveal the reflections of deindustrialization of the 1980s (Townsend 1983). The crisis of deindustrialization severely affected old industrial regions mainly based on old industries such as textile manufacturing, resource extraction such as coal mining and iron and steel manufacturing industries and further these regions have been indicated to show structural, organizational and technological weaknesses (Jones and Wild 1991)

Deindustrialization goes beyond the negative effects and the repercussions of these effects can be set as chain reactions on other sectors and on the macro-economy (Nel et al. 2003). One other dimension of deindustrialization can be set as the common ground it shares with urban decline process.

Urban demographic change in relation with deindustrialization has been remarked in terms of negative net migration rates and declining birth rates as similar indicators of

urban decline referred by Clark (1989). Furthermore, it is acknowledged that employment losses, low capacity for regeneration, urban and national economic decline are the common indicators to discuss deindustrialization and urban decline.

The relationship between national and local concern the difference that local brings in both experiencing the impacts and responding to changes brought by national policy changes (Massey 1984). According to their local characteristics and socio-spatial characteristics, localities undergo changes in diverse ways. Therefore, their responses can also be assumed to be different. The different preexisting structures create differences in experiencing of processes of change and thus reveal different impacts and responses to change (Işın 2009).

Deindustrialization and local restructuring processes are interwoven. Restructuring, as a response to change, concerns two basic discussions. The first discussion depends on response capacity in restructuring the process considering basic characteristics of old industrial regions and relationships within intra structural actors (institutions, firms, etc.) which are discussed with reference to social capital, transformative capacity leaning on lock-in and path dependency in the development literature (Işın 2009).

The second discussion approaches the restructuring process via action oriented strategies and related policies. These provide concrete experiences related to tools, actors and further impact assessment on old industrial regions after restructuring process. As a result, it is possible to assess whether the restructuring process acts on severely affected old forms of industrial production that are integrated with socio-spatial structure and with concerned local characteristics in real terms, or whether the out of context condition of the former socio-spatial structure is excluded from new paths for development within the transformation process. (Işın 2009)

3 RESPONSE CAPACITY TO CHANGE

Reactive and pro-active actions attempted to struggle with outcomes of deindustrialization on the labor and local community sides are observed in coal mining communities. Specific buffer mechanisms that introduce survival strategies for the local community, particularly labor households, remain an important component of investigation of responses to the impacts of the deindustrialization process in old coal mining regions (Işın 2009).

Generally, the economic base of coal mining regions is not much diversified. Işın (2009) states that, monostructure has repercussions on formation of strong ties between actors and the level of vulnerability in change, thus in the restructuring process in case of a too narrow local economy in a coal mining region. To an extent, these characteristics reflect the constraints these localities experience in formation of endogenous potential in giving response to change and creating strategies to cope with the crisis condition. Accordingly, this crisis condition may be either led by structural changes, such as deregulation, disinvestment and deunionization processes, or by new technologies and new demands on environmental cost minimization on coal content, both at the state and the global scale (Işın 2009).

Old industrial regions dominated by coal mining, heavy industry, shipbuilding and textiles are stated to be most severely affected by deindustrialization and industrial decline. Likewise, for the West Germany and Britain cases Jones and Wild (1991: 16) stress that “regions with a heavy dependence on resource endowments of coal and ironstone, port-linked industries or textiles, all redolent of nineteenth century patterns of industrialization, dominate the locations of decline” in Işın (2009).

The relationship between single-industry dominance and coherence in local social structure in addition to the relationship between working practices and solidarity in coal mining localities reveal greater

resistance to change on the labor side (Massey 1984, Işın 2009).

Turner (2000) stresses the single economic base of coal mining towns and the difficulties in regeneration of these localities. Due to the specific characteristics of coal mining towns, coal mining towns reveal and lead stagnancy in terms of both economic and social dimensions within a process of change, especially when indicating a single base economy. Complementarily, the underdeveloped and disadvantageously progressed small business sector peculiar to coal mining communities; the single activity based nature of many localities associated with coal have resulted in problems for any form of economic regeneration strategy due to the dominant specific skills indigenous to working practices in coal mining industry, usually intergenerational transfer of skills, and the unvaried local economic base to motivate alternative capabilities (Turner 2000, Işın 2009).

The capability of developing endogenous potential is considered important in intervention in the restructuring process (Butzin 1991). One of the burdens of developing endogenous potential may be the inability to generate bottom-up strategies collectively. One of the reasons of such a phenomenon may present a tradition of external expectation of subsidization for a long period of time. In other words, as Massey (1984: 207) states, change in coal mining areas is in fact the change in their externally directed economic control of the means of production and possession, which is what Massey calls “pre-existing economic peripherality”.

Evaluation of response problem to decline is taken into consideration to introduce a base for why and at what perspectives in dealing with and overcoming decline in relation to restructuring. After evaluating deindustrialization, industrial decline and the restructuring process at the global and national levels, restructuring processes and their repercussions on old industrial regions, local response and local restructuring become vital (Işın 2009).

The failure and success stories in local and regional restructuring provide clues in evaluations about response capacity. The decline of old industrial regions and their restructuring problems are subjects for research in school of evolutionary technical change in economic geography, in development studies and in embeddedness literature (Hassink, and Shin 2005, Hassink 2007). Işın (2009) puts forward that declining old industrial regions can be evaluated from the three mentioned perspectives. Localities dominated by steel, coal mining, and shipbuilding have characterized resource-based mono structural areas as old industrial regions (Hassink and Shin 2005), which can be taken into consideration as specific cases in evaluation of response capacity to decline and change. Declining old industrial regions, some of which can be considered as geographical production clusters, are stated to carry characteristics of insularity mostly inferior to resource-based mono structural areas and also areas specialized in consumer goods (e.g. textiles) in particular (Steiner 1985, Hassink and Shin 2005). Also, it is interpreted that declining old industrial regions, independent of whether they exist in a geographical cluster or not, are stated to indicate a loss of regional or national competitiveness which stresses organizational structure alongside the technological changes or changes at the firm level (Porter 1990, Grabher 1993, Glasmeier 1994, Enright 1995, Steiner 1998, Hassink 2005, Hassink and Shin 2005, Hassink 2007).

The two major concepts of lock-in and path-dependency are highlighted importance while evaluating response capacity to change. In a more detailed way, these two concepts are useful in understanding characteristics defining the current situation of old industrial regions, and in finding out the relations and assets in their experience of change and in their response capacity to change (Işın 2009). Pointing out that there exists no clear definition on regional lock-in concept, Martin and Sunley (2006: 395) define path dependence as being “locked

into development paths that lose dynamism" and also as the protection against danger and against "reinvention through successive new paths or phases of development". They admit that regional path creation and path-dependence are important assets for economic landscapes in this context.

Evaluation of decline in context of industrial evolution is denoted to be considered in two ways (Grunsven and Smakman 2005). One is explained to take into consideration decline as problems of adjustment in the context of path dependency and lock-ins concerning interaction patterns between economics, political and institutional actors because they affect ability to react. The second conceptualization of decline approaches decline as a natural inevitable process based on decline of the mono structure through cumulative decline in output and further damage of the local economy through negative feedback (Boschma 2003, Grunsven and Smakman 2005).

Işın (2009) stresses that the lock-in concept is used to describe decline in old industrial areas under domination of a traditional heavy industry by referring to (David 1985, Arthur 1989, Grabher 1993, Hassink, 2005, Hassink 2007). Lock-ins are explained to act as barriers to restructuring while hindering endogenous development (Hassink 2007) and also inner potential for creativity (Hassink and Shin 2005).

Responses to failure mechanisms are mentioned to arise in three forms. Hassink (2007) affirms that renewal, as the first form, expresses a tendency for diversification and innovation oriented development interrelating with weak lock-in and quiet restructuring, reflecting low resistance to change (Hassink 2007). The second form of response is stagnation or gradual decline (Chapman, McKinnon and Cumbers 2004, Hassink, 2007). The third form of overcoming failure mechanisms is presented as adjustment referring to an attempt to preserve the existing development path while only creating significant changes to sustain the prosperity of the cluster, which is related to noisy restructuring and hence a relatively high resistance to change (Hassink 2007, Işın, 2009).

These discussions provide insight to re-evaluate decline in old industrial regions in terms of new paths in development, main strategies of renewal, adjustment, reinforcement of decline and offer information on creation of potentiality in transformation through characteristics of relationships among actors in positioning to change (Işın 2009). Old coal mining regions can be highlighted here to further look into via specific characteristics of coal mining regions and coal cities.

4 INTERVENTION ON DECLINING COAL CITIES AND REGIONS: STRATEGIES AND POLICIES

When discussing intervention on coal cities there emerge contradictory consequences of restructuring concerning the former employment structure and spatial change. Massey (1984) denotes that the main strategy of restructuring following the decline of coal mining industry is diversification away from declining sectors economically and away from the region spatially. Stressing effectiveness of diversification and multinationalization on local capital and local labor, it is also added that there is a tendency of changes in regional/local capital toward supraregional integration. Moreover, the labor side preferences of multinationals of female labor in a condition faced with redundant organized male labor is saved to be prevalent in reorganization of skills in the production process and in class structure within the locality (Massey 1984, Işın 2009).

The change in the intervention of the state in industrial development has meant much for monostructural, big public firms in relation with structural changes having a tendency of market-led policies. Thus, disinvestment policies have put pressure on big public firms while affecting the whole socio-spatial structure (Işın 2009).

The regeneration and renewal efforts in the former coal mining towns experience difficulties due to the relatively low ability

to transform. This low transformation ability could be linked to homogeneous, coherent structure characterized by working practices together with social and economic relations and strong ties specific to coal mining regions (Işın 2009). This fact is emphasized by Turner (2000) who states that local economies of old coal mining localities have very limited capacity to offer local population jobs and other economic activities after pitfalls. So in a way, special characteristics of coal mining towns are considered to act as a catalyzing factor in resistance to change and are more vulnerable in a process of change and restructuring (Işın 2009).

Regarding the difficulties in taking action against and responding to mine closures, as one of the indicators of deindustrialization in coal cities, it has been indicated that the typology of local strategic responses reveal four key stages of intervention in mine closures as attempts to preserve existing economic life, finding and expanding existing alternative local jobs, development of new activities and movement into high technological sectors (Liljenas 1992, Nel et al. 2003).

It is emphasized that intervention attempts in local restructuring and responding to impacts of deindustrialization in coal mining regions are difficult compared to that of other localities. Consequently, Turner (2000) has remarked the main problems of the inability to attract inward investment as the economically unattractive local settlement, old infrastructure, challenges brought by geography, and isolation and poor accessibility in old coal mining regions. He further comments that the regeneration strategies of coalfields through job creation via enterprise zones, via proliferating small businesses and via reindustrialization attempts are rarely successful. Nonetheless, it is acknowledged in the same article that improvements in training and infrastructure are evident in attempts to attract inward investment. Local economic change which signifies the tertiarisation process is acknowledged to offer less skilled, less income service jobs for redundant skilled labor, and security remains in question (Tomaney, Pike and Conford 1999, Turner 2000, Işın 2009).

Işın (2009) discusses that industrial change and socio-spatial change processes are mutually interacting dynamics in the restructuring process. Restructuring experiences inform intervention strategies and policies in various ways which are both affected by mechanisms on a wider scale and simultaneously impact on local and regional structures. Restructuring is evaluated multi-dimensionally. Change in old forms of industrial production, hence previous paths of development lay on common ground to the deindustrialization and restructuring processes. Işın (2009: 41) indicates that restructuring can briefly be observable through such bases:

- "restructuring in regional economy comprising restructuring of urban economic base measured via changing employment structure and occupational schemes
- restructuring within the previous economic sector itself
- restructuring within the firm: changing policies on labor, property, organization, relationship with other firms, form of capital
- institutional restructuring: trade union; availability of social capital
- restructuring within spatial pattern, urban restructuring" (Işın 2009: 41)

There exist responsive attempts to the impacts of deindustrialization that create the characteristics of a restructuring process in a locality. Restructuring appeared on the agenda in the 1980s and deepened its conceptualization in the 1990s via changing global and state policies and constraints on growth and development. Local response to such a change has included various intervention bodies, tools and policies together with joining the restructuring process in terms of inner potentialities and context-dependent local characteristics.

Işın (2009: 42) puts forward that intervention facing out coming impacts of deindustrialization concern what main strategies have put on the agenda. Accordingly, three forms of reorganization are set after deindustrialization:

• “Intensification that comprises improvements in productivity across a wide range of plants without heavy new investment.

• Investment and technical change that occurs where employment decline is accompanied by heavy net capital investment providing that the new investment leads to replacement and closure but mobile employment remains there.

• Rationalization involving complete or partial plant closures due to lack of profitability and hence leading job losses and unemployment” (Massey and Meagan 1978, Townsend 1983).

Furthermore, Martin (1989) suggests six strategies for intervention in regional and local restructuring (as cited in Spooner, 1991:123 and in Işın 2009: 42):

• “reindustrialization (most often through the development of high-tech industry);

• modernization of the existing industry

• tertiarization

• reskilling and ‘flexibilization’ of the labor force;

• infrastructure renewal

• the creation of regionally- and locally-based financial markets”

Emphasizing the relationship between economic restructuring and urban restructuring, Clark (1989) states the main intervention strategies in response to urban decline. In this sense, main points of emphasis arise as below:

• “spatial consequences of changes in size and character of the manufacturing sector

• the consequences of shift of employment

• counterurbanization as a demographic response to the locational dictates of capital

• secondary consequences of sectoral policies” (Işın 2009: 42-43)

Deindustrialization, industrial and economic restructuring give insights to urban decline and urban restructuring. Clark (1989) describes this relationship by focusing on the ceasing of agglomerative forces of the former industry. He further states three main perspectives in intervention toward urban decline. Işın (2009) summarizes them. The first is reviving the cities through revival policies in order to reverse decline. The second is recapturing the cities on aims of minimizing the harmful effects of decline and re-attracting lost population and industry by expanding the boundaries of cities. While explaining this intervention strategy, the new locational choices of industry outside the city center, especially rural areas for the UK case, was stressed. The third strategy suggested is reinforcing decline which proposes to encourage decline and orient growth to somewhere other than the old industrial and spatial structure.

Intervention strategies are subject to responding to regional change. Deindustrialization, reindustrialization and tertiarization are stated to be three mutually interacting processes indicating regional economic change in this regard, (Jones and Wild 1991). Keeble (1991: 41) briefly defines these interacting processes through an evaluation of European regional economic restructuring in the 1980s as describing deindustrialization through evident manufacturing decline, especially of employment by focusing on nineteenth century ‘smokestack’ industries (steel, shipbuilding, heavy engineering, textiles) and old industrial regions; by describing reindustrialization through small firm or new firm resurgence, often in new, less-industrialized regions and rapid growth of ‘high technology’ industry, especially based on microelectronics and widespread adoption of new computer-based technologies by existing industries and by describing tertiarisation process including growth of tourism, recreation and leisure industries (Işın 2009).

Jones and Wild (1991:18) in Işın (2009: 44) attract attention to three interrelated processes of economic development, each with their characteristic location logic and spatial division:

• “.. the creation of new industrial spaces through the medium of new types of manufacturing industries”

• “.. the application of new industrial investment to foster the reindustrialization of old industrial regions”

• "..the immense pressures for change, generated by the increased tertiarisation of the economies of selected major cities" (Jones and Wild 1991: 18) in Işın (2009: 44).

The new industrial spaces, unlike the old ones, have demands on knowledge and innovation oriented resources and capital rather than demands on raw materials and transportation (Işın 2009). Also, in spatial terms, the establishment of new industrial spaces outside the old industrial regions is stressed while old industrial regions undergo underinvestment or disinvestment (Jones and Wild 1991). Likewise, Butzin (1991) states that new industries tend to choose to establish their own spatial pattern of industry in new regional locations rather than reuse the already established industrial locations.

Alongside the disintegration in production process in geographical means, the choices of the new industries for location have comprised diverse firm size and externalities via reach to information, research and development facilities, advanced service activities and advanced technology (Butzin 1991, Jones and Wild 1991). This points to cooperation of universities and new industry as observed in technopoles and science parks (Işın 2009).

Reindustrialization of old industries is confirmed to be achieved by using processes and products of the new technology as inputs into production process of old declining industries, such as iron and steel industry (Jones and Wild, 1991: 19).

The restructuring process has come to involve two bases of intervention revealing constraints on old industrial regions:

• "..inadequate rate of generation of local businesses, especially in the high tech and information spheres"

• ".. imposition of "checks upon the types of industrial enterprises, which these regions are able to attract" (Jones and Wild 1991: 23) in Işın (2009: 46).

Işın (2009) highlights that the reindustrialization process creates a contradictory situation for the employment structure and labor working in old industries. Feminization of labor, demand for unskilled and semi skilled female labor, especially for part-time, low paid service jobs remain indicative in deindustrializing old industrial regions in this context (Jones and Wild 1991, Turner 2000).

Following the discussion on employment structure change, Jones and Wild (1991: 24) clarify the tertiarisation process by defining it as "the shift in the employment structure from industry to services-from secondary to the tertiary (including quaternary) sector-which characterizes the post-industrial period". Jones and Wild (1991: 25) also point out and relate the inner-city decline by tertiarisation process revealing decentralization of economic activity and population (Işın 2009). They further emphasize the severe socio-economic impacts of tertiarisation process on local populations in terms of decline in jobs parallel to inner urban deindustrialization in the British experience. Three key factors are evident in recovery and regeneration of British inner cities:

• "the cardinal role of property-led development schemes";

• "the pivotal role of service based activities in the employment"

• "the dominance of private capital and entrepreneurship" (Jones and Wild 1991: 25 in Işın 2009: 47).

For further evaluation of the tertiarisation process and property development schemes on old economic and social structure, attention is drawn to the conflicting situation led by them through reinforcing economic, social and spatial inequalities (Jones and Wild, 1991).

Jones and Wild (1991) evaluate the British case whose regional policy comprised enterprise-led initiatives within a deregulative structural change and immense investments in constructions of recreation, leisure, consumption spaces and offices directed to tertiarisation and the West Germany Case founding on regional policy mainly on environmental problems through retrieving and rehabilitating strategies for derelict land in the Ruhr.

Regional imbalances are stressed relying on the diverse spatial impacts and demands of deindustrialization and new

industrialization (Işın 2009). Regional economic recovery is expected to come out through utilizing diversifying regional economic development policies regarding industrial restructuring (Cooke 1995).

Cooke (1995) indicates one dynamic behind regional policies on specialization as foreign direct investment by pointing out the policy responses considering the 1990s as depending on increased regional competitiveness through integration of regional and global networks of innovation and production. In this respect, Cooke emphasizes the active roles of regional production clusters and their relations with a global network of production and innovation for regional competitiveness(Işın 2009).

Işın (2009) stresses that, having fulfilled their restructuring process so as to intervene in the impacts of deindustrialization and generate new paths for development, most Anglo-American cases have various policy responses and revitalization attempts. These examples illustrate an evident shift from heavy industries to culture industries in relation with universities, arts and culture; urban renewal practices for old heavy industry towns through image renewal; development of regional technology plans by development agencies and shift from heavy industries to cultural heritage tourism as part of urban regeneration and image renewal (Cooke 1995).

Restructuring through reinforcement of decline remains one of the strategies of regional economic restructuring in old industrial regions (Işın 2009). This strategy is characterized by no direct or real effort to reverse industrial decline as Cooke (1995) points out for South Wales Case in the UK. Stagnating government expenditure accompanied by idle regional spending that assists declining old industrial areas in the 1980s and the 1990s are given as examples of some tools for reinforcement of decline strategy (Cooke 1995). Furthermore, urban policy on private property development in addition to strengthening inward investment for new jobs are denoted to be complementary strategies. The proliferation of indigenous and medium sized firms demanding female employment is set as one of the main strategies while letting the traditional industries of coal, steel, shipbuilding or textiles decline accompanied by a large group of redundant labor. Cooke has specified this also as one of the cases of external diversification externally driven by government policies. In contrast, the internal diversification strategy comprises the inclusion of previous industrial workers in the restructuring process (Cooke 1995), which may enable reemployment of the former labor in the new industrial activities through training (Işın 2009).

Training initiatives, and governmental and private sector initiatives are indicated as possible tools of diversification through reindustrialization and revitalization (Deitrick and Beauregard 1995). Regional institutions, such as non-profit organizations that support the development of advanced technology and modernization of manufacturing, may become actors of intervention in declining industrial regions in this regard (Işın 2009).

Spatial restructuring provides insight to industrial restructuring that proliferates the new socio-economic and socio-spatial structure (Massey 1984). In the urban restructuring stage, the new demands on housing and market have remained striking in relation with the new division of labor of higher incomes (Cooke 1986, Spooner 1991, Işın 2009).

Işın (2009) lastly attracts attention to household survival strategies so as to be be considered as a response and intervention on the consequences of deindustrialization. She saves that decreasing household consumption demand and purchasing power due to contraction in the labor market motivate households to create their own survival strategies, as carrying potentialities of creation of buffer mechanisms as response to socio-economic transformation in order to slow the pace of change. Işın (2009) highlights that these buffer mechanisms are embedded in place specific characteristics and local idiosyncracies and they serve as a ground to grasp the socio-economic dimension of industrial decline at the

household level in deindustrializing old industrial regions, in particular, the most directly affected households such as in lain off blue collar labor households.

5 DISCUSSION

Coal cities and coal mining regions can be taken as specific socio-spatial contexts to look into deindustrialization and restructuring processes due to strong binds between production and division of labor and urban context. In general, the homogeneous, insular and monostructural characteristics of coal mining localities play major roles in severe decline impacts of deindustrialization which are observable mostly in urban depopulation and unemployment at the first stage and further disintegrating production linkages among interrelated sectors within industrial regions at the regional level. In relation with deregulation, disinvestment, deunionization processes, deindustrialization remains all-inclusive hiding in itself economic, demographic, socio-pscyhological and environmental impacts and indicators. When it comes to giving response to change, in particular, deindustrialization and decline, and further intervention strategies, the characteristics of coal cities or coal mining regions play major roles making them more vulnerable and more limited in the sense of developing response capacity. Apart from reindustrialization and new industrialization, tertiarization reveals the dramatic transformation from production to consumption facilities in urban economy, mainly comprising leisure and recreational facities in addition to industrial cultural heritage evident in coal museums in urban context.

Rethinking Impact Assessment of Mining Projects in the Context of Ecosystem Services

D. Damigos, M. Menegaki, D. Kaliampakos

ABSTRACT During the last years there is an ongoing discussion among scholars, both academics and practitioners, about whether it is useful to weave the concept of Ecosystem Services into the environmental assessment framework of industrial and other activities. Although it is argued that this may introduce a new level of complexity, the concept of Ecosystem Services, i.e. the benefits generated by ecosystems for human well-being, seems to becoming an important component of mainstream environmental decision making. As such, it is more than probable that mining sector will be affected in certain ways. Towards this direction, this paper wishes to contribute to a better understanding of the role of Ecosystem Services on the mining sector by providing a brief literature review and highlighting central topics with regards to potential applications, perspectives and challenges around this issue.

Keywords: Ecosystem services, impact assessment, mining

1 INTRODUCTION

It is widely established that surface mining and quarrying activities can have significant impacts of natural and social environments. Thus, mineral works are highly regulated worldwide.

One of the most common legislative requirements and obligations related to permitting of mining operations is the preparation of an environmental impact assessment (EIA) study of the proposed mining project. Typically, EIA can be defined as "*…a process for identifying the likely consequences for the biophysical environment and for man's health and welfare of implementing particular activities, and conveying this information, at a stage when it can materially affect their decision, to those responsible for sanctioning the proposals…*" (Munn, 1979).

Just like in other sectors, the implementation of the EIA process in mining activities within different countries is inconsistent. For instance, in EU countries despite commonalities in European legislation there are no common processes owing to existing and sometimes highly bureaucratic frameworks (Telfer et al., 2009). The situation is more or less the same in the USA, since the environmental legislation is different and often conflicting depending on whether it is considered under federal, state, or county regulation requirements (ibid.). Nevertheless, and apart from the differences in the details, legislation for mining-related EIA studies encompasses some common elements, such as characterization and of the project, estimation of emissions to the water, soil and atmosphere, evaluation of landscape changes, assessment of predicted impacts on abiotic and biotic environment, monitoring and mitigation of environmental impacts, consultation with the affected community etc.

In order to enhance the environmental effectiveness of current regulatory approaches, a discussion has emerged during the last years on the potential role of Ecosystem Services within the EIA framework. Ecosystem Services (ES) are the benefits generated by ecosystems for human

well-being and are at the core of modern social-ecological research, in both academia and industry, especially after the Millennium Ecosystem Assessment adopted the ecosystem approach (MEA, 2005). Nowadays, there are a few examples of seminal work that are driving this area forward (MEA, 2005; TEEB, 2011; Haines-Young & Potschin, 2013). In addition, there are some efforts towards incorporating Ecosystem Services in international and national environmental policy and guidelines or other forms of support have been produced (e.g. CBD, 2004; DEFRA, 2007a; OECD, 2008; NER, 2010; Landsberg et al., 2011; Landsberg et al., 2014; UNEP, 2014).

As mentioned by Baker et al. (2013), from the existing guidance documents, two key conclusions are drawn regarding the inclusion of Ecosystem Services in environmental assessment:

- Using ES presents a more complete, holistic and integrated consideration of the socio-ecological system.
- The ES concept is an effective framing of the environment in terms of communicating with and influencing stakeholders and decision makers.

On the other hand, it is argued that the inclusion of ES in EIA studies may introduce a new level of complexity (e.g. Chan et al., 2012). Yet, the concept of Ecosystem Services seems to becoming an important component of mainstream environmental decision making by permitting authorities and corporations (e.g. de Groot et al., 2010; Karjalainen et al., 2013).

Taking into consideration the above-mentioned remarks, it is more than probable that mining industry will be affected in certain ways from this new trend. So far, however, the discussion within the sector has been rather limited. This paper wishes to contribute to a better understanding of the role of Ecosystem Services on the mining sector by providing a brief literature review and highlighting central topics with regards to potential applications, perspectives and challenges around this issue.

2 ECOSYSTEM SERVICES APPROACHES AND EIA

2.1 Classification Systems of ES

The concept of Ecosystem Services seems attractive because it describes some of the ways that humans are linked to, and depend on, nature. For instance, describing Ecosystem Services and how humans change their capacity to deliver benefits, could help towards mapping or valuing economically the natural capital (Young & Potschin, 2013).

So far, researchers have proposed different approaches to categorize ecosystem goods and services. For example, Boyd and Banzhaf (2007) viewed Ecosystem Services as the components of nature directly enjoyed, consumed, or used to yield human well-being. Wallace (2007) defined Ecosystem Services based only on benefits people obtain from end services of ecosystems, while Fisher et al. (2009) argued that Ecosystem Services are the aspects of ecosystems utilized (actively or passively) to produce human well-being.

Internationally three classification systems are available, as shown in Table 1, and mostly recognized towards classifying Ecosystem Services, namely MEA, TEEB and CICES, which relate to a large extent to each other (Maes et al., 2013).

The Millennium Ecosystem Assessment (MEA - http://www.maweb.org) was the first large scale ecosystem assessment. The MEA classifies Ecosystem Services into four groups, namely (MEA, 2005):

(1) provisioning services (i.e., goods or products obtained from ecosystems, such as food, timber, fiber, and freshwater);

(2) regulating services (i.e., contributions to human well-being arising from an ecosystem's control of natural processes, such as climate regulation, disease control, erosion prevention, water flow regulation, and protection from natural hazards);

(3) cultural services (i.e. recreation, spiritual values, and aesthetic enjoyment); and

(4) supporting services (i.e. natural processes, such as nutrient cycling and

primary production, that maintain the other services).

The MEA framework was adopted and was further refined by TEEB and CICES. More specifically, the Economics of Ecosystems and Biodiversity framework (TEEB - www.teeb.org) proposes a typology of 22 Ecosystem Services divided in four main categories, following mainly the MEA classification: (1) provisioning services; (2) regulating services; (3) habitat services; and (4) cultural and amenity services (TEEB, 2010 & 2011). More specifically, TEEB omits supporting services, which are seen as a subset of ecological processes, while, habitat services have been identified as a separate category to highlight the importance of ecosystems to provide habitat for species and gene-pool "protectors", such as natural habitats allowing natural selection processes to maintain the vitality of the gene pool (Maes et al., 2013).

Finally, the Common International Classification of Ecosystem Services (CICES - http://cices.eu) has been developed to help negotiate the different perspectives that have evolved around the Ecosystem Service concept. It assists in the exchange of related information and offers a structure that links with the framework of the UN System of Environmental-Economic Accounting (SEEA). Thus, CICES has refined MEA framework to reflect some of the key issues that have been discussed in the wider research literature (Haines-Young & Potschin, 2013). CICES is more explicitly hierarchical in structure. At the highest level there are three familiar services used in MEA called 'Sections', namely: (1) provisioning (i.e. all nutritional, material and energetic outputs from living systems, where a distinction is made between provisioning and material outputs arising from biological or organic materials and water); (2) regulating and maintenance (i.e., all the ways in which living organisms can affect human performance by mediating or moderating the ambient environment); and (3) cultural (i.e. all the non-material and normally non-consumptive outputs of ecosystems that affect physical and mental states of people, which can involve individual species, habitats and whole ecosystems). Below these Sections are nested a series of 'Divisions', 'Groups' and 'Classes' (Haines-Young & Potschin, 2013).

A major difference between MEA and CICES is that CICES excludes the supporting services from the classification and focuses only on the provisioning, regulating and cultural components. The reason for this was to avoid the problem of 'double counting' if ecosystem and economic accounts are to be linked. Furthermore, CICES and TEEB classifications treat 'habitat services' differently. TEEB identifies them as a distinct grouping at the highest level, while CICES regards them as part of a broader 'regulating and maintenance' section (ibid.). The correspondence between these classifications as provided by Maes et al. (2013) is illustrated in Table 1.

2.2 Ecosystem Services and EIA Studies

Environmental impact assessment (EIA) is a well established procedure in the world as a means to assess the impacts of projects that can potentially impact the environment and, consequently, the Ecosystem Services provision in multiple ways. Weaving Ecosystem Services into EIA studies could enhance the impact assessment process (Geneletti, 2011). Thus, new regulatory and financial impact assessment standards require that EIA studies systematically address impacts on Ecosystem Services (Landsberg et al., 2011). However, owing to lack of guidance on how to address Ecosystem Services, and what its added value is, EIA practitioners still are not engaged to that concept (Honrado et al., 2013). As a result, the implementation of the Ecosystem Services in the context of EIA practice is still quite immature (ibid.).

Table 1. Ecosystem Services categories in MA, TEEB and CICES

MA categories	TEEB categories		CICES v4.3
Food (fodder)	Food	**Provisioning services**	Biomass [Nutrition]
			Biomass (Materials from plants, algae and animals for agricultural use)
Fresh water	Water		Water (for drinking purposes) [Nutrition]
			Water (for non-drinking purposes) [Materials]
Fibre, timber	Raw Materials		Biomass (fibres and other materials from plants, algae and animals for direct use and processing)
Genetic resources	Genetic resources		Biomass (genetic materials from all biota)
Biochemicals	Medicinal resources		Biomass (fibres and other materials from plants, algae and animals for direct use and processing)
Ornamental resources	Ornamental resources		Biomass (fibres and other materials from plants, algae and animals for direct use and processing)
			Biomass based energy sources
			Mechanical energy (animal based)
Air quality regulation	Air quality regulation	**Regulating services (TEEB)**	[Mediation of] gaseous/air flows
Water purification and water treatment	Waste treatment (water purification)		Mediation [of waste, toxics and other nuisances] by biota
		Regulating and supporting services (MEA)	Mediation [of waste, toxics and other nuisances] by ecosystems
Water regulation	Regulation of water flows		[Mediation of] liquid flows
	Moderation of extreme events	**Regulating and maintenance services (CICES)**	
Erosion regulation	Erosion prevention		[Mediation of] mass flows
Climate regulation	Climate regulation		Atmospheric composition and climate regulation
Soil formation (supporting service)	Maintenance of soil fertility		Soil formation and composition
Pollination	Pollination		Lifecycle maintenance, habitat and gene pool protection
Pest regulation	Biological control		Pest and disease control
Disease regulation			
Primary production	Maintenance of life cycles of migratory species (incl. nursery service)		Lifecycle maintenance, habitat and gene pool protection
Nutrient cycling (supporting services)			Soil formation and composition
			[Maintenance of] water conditions
	Maintenance of genetic diversity (especially in gene pool protection)		Lifecycle maintenance, habitat and gene pool protection

Table 1. Ecosystem Services categories in MA, TEEB and CICES (Cont'd)

MA categories	TEEB categories		CICES v4.3
Spiritual and religious values	Spiritual experience	**Cultural services**	Spiritual and/or emblematic
Aesthetic values	Aesthetic information		Intellectual and representational interactions
Cultural diversity	Inspiration for culture, art and design		Intellectual and representational interactions Spiritual and/or emblematic
Recreation and ecotourism	Recreation and tourism		Physical and experiential interactions
Knowledge systems and educational values	Information for cognitive development		Intellectual and representational interactions Other cultural outputs (existence, bequest)

Source: Maes et al., 2013

There are some recent efforts to provide technical guidance to address Ecosystem Services in impact assessment. These include the Convention on Biological Diversity's voluntary guidelines on including biodiversity and Ecosystem Services in impact assessment (Slootweg et al., 2006) and the OECD's recommendations on how to include Ecosystem Services in Strategic Environmental Assessments (OECD, 2008). A more sector oriented approach regarding ecosystem service dependencies for oil and gas developments has been proposed by IPIECA/OGP (2011).

Recently, a guidance manual was released by UNEP (2014), which is the output of the GEF funded "Project for Ecosystem Services" (ProEcoServ) implemented by the Ecosystem Services Economics Unit, DEPI. The methodological approach is divided into four stages each comprising two or three specific tasks, as follows:

- Stage 1: Establish the Ecosystem Services context
- Stage 2: Determine and assess priority of Ecosystem Services
- Stage 3: Identify alternatives and assess impacts on Ecosystem Services
- Stage 4: Follow up on Ecosystem Services

This approach, as mentioned, aims at integrating Ecosystem Services in Strategic Environmental Assessment (SEA). Nevertheless, provided that the ProEcoServ project wishes to integrate ecosystem assessment, scenario development and economic valuation of Ecosystem Services into development planning even at local scale, it could be applied in EIAs, as well.

The most relevant and perhaps integrated effort to establish a detailed guidance framework for EIA practitioners, namely the "Ecosystem Services Review (ESR) for Impact Assessment (IA)", has been carried out by Landsberg et al. (2011) and was recently updated (Landsberg et al., 2014). The ESR for IA approach builds on the elements and causal relations of the original MEA framework and consists of six steps implemented in following stages:

- The Scoping stage involves one step (Step 1) and aims at identifying the key Ecosystem Services that could be impacted by, or could constrain the successful implementation of, the project.
- The Baseline and impact analysis stage includes Steps 2, 3, 4 and 5 and its aim is twofold: (a) to establish baseline for key environmental and social issues and for priority Ecosystem Services, and (b) to assess project impacts and project dependencies on key environmental and social issues and on priority Ecosystem Services. More specifically, Step 2 defines the Ecosystem Services on which to conduct the impact and dependence assessments. Step 3

establishes the geographical boundaries of the ecosystem service impact and interdependence assessments and identifies indicators of impact and dependence. Step 4 determines how priority Ecosystem Services currently contribute to affected stakeholders' livelihoods, health, safety, or culture. Finally, Step 5 assesses project impacts and dependencies on priority Ecosystem Services and identifies which of these services require mitigation or management measures.

- The Mitigation stage includes the last step (Step 6) of the methodology. It aims at identifying appropriate biophysical and/or socioeconomic measures to mitigate impacts and manage dependencies on Ecosystem Services for incorporation into environmental and social management plans. These measures should be monitored and assessed against the objectives of: (a) achieving at least no loss of Ecosystem Services benefits by global and local stakeholders, and (b) ensuring planned operational performance.

So far, there are only limited examples of the use of Ecosystem Services within environmental assessment. Baker et al. (2013) summarize five EIA and SEA case studies. These illustrate a range of approaches to using Ecosystem Services in environmental assessment from Portugal, South Africa and UK. Based on the analysis of the case studies, Baker et al. (2013) discuss the major strengths and weaknesses of encompassing Ecosystem Services in environmental assessments.

Among the benefits, the authors identfy that Ecosystem Services provide a more integrated description of the environment and emphasize on wider economic benefits of certain habitats and land cover types offering alternative information to policy and decision makers, as well as to stakeholders and communities. On the other hand, it is argued that the integrated nature of Ecosystem Services presents an inherent difficulty and requires significant primary research to be undertaken to form an effective baseline, especially for valuation purposes. In addition, it is noted that only certain types of plans, programmes or projects may be relevant for using Ecosystem Services. They conclude, however, that incorporating Ecosystem Services in environmental assessment is probably more of a help than a hindrance and may help in addressing problems with current environmental assessment practices.

3 ECOSYSTEM SERVICES AND IMPACT ASSESSMENT IN MINING SECTOR

Focusing on mining activities, two general questions pertinent to the mining sector should be addressed: (a) Why should Ecosystem Services be considered in impacts assessments of mining projects; and (b) Have Ecosystem Services been used in mining practice?

3.1 Involving ES into EIAs of Mining Projects

As regards the first question, there is a number of reasons why the mining sector should become more familiar with the concept of Ecosystem Services. Firstly, it can be inferred that the concept of Ecosystem Services is becoming mainstream at all levels of environmental decision making because it provides a new way to approach environmental management (e.g. Carpenter et al., 2009; de Groot et al., 2010; Chan et al., 2012; Karjalainen et al., 2013). Secondly, this trend is reflected at the standards and requirements of organizations that are associated with the mining sector, such as the International Finance Corporation (IFC). The IFC, founded in 1956 with 182 member countries, holds equity in over 722 companies worldwide, including 184 fund management groups.. With respect to mining industry, the IFC's Mining Group provides equity and loan financing for mining companies to build projects that reward owners, investors, and local communities. The IFC's investment

portfolio in mining was around $500 million in 2011 and included 37 mining projects of Rio Tinto, Anglo American, NewMont, Minera Escondida, Lonmin and other companies in 25 different countries (IFC, unknown). In 2012, IFC's investment portfolio in mining, oil, and gas was $2.3 billion (IFC, 2012a). In 2013 and 2014, the IFC's new commitments in the sector totaled $389 and $441 million, respectively (IFC, 2014). The IFC finances projects that meet certain criteria. In January 2012, the IFC set out the Performance Standard 6 "Biodiversity Conservation and Sustainable Management of Living Natural Resources" that requires IFC-financed projects to preserve the benefits from Ecosystem Services, reflecting this recent trend. Furthermore, the IFC requires that the environmental and social risks and impacts identification process considers a project's dependence on Ecosystem Services.

For mining companies, it is more than evident that obtaining a formal operating licence from regulating authorities is no longer enough, as it has become an increasingly insufficient means of satisfying society's expectations with regard to mining issues (Bridge, 2004). Thus, it is widely recognized that mining companies need to gain also a "social licence to operate" that includes revenue sharing, so as to avoid conflicts with local communities (Prno & Scott Slocombe, 2012; Prno, 2013; Owen & Kemp, 2013; Moffat & Zhang, 2014). There are several definitions of "social license to operate". In general, it can be said that a "social licence to operate" exists when "*a mining project is seen as having the broad, ongoing approval and acceptance of society to conduct its activities*" (Prno, 2013). Several factors may affect the "social licence to operate" outcomes. In general, it is argued that sustainability considerations, participation of the public in decision making process and securing and provisioning of local benefits are crucial elements in obtaining the "social licence to operate". All these factors are strongly anchored with the concept of Ecosystem Services either explicitly or implicitly. For example, the "Ecosystem Services Review for Impact Assessment" (Landsberg et al., 2014), as described earlier, facilitates integration of the environmental and social assessments. Thus, it is considered to be useful among others to projects that:

- may alter ecosystems on which people and communities have a high level of dependence for maintenance of their livelihoods, health, safety, or culture
- are controversial and require the project developers to be proactive in their relations with affected stakeholders to avoid legal battles or delays in project implementation or operation.

Both cases are quite relevant to mining operations. In addition, Landsberg et al. (2014) argue that integrating Ecosystem Services in environmental assessment provides significant benefits to global and local stakeholders, due to the fact that stakeholder engagement becomes more inclusive, the assessment of the impacts of the project over its life cycle is more comprehensive, and the target of mitigation measures is to maintain pre-project benefits to local communities that derive from impacted ecosystems.

Finally, Ecosystem Services concept is important to mining sector because there is a need to justify the overall impact of a mining project in the context of a social cost-benefit analysis, so as to decide whether the exploitation of mineral resources is socially desirable. in the last three decades, there has been an increasing effort in mining project appraisals to account for environmental and social impacts, apart from the traditional techno-economic valuation in the decision-making process driven by market values. For example, Resource Assessment Commission (Imber et al. 1991) used a non-market valuation approach, namely Contingent Valuation, in order to assess the environmental value of the Kakadu Conservation Zone and to decide whether or not to permit the exploitation of mining deposits found in the region. The Department of the Environment, Transport and the Regions (DETR) conducted two separate studies aiming at calculating a tax

on the output of aggregates based on the externalities generated by quarrying activity (London Economics, 1998 & 1999). In Greece, the Council of Greek State ruling on the case of TVX's investment at Olympias area, in Northern Greece with the Decision Record 613/2002 concluded that the environmental impacts (water pollution, devastation of forests, land occupation, etc. and the risk of a severe environmental accident due to the use of cyanide in the extraction process) outweighed overall economic benefits, resulting in the cassation of the mining investment (Damigos, 2006).

To this end, Ecosystem Services valuation will play an important role. According to TEEB (2010), ecosystems generate output values (e.g., food production, climate regulation and recreational value) and insurance values. The latter is closely related to the "option value". Provided that Ecosystem Services can directly and indirectly affect human well-being, they link well to taking an economic approach. Under the Total Economic Value (TEV) conceptual framework, people derive utility from the actual or potential use of ecosystems and for reasons not connected with use, i.e. create use and non-use values. Use values involve direct use (i.e. individuals make actual use of an ecosystem service), indirect use (i.e. individuals benefit from ecosystem services supported by a resource rather than directly using it) and option value (i.e. the value of ensuring the option to use a resource in the future). Non-use values derive from the knowledge that the environment is maintained and include altruistic, bequest and stewardship motivations (DEFRA, 2007b). So far, however, there are limited efforts dedicated to establishing monetary values for Ecosystem Services (e.g. Costanza et al., 1997; de Groot et al., 2012).

3.2 ES and Recent Mining Practice

Not surprisingly, there are very limited efforts in incorporating Ecosystem Services in mining sector.

Rosa & Sanchez (2013) used the "Sapo-Ferrugem" mine mining project in Minas Gerais State, Brazil, in order to test the Ecosystem Services approach (ESA) to the 'traditional' environmental impact assessment (EIA). The research steps were, as follows:

(1) Compiling a summary description of the present environment conditions with an emphasis on identifying affected ecosystems and their services from the baseline featured in the Environmental Impact Statement (EIS);

(2) Compiling from the project description featured in the EIS a list of major project activities;

(3) Identifying Ecosystem Services that could be affected by the project;

(4) Adjusting the identification of Ecosystem Services to the results of a rapid appraisal;

(5) Identifying, from the rapid appraisal, beneficiaries of Ecosystem Services;

(6) Reviewing all impacts described in the EIS and searching for possible matching with Ecosystem Services.

In order to compare the ESA with the traditional EIA approach, the impacts described in the EIS were arranged in a matrix to show the correspondence with the impacted ES. The analysis showed that the 'traditional' EIS identified 10 physical, 12 biotic and 20 social negative impacts. The biotic and nine of the ten physical negative impacts were also identified by the ESA, but only nine out of the twenty negative social impacts described by the EIS could be identified through the ESA. The conclusion was that: (i) some impacts identified in the EIS cannot be described by the ESA; (ii) some impacts are equivalent under both approaches and (iii) the ESA allowed the identification of several effects not identified by the traditional approach.

King (2013) attempted to show how ESA could offer a systematic framework to enhance, structure, and communicate the benefits offered by quarry restoration. More specifically, the findings include the types of ecosystem services that restored quarries could generate for four common habitat types (i.e., heathlands, grasslands, wetlands and farmland) and how ecosystem services

from these habitats may be valued to assess public benefits in environmental consideration. To this direction, a number of business opportunities and threats are identified in relation to ecosystem service trends and key recommendations for the sector are stipulated.

Larondelle & Haase (2012) implemented ESA to assess the impacts of mining activity over a considered 100-year period, to pre- and post-mining landscapes. Using one of the largest opencast lignite mining areas in Europe, in Eastern Germany, south of Leipzig, they recorded historical land use data from maps and outlined three future potential land use scenarios based on current planning documents in order to: (1) assess the pre-mining, mining and post-mining landscapes with respect to function and sustainability; (2) apply ESA to this assessment; and (3) evaluate the applicability of the Ecosystem Services concept to mining impact assessment and post-mining landscape patterns. Although the authors recognize that there are shortcomings related mostly to the choice of Ecosystem Services and indicators, the results indicate that it is possible to provide information for the planning process about what natural and ecosystem potential was eliminated by mining and what restoration offers.

Alcoa & CBBC (2011) applied the Corporate Ecosystem Services Review (ESR) developed by the World Resources Institute (WRI) as a complementary approach to carrying out an EIA study for the modernization of Alcoa's Baie-Comeau smelter in Quebec, Canada. The ESR process involved the following steps:

(1) Selection of the scope and boundaries of the analysis.

(2) Identification of priority ecosystems services by evaluating the degree of the facility dependence and impact on 24 ecosystem services.

(3) Assessment of the level of dependence and impact in priority ecosystem services.

(4) Identification of business risks and opportunities that may arise due to the trends in priority ecosystem services.

(5) Development of strategies that will be implemented both at the existing plant and within the modernization project to incorporate the findings of the ESR.

According to Alcoa & CBBC (2011), the ESR methodology raised certain questions, related to the determination of the scope and the boundaries of the considered industrial system, the understanding of some Ecosystem Service categories where the relationship with other ecosystem services made it difficult to discriminate impact and dependence.

Finally, Olsen et al. (2011) examined the benefits of Rio Tinto's plan to support the conservation of approximately 60,000 hectares of lowland rainforest in Madagascar in order to compensate in part for the unavoidable residual impacts of its mining mineral sands operations on the region. This plan is part of Rio Tinto's policy goal of net positive impact (NPI) on biodiversity in its operations. The analysis covered the biodiversity and ecosystem services of a large part of Tsitongambarika, the largest expanse of lowland humid forest remaining in southern Madagascar, and aimed to quantify and value changes in ecosystem services resulting from proposed interventions. The considered ecosystem benefits were: wildlife habitat, hydrological regulation and carbon storage, while the costs of conservation included up-front investment and maintenance costs of protected areas, as well as lost opportunity costs that local people bear when they lose access to land that has historically provided food and cash income, and a resource for agricultural expansion. Furthermore, the study concluded that there were significant net economic benefits associated with conservation, mainly due to carbon storage benefits.

4 DISCUSSION AND CONCLUDING REMARKS

Mining projects, like other human activities, may have significant impacts on Ecosystem Services, and, consequently, on human well-being. There are strong arguments in the

literature that support the need to incorporate Ecosystem Services in environmental assessments, at all levels of decision-making. Nevertheless, the process is still in its infancy.

There are, so far, certain weaknesses, as an accurate understanding of not only concepts such as ecological process, biodiversity or of ecosystem service itself, but also of its classification is required (Rosa and Sanchez, 2013). The literature provides different classifications of Ecosystem Services with notable differences is some cases. In addition, there are certain inconsistencies with regard to the implementation of the environmental assessment process in mining activities within different countries, which further complicate the implementation of ESA. In order to improve this situation, a more consolidated methodological framework will have to be established based more on globally standardized classifications than on the legislation and the characteristics of each country.

Due to the aforementioned reasons the applications of ESA in strategic and policy environmental assessment in general and in mining sector in particular are quite limited. Nevertheless, the mining sector should become more familiar with the concept of Ecosystem Services not only because it becomes mainstream in several standards and requirements of governmental and other organizations, but also because it may help in successful conflict management and negotiations within the permitting and social licensing processes.

Energy Spectrum In India

B. Prasad
CMPDIL, a subsidiary of Coal India Limited, Ranchi, India

R. Prasad
Colorado School of Mines, CO, USA

ABSTRACT This paper presents a comprehensive review of energy sources in India such as Coal, Lignite, Natural Gas, Crude Oil, Hydro Power, Nuclear Power and Renewables. First, we look at how share of each fuel in total energy production and consumption in India is varying from 2000-01 to present and their projections until 2021-22. Then, we analyse each of the different energy source by examining its reserve, historic and projected demand, consumption and production. Further, we discuss key challenges and opportunities emerging in each of these sources. Finally, we discuss implications of energy security and environmental aspects on the development of various energy sources. This comprehensive analysis of each of these major energy sources leads us to the fact that despite the need to develop renewable and alternate energy sources in view of long-run sustainability, our dependence on primary energy sources especially coal is irreversible in the long-run.

Keywords: Energy Sources, India, energy security, environmental aspects

1 INTRODUCTION

As energy consumption level is generally known to be a certain indicator of rise in living standard in context of modern industrial civilization, it is even more important for emerging economies like India, to meet the ever-increasing energy requirements to meet the development needs. With burgeoning population, particularly in emerging economies like India, it is imperative to develop energy resources to meet the energy requirements and developmental needs of the country with due emphasis of sustainability.

2 WORLD ENERGY SCENARIO

World energy consumption is expected to increase from 524 quadrillion Btu in 2010 to 630 quadrillion Btu in 2020 and 820 quadrillion Btu in 2040. The current share of coal in global power generation is over 40%. Global oil reserves are almost 60% larger today than 20 years ago, and the production of oil has gone up by 25%. If the unconventional oil resources, including oil shale, oil sands, extra heavy oil and natural bitumen are taken into account, the global oil reserves will be four times larger than the current conventional reserves.

3 INDIAN ENERGY SCENARIO

Though India is the fourth largest consumer of electricity after China, USA and Russia, its per capita energy consumption was 585 kilograms of oil equivalent (kgoe) in 2009, far lower than the global average of 1797 kgoe. Total primary commercial energy demand is expected to reach 937.26 million tons of oil equivalent (mtoe) in 2016-17 and 1219.76 mtoe by 2021-22. Coal, followed by Crude Oil and Natural Gas continue to be major fuel sources even until 2021-22 to meet this energy demand.

However, only 669.5 mtoe is expected to be met by domestic production with the remaining 267.76 mtoe by imports in 2016-17.

Table 1. Share of each fuel in total energy consumption in India

	2000-01	2006-07	2011-12	2016-17
Coal & Lignite	50.36	53.22	53.45	55.41
Crude Oil	37.45	33.41	31.51	26.04
Natural Gas	8.49	6.99	10.32	13.46
Hydro Power	2.17	2.53	2.17	1.79
Nuclear Power	1.49	1.24	1.57	2.26
Renewable Energy	0.04	0.22	0.98	1.43

3.1 Coal and Lignite

Coal (including lignite) is the mainstay of India's energy sector and accounted for over 58% of total installed electricity generation capacity of 223344 MW as on 31.03.2013 and occupies a share of 79% of total electricity capacity addition target of 118,537 MW for 12th FYP to support the targeted 9% GDP growth rate. By 2016-17, coal requirement to meet the forecasted consumption by various sectors by works out to around 980.5 MT. With increasing demand for energy and absence of coal deposits in Indian states of Tamilnadu, Gujarat, Rajasthan, Pondicherry, Jammu & Kashmir and Kerala, these states will benefit with the exploitation of their lignite reserves as they are facing high transportation costs in transporting coal from far off coal fields.

3.1.1 Reserves

The total updated geological reserves of Coal stands at 293.497 billion tonnes as on 01.04.2012 up to a depth of 1200m and that of Lignite at 40.91 billion tonne. Critical analysis reveals that reserves position in the long-term perspective is far from satisfactory. Tamilnadu has 80.41% of the Indian Lignite reserves. Also, there has been significant increase in proved Lignite reserves in recent years increasing the potential for immediate exploitation of reserves. Category-wise coal & lignite resources, as per Geological Survey of India (GSI), as on 01-04-2012, are given in Table-2.

Table 2. Coal & Lignite Reserves in India (In Billion Tonne)

	Proved	Indicated	Inferred	Total
Coal	118.15	142.17	331.84	293.5
Lignite	6.15	25.79	8.97	40.91

3.1.2 Production

During the 11th FYP (2007-12), the growth in all India coal production showed an increasing trend in the first three years. However, in 2010-11, the production growth was not the expected mainly due to delay in Forestry & Environmental Clearances (FC & EC), besides land acquisition, Rehabilitation and Resettlement (R&R) and coal evacuation. In 2013-14, all India raw coal production is 565.64 MT as against the target of 604.55 MT. Coal production is projected to increase at a Compound Annual Growth Rate (CAGR) of 7.57% during 2012-17 and reach 795 MT in 2016-17. Coal production across the terminal year of plan periods is shown in Figure-1. Lignite is projected to be 68.60 MT by 2016-17 and 104.55 MT in 2021-22.

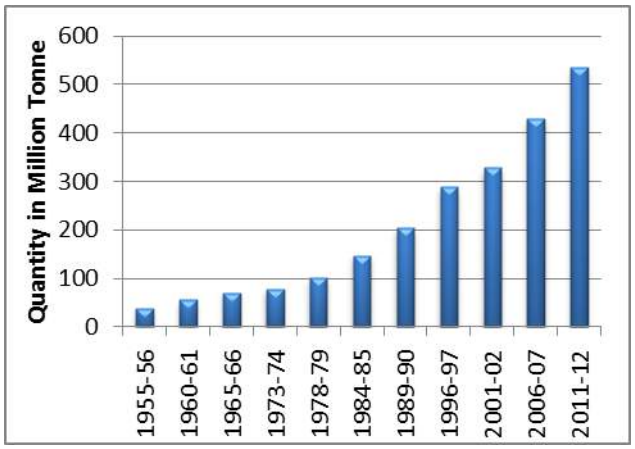

Figure 1. Coal Production

3.1.3 Demand

The demand for coal is projected to reach about 980 MT in 2016-17 Sector-wise coal demand is shown in Figure-6. Going forward, the demand projection for 2021-22 is 1373 MT. The demand for Lignite is projected to reach 71.96 MT during 2016-17 and 108.62 MT by 2021-22.

3.1.4 Demand-supply gap

In 2016-17, a supply-demand gap of 265.50 MT is projected comprising of 35.50 MT of coking coal and 230.00 MT of non-coking coal. The supply-demand position for 2016-17 is shown in Table-6. Of the total 10.14 MT shortfall in lignite production during the total twelfth plan period, Gujarat state will face a highest shortfall of 9.00 MT.

Table 3. Supply-Demand position of Coal in 2016-17 (in MT)

Source	Coking	Non-Coking	Total
Demand	67.20	913.30	**980.50**
Availability			
CIL	15.74	540.66	556.40
SCCL	0.00	57.00	57.00
Others	15.96	85.64	101.60
Indigenous	31.70	683.30	**715.00**
Gap(-)	35.50	230.00	**265.50**

3.1.5 Challenges in coal production

Although, India's coal demand increased at a CAGR of 8.5% during 2007-11, CIL's production increased at CAGR of 4.6% only. While time consuming procedures to obtain environmental clearances from MOEF and land from state governments being the primary reason for the slow growth in production, this shortage would continue to be a serious issue for the energy security of India.

a. Coal Imports

As mentioned earlier, coal imports are projected to reach 265.50 MT by 2016-17. The major import sources of thermal coal are Indonesia and South Africa. Indonesia contributes to 70% of India's thermal coal import. In the recent past, there have been regulatory changes in the nations like Indonesia. Thus coal imports from Indonesia are expected to face a hit. For coking coal import, Australia is the primary destination. It accounts to more than 80% of India's coking coal imports. Australia has recently proposed Mineral Resources Rent Tax (MRRT) which would increase cost of Australian coal. This is expected to impact Indian steel industry. Thus it is very important for India to diversify its import sources. Moreover, coal imports have concerns around limited supporting infrastructure, huge price difference between imported and domestic coal and changing regulations in the source countries.

b. Acquisition of Foreign Coal Assets

With a large number of captive coal blocks allotted being struck in obtaining various clearances for mining, companies are depending mostly on coal imports. India is facing stiff competition from other Asian economies like Japan, South Korea and China in terms of coal imports. It is therefore, necessary to secure sustainable supply of coal through available options such as long term off-take contracts with coal producers and overseas acquisition of assets

At present Coal India Ltd. has only two blocks in overseas. It is currently conducting drilling operations to assess the size and quality of the fuel in Mozambique. It has also signed an initial agreement with South Africa's Limpopo provincial government for exploring the possibility of developing coal mines. But, acquisition of coal assets in foreign countries by domestic mining players is fraught with its own set of challenges. Locating quality mines, managing supply chains, reducing financial risks and recognizing external risks are important to make an acquisition succeed.

c. Investment

Coal mining is virtually closed for private sector except for captive mining purposes. But to meet the burgeoning demand for coal, there is a need to bring in new technologies and modern mining methods to improve productivity and sustainability of operations. Competition among the players will help improve performance.

d. Infrastructure

Lack of proper road connectivity, railway wagons, 24/7 availability of power, port facilities, have put brakes on the growth of coal mining industry in India. Further, there are concerns that there are very limited

manufacturers of mining equipment and machinery in the country. Hence, there is a need for indigenous development of mining equipment with government support through R&D funding to technical institutes.

e. Policy issues

There is a pressing need for adequate regulatory interventions to ease out the various concerns plaguing the sector. Major concerns such as land acquisition and R&R, environment and forest clearances, institutionalization of coal regulator can be alleviated to a significant extent with dynamic policy framework.

f. Quality of Coal & Washing

Another major problem associated with Indian coals is its high ash content (15-45%) and low calorific value. There is an urgent need for introducing new techniques and technologies for beneficiating Indian high ash coals. Dry ash beneficiation is one of the promising areas which is now being considered by Indian coal producing companies for their adoption.

3.1.6 Challenges in lignite production

a. Technological Constraints

Currently available technology for lignite mining in India is not suitable for production below 150 meters. With 80% of lignite reserves being below 150 meters in India, there is a need for upgradation of technology to extract deeper deposits of up to 300m under tough geo-mining conditions.

b. Land Acquisition

While opencast mining being the only viable option for lignite mining and with majority of the lignite reserves in Tamil Nadu and Gujarat are under fertile agriculture land with thick population, land acquisition has become a major concern.

c. Regulatory issues

With the requirement of tariff based competitive bidding route to set up lignite based thermal projects, there is an increased difficulty in getting faster clearance for lignite projects.

3.1.7 Ways to increase coal supplies

a. Exploration is considered a risky venture. So Govt. must encourage investments in this sector through proper incentives and security of tenure.
b. Taking action on pending mining applications within a time bound manner i.e. by imposing a time limit for clearing an application.
c. At present, all related subjects such as land, water, mineral, environment and forest etc. are administered by different departments and ministries as a result of which processing of mining applications is becoming very complex. So a Single Window Clearance Agency (SWCA) could bring speed in decision-making and application processing.
d. A lot of mining leases have been granted in the past comprising of small areas to individuals. The mine owners are not able to develop them economically and would like to dispose of these areas. States may allow transferring these assets at a premium so that these dormant assets can be developed to increase supply in domestic market, leading to the utilization of dormant resources.
e. The exploration and exploitation of minerals requiring huge capital should be extended to experience the same benefits and incentives that are available to the Oil & Gas sector under the new Exploration Licensing Policy (NELP).

3.2 Natural Gas

Last decade has showed growth in Indian gas sector and has slowly emerged as one of the primary source of energy for India along with coal and oil. As on 31.03.2012, total gas-based power generation capacity of 20110 MW accounts for 9% of total installed capacity in India.

3.2.1 Reserves

Natural Gas (NG) reserves in India have grown at a CAGR of 2.63% from 1100.99 billion cubic meters in 2005 to billion cubic meters 1354.76 in 2013.

3.2.2 Production

The total domestic gas availability during is expected to increase from 124 Million Metric Standard Cubic Meter per Day (MMSCMD) in 2012-13 to 209 MMSCMD in 2016-17.

3.2.3 Demand

Demand for natural gas in India is expected to grow at a very rapid rate. Demand is expected to increase from 194 MMSCMD to 473 MMSCMD during the period 2011-2012 to 2016-2017.

3.2.4 Demand-supply gap

With increasing demand, dependence on imports is increasing steadily because of limited domestic supplies as shown in Table-4.

Table 4. Demand-Supply Gap of NG

(MMSCMD)	2012-13	2013-14	2014-15	2015-16	2016-17
Supply	124	149	170	177	209
Imports	63	87	87	129	150
Demand	**187**	**236**	**257**	**306**	**359**

3.2.5 Challenges

1. Due to a limited investment from foreign companies as evidenced in recent NELP bidding rounds, there is a delay in bringing technological expertise, diverse project experience.
2. With ambiguity over the gas pricing issues and a lack of predictive policy framework, it is getting difficult to increase participation by foreign companies.
3. Mature gas fields like PannaMukta Tapti, Bassein and Niko have declining production levels.

3.2.6 Opportunities

1. The Indian sedimentary basins and deep water areas largely remain unexplored which indicates the potential for large hydrocarbon discoveries. This creates opportunities for the investors possessing relevant technical expertise.
2. The CBM Policy devised by Government of India encourages investment and provides favourable investment climate like freedom to sell CBM in the domestic market, infrastructure status exemption from payment of customs duty on imports required for CBM operations and fiscal stability.
3. According to US Energy Information Administration in April 2011, India has technically recoverable shale gas resources of nearly 63 trillion cubic feet.
4. Underground Coal Gasification (UCG) has been notified as one of the end uses under the government captive mining policies and these projects requires technical expertise that none of the domestic companies possess at present which provides a good space for investment.
5. A decline in the domestic gas supply along with increase in the gas demand has created opportunities for developing LNG import facilities, providing opportunities to investors, service providers, equipment suppliers and Engineering, Procurement and Construction (EPC) contractors.

3.3 Crude Oil

With only 0.5% of world's proven oil reserves and 15% of world's population, pressure on increasing crude oil production to meet the exploding demand for energy has placed Crude Oil one of the sought over energy sources available in India.

3.3.1 Reserves

Crude Oil reserves in India have reduced from 786.04 Million Metric Tonne (MMT) in 2005 to 758.27 MMT in 2013 as shown in Figure-2.

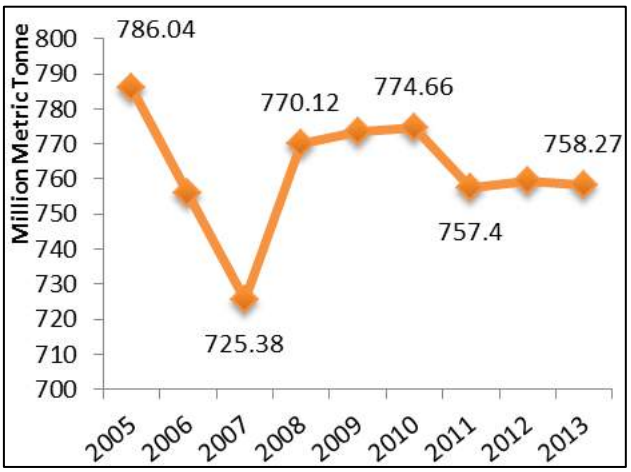

Figure 2. Crude Oil Reserves in India

3.3.2 Production

Supply of petroleum products/crude oil is likely to increase from 42.305 Million Metric Tonne Per Annum (MMTPA) in 2012-13 to 41.156 MMTPA in 2016-17.

3.3.3 Demand

Demand for petroleum products is likely to increase from 147.997 MMTPA in 2011-12 to 186.209 MMTPA in 2016-17 at a CAGR of 4.7%.

3.3.4 Demand-Supply Gap

Over the 12th Five Year Plan period, the growth in domestic production is not sufficient to meet the projected demand. This results in increasing dependence on imports, with the share of crude imports increasing from around 76.6% in 2011-12 to 77.8% in 2016-17 as shown in Table-5.

Table 5. Crude Oil Demand-Supply Gap (in MMTPA)

Year	2012-13	2013-14	2014-15	2015-16	2016-17
Supply	42.3	45.6	44.8	42.6	41.2
Demand	152.9	160.4	168.6	177.0	186.2
Gap(-)	110.6	114.8	123.8	134.4	145.0

3.3.5 Challenges

1. Upstream skills, technology and equipment shortage are some of the major issues faced by the industry. The industry is especially pressed with the shortfall of technical and experienced personnel like Reservoir engineers.
2. Only half of the country's potential basins have been explored, and large blocks offshore remain untested, especially in deep water.

3.3.6 Opportunities

1. Most of the existing refineries in India are old and need massive investment to make them complaint with the stringent fuel emissions norms introduced in India. Refinery capacity additions also will require the setting up of new pipelines in India or increasing capacities of the existing ones.
2. India offers huge opportunities for equipment supplies of Exploration and Production (E&P) industry. Companies like Oil and Natural Gas Corporation (ONGC) and Oil India Limited (OIL) are investing heavily in Increased Oil Recovery (IOR) and Enhanced Oil Recovery (EOR) techniques.

3.4 Hydro Power

Being a renewable and clean source of energy, the vast hydro-power potential can be harnessed with due consideration for ecology conservation. Moreover, given the operational flexibility of hydro-power plants, it can be used to meet peak demand scenarios.

3.4.1 Hydropower potential in India

As per the reassessment studies undertaken by the Central Electricity Authority (CEA) in 1978-87, India's total theoretical hydropower potential at 60% load factor was assessed as 301,117 MW and the economic potential at 84,044 MW.

3.4.2 Hydro-based capacity addition

During 2007-11, only 5544 MW of hydro-based power generation capacity is installed as against the target of 15,627 MW. Private companies have lagged behind the state-run

units in meeting their targets. The total installed hydro-based capacity as on 31.03.2013 is 39491 MW, occupying 18% of total all India generation capacity. India is planning to add 9204 MW Hydro capacity by 2016-17. The sector-wise break-up of this capacity addition requirement is shown in Table-6. North-East has a huge potential for hydro power of around 50,000 MW, challenges related to the evacuation of power has made the progress in this area very slow.

Table 6. Hydro Capacity Addition Target during 2012-17 (in MW)

Sector	Central	State	Private	Total
	5632	1456	2116	9204

3.4.3 Challenges

1. With significant land requirement for large plants, land Acquisition is a major constraint in undertaking various hydro-power projects.
2. Because of increasing public resistance due to relocation, R&R issues have become another major constraint.
3. Delays in EC&FC are leading to increase in already high capital expenditures.
4. Limited transmission and evacuation infrastructure in high hydro-power potential areas.

3.4.4 Opportunities

1. Nearly 95% of the hydro-potential is north-eastern states of India is untapped.
2. Given the need for robust engineering services to undertake projects in more difficult terrains, there is a great market opportunity ahead for EPC contractors and technology providers.
3. With the sector offering option of 100% foreign equity, this sector remains attractive for investors looking for higher returns over a long term of 30 to 50 years.

3.5 Nuclear Power

Nuclear power is economically competitive and therefore can provide large base load generation. It contributes to de-carbonization of power sector, being devoid of greenhouse gas emissions, with lifecycle emissions comparable with hydro and wind power.

3.5.1 Nuclear power potential in India

Though India has only 1.5% (as of 2009-Wikipedia) of global Uranium reserves, it accounts for 1/3rd of global reserves of Thorium. India's three-stage nuclear power programme formulated by Dr.Homi Bhabha considers both the Uranium and Thorium reserves. With the known uranium reserves, first-stage programme can generate about 10,000 MW based on Pressurised Heavy Water Reactors (PHWRs). This potential can be increased by another 20,000 MW in the second-stage programme based on Fast Breeder Reactors (FBRs). Utilizing Thorium in the third-stage reactors the energy potential is very high. The stage-wise Nuclear Energy Potential based on domestic resources is as given in the Table-7

Table 7. Stage-wise Nuclear Energy Potential in India

Particulars	Stage	Reserves	Electricity
			MW
Uranium Metal			
In PHWR	I	170,000-t	10,000
In FBR	II		5,00,000
Thorium-Metal		2,25,000-t	
In Breeders	III		Very Large

3.5.2 Nuclear power generation

Nuclear power generation in India has increased 18634 GWh in 2006-07 to 25471 GWh in 2013-14 (upto December 2013).

3.5.3 Capacity addition

As on 31.03.2013, India has 4780 MW of Nuclear-based generation capacity and is planning to add 2800 MW nuclear based capacity during 2012-17.

3.5.4 Challenges

1. High Capital Investment and rising compliance costs have been hindering the speedy execution of new projects.
2. Public concern about plant operations and final waste disposal is delaying the clearances issued by the government.
3. Increasing concerns by foreign equipment suppliers regarding liabilities in case of nuclear accident is delaying the procurement of equipment.
4. There is no nuclear insurance pool in India, apparently due to restrictions on inspection of facilities by international pools.

3.5.5 Opportunities

1. With increasing positive signs of international cooperation, new opportunities in the area of import and export of nuclear goods, equipment and services will open up.
2. With designs of nuclear power plants becoming more effective, cost of electricity generated is competitive.
3. Cost of nuclear fuel is low because of the use of domestic thorium.
4. Economics of nuclear power generation can be improved significantly if plants are built away from coal reserves i.e. in north-western, western and southern India.

3.6 Renewables

Renewables generally include Wind, Small Hydro, Biomass Power, Waste to Energy, Bagasse Cogeneration and Solar Power. Of these sources of energy, Wind based energy generation is occupying a major share in the country.

3.6.1 Capacity addition

During 2007-11, 14,661 MW of capacity has been added through Grid Interactive Renewable Power.

3.6.2 Cost of renewable electricity generation

Cost of solar based power generation is the highest among the renewables at around 10.39-12.46 Rs/kWh and small hydro based power generation is the lowest at 3.54-4.88 Rs/kWh. The estimated cost of electricity generation for various renewable sources is shown in the Table-8.

Table 8: Cost of Power for Various Renewable Energy Sources

Source	Estimated initial Capital Cost (Crore Rs./MW)	Estimated cost of electricity generation (Rs. /kWh)
Small Hydro Power	5.50-7.70	3.54-4.88
Wind Power	5.75	3.73-5.96
Biomass Power	4.0-4.45	5.12-5.83
Bagasse Cogeneration	4.2	4.61-5.73
Solar Power	10.00-13.00	10.39-12.46

3.6.3 Capacity addition requirement

As per the norms laid out by The National Action Plan for Climate Change (NAPCC), share of renewables in electricity mix should reach 12% by 2016-17. Given the present installed capacity of 24,503.45 MW (CEA), there is a requirement of 30,000 MW of capacity addition to meet those norms.

3.6.4 Challenges

1. Solar P.V. key challenge

a. PV technology is less amenable to very large scale and widespread grid connectivity due to bottlenecks in storage and hence the ability to have a flexible dispatch schedule.
b. The performance of the modules depends significantly on the manufacturer of the cells and the module. The ability of the developer to improve the cost & performance is limited.

2. Solar Thermal-key challenge

a. There is presently negligible indigenous manufacturing capability for Concentrated Solar Power (CSP) projects and have to be sourced from few global manufacturers.
b. Solar thermal installations, which require large amounts of dedicated land, are competing with other necessities that require land as well.
c. Presently, there are no installed CSP projects in the country. Thus, project management and installation capability are questionable.

3. Biomass key challenges

a. Unlike other Renewable Energy technologies, biomass technology requires feedstock as fuel for power plant, entailing an additional and significant cost to the project developer.
b. High and fluctuating cost of biomass is a major issue in this sector. The cost of biomass has almost doubled in the last 5 years.

4. Hydro-power challenges

Small Hydro power (SHP) projects are location specific, varying significantly in costs and feasibility depending upon topography, hydrology, geology and approachability. Despite support from government by the way of financial support and other policy incentives, SHP has not made significant progress due to the above said technical challenges as well as procedural challenges.

5 Grid integration has become a serious challenge to readily start more projects.
6 Lower subsidies and growing material input costs is another major issue in wind based power generation.

3.6.5 Opportunities

Steadily, India is looking to build a strong renewable energy portfolio in coming years. Government of India (GOI) is offering a number of incentives to accelerate investment in Renewable energy space. The renewable purchase obligations (RPO) requirements set by state regulators and REC mechanism is expected to create demand for renewable energy across solar and non-solar sources. In addition, several benefits like accelerated depreciation, preferential tariff and generation based incentives offer attractive incentives to the investors in renewable energy.

a. Solar

There is an emphasis on setting up manufacturing capacity of 2500 MW of solar cells/ modules and 2500 MW equivalent capacity of components/sub-systems of solar thermal power plants by 2016-17. With this, we can expect the cost of solar cells/modules and components of power plants to come down and thus cost of producing energy may decrease. The recent solar bids concluded are an indication that the players are becoming increasingly competitive in this space.

b. Bio-mass

The GOI has announced a proposed “biomass mission” in late 2011 which may target the installation of 1600MW of biomass power by 2020. This is likely to provide ample opportunities to investors. In light of the ever rising demand for biomass feedstock, energy plantations and captive generation can become promising business opportunities in the biomass sector.

c. Small Hydro Power (SHP)

Since SHP is an old and matured industry, there are large number of SHP units, requiring renovation and modernization.

4 ENERGY SECURITY

The policy and planning is largely controlled by the central government in India’s federal political set up. According to the Indian Energy Policy report of 2006, the country’s hydrocarbon resources will be grossly inadequate to meet its demand. The government has taken certain steps to build infrastructure for energy security.

4.1 Strategic Petroleum Reserves

GoI has set up the Indian Strategic Petroleum Reserves Ltd (ISPRL), which is building three huge underground caverns that can hold beneath the earth that can hold 14 days' worth of oil. Moreover, the new facilities will have a combined capacity of 39 million barrels.

4.2 Overseas Acquisition in O&G

India has carefully entered into cooperative relationships with several oil-producing countries in Africa and the Middle East.

The ONGC Videsh Ltd (OVL) has invested 11 billion USD abroad. In addition, a number of other investors, both public sector undertakings and private players, have also invested in 50 other projects in 19 countries. The OVL oil equity so far accounts for only 9% of India's current oil import requirements. If these assets were to meet at least 10% of the requirements in 2031-32, the investments will have to be increased six times. To import natural gas, LNG terminals have been set up at Dahej and Ratnagiri and a new one is under implementation at Kochi. Imports of 7.5 million tonne of LNG on a long-term supply basis for 25 years have been planned by Petronet LNG at Dahej under an agreement with Qatar. Another 1.5 million tonne has been planned through a tie up with Exxon Mobil for 20 years from Gorgan LNG project in Australia.

4.3 Overseas Acquisition in Coal

India will have to import large quantities of coal in the future. Though a number of private players have invested in mines in Indonesia and Australia, Coal Videsh, formed under the Ministry of Coal, has done very little business so far. Around 70% of 950,000 MW of power requirement in 2031-32 will be from coal. Thus, there is a need to give a very strong push to the mining investments abroad.

4.4 Sovereign Wealth Fund

The government proposed to set up a Sovereign Wealth Fund of 10 billion USD from the disinvestment proceeds to team- up with state-run companies for acquiring overseas raw material and energy assets including crude oil, gas and coal. The fund will be financed through the budget. Also, the budget division has proposed that large PSUs such as ONGC have reserves that can be used by this fund for acquiring energy assets aboard. This can be a second source of funding. The third source of funding can be the RBI's forex reserves. But this still needs to be debated, as the RBI may not be in favour of this.

4.5 Energy Efficiency

India's energy efficiency is the fifth-lowest in the world. Therefore, it is imperative to have a consistent energy policy, relentlessly pursue energy efficiency and conservation, maximise coal production, improve the rail and port infrastructure and develop alternative infrastructure for coal transportation such as coastal rivers.

5 ENVIRONMENTAL ASPECTS

The largest contributors of Greenhouse gases are power stations (many of which burn coal or other fossil fuels), industrial processes, transportation fuels (generally fossil fuels), and agricultural by-products (mainly methane from enteric fermentation and nitrous oxides from fertilizer use). Between 1750 and 2007, about two-thirds of anthropogenic CO_2 emissions were produced from burning fossil fuels, and about one-third of emissions from changes in land use. Rapidly advancing technologies can achieve a transition of energy generation, water and waste management, and food production towards better environmental and energy usage practices using methods of systems ecology and industrial ecology.

6 CONCLUSION

Considering the current generation capacities and future potential of various energy resources along with their associated challenges and opportunities, below mentioned are some of the issues which must be given due emphasis to meet India's energy needs and to become energy independent.

1. At the current level of coal production, proven coal reserves are estimated to last for over 100 years. Even though there is an increasing gap between demand and supply, coal-based energy is the most economic option. Thus, there is a need to quickly expand domestic production.
2. Around 35% of non-metallurgical coal reserves are occurring at a depth of 300-1200 m, to access these reserves there is a need for up gradation of technology in existing coal mines by introducing mass production technologies, particularly in underground mines with due consideration of environmental and social impacts.
3. There is a pressing need to undertake reforms in the areas of exploration, project formulation, clearances and licences.
4. With 12% of sedimentary area being unexplored and 22% being poorly explored, there is a need to increase the exploration activities to bring out more reserves. Also, deep water exploration is another important area to focus upon.
5. Strategic acquisition of foreign oil, gas and coal reserves should be given more emphasis by integrating our energy security interests into foreign policy decision through energy diplomacy.
6. Given the challenges associated with ensuring required supply of energy, there is a need to address energy demand by achieving desired level of energy efficiency.
7. There is a need to improve our regulatory framework to encourage investments in various energy sectors.
8. Unconventional energy sources must be given due priority by investing in infrastructure to facilitate the development of these sources like Coal Bed Methane, Underground Coal Gasification and Shale Gas.
9. Adoption of latest IT tools for effective utilization of human resources and machinery.
10. Highly efficient and flexible power plants with Carbon Capture and Storage Technologies have to be given due importance.
11. Thrust on nuclear energy with the use of substantial reserves of Thorium in India.
12. A clear cut policy on Coal to Liquid will help to reduce oil imports.
13. Measures to switching from oil to natural gas will lead to conservation of oil resources.
14. Strict vigilance and control over energy transmission and distribution losses will help in reducing energy imports.
15. There is an immediate need to take steps to reduce our dependence on energy imports as the imports is slated to reach $230 Billions (13.8 lakh crore rupees) in the next decade.
16. Develop smart grids and dedicated information technology to improve power supply of our now integrated national grid.
17. Absorb commercially available technologies like Integrated Gasification Combined Cycle (IGCC) to boost thermal efficiency and thereby boost generation.
18. Currently available technologies like supercritical and ultra-supercritical steam boilers must be given more emphasis than conventional pulverised coal technology.
19. There is also need for refitting and redesigning of commercially available technology, given the high ash content of our coals.

Forecasting of Turkey's Coal Consumption Using Grey Prediction Technique

I. Karakurt, G. Aydin, S. Kaya
Karadeniz Technical University, Mining Engineering Department, Trabzon, Turkey

C. Hamzacebi
Karadeniz Technical University, Industrial Engineering Department, Trabzon, Turkey

ABSTRACT: Coal is by far the most plentiful energy resource in Turkey. Domestically produced coal accounts for more than half of the country's total energy production. Coal has been consumed primarily for power generation, steel manufacturing, and cement production. Due to its importance in country's energy balance, modeling and forecasting of coal consumption is an important issue for government, energy sector investors and other corporations in Turkey. In this study, therefore, coal consumption of Turkey was forecasted using a Grey modeling (1,1) technique. The data used in the study was composed of coal consumption in Turkey for the period of 1965-2013. Using these historical data, the coal consumption of Turkey was forecasted for the period of 2014-2025. Additionally, the performance of forecasting was measured using mean absolute percentage error (MAPE) and mean absolute error (MAE).

Keywords: Grey prediction technique, mean absolute percentage error, mean absolute error

1 INTRODUCTION

The world energy demand has rapidly risen as a result of social and economical growth, urbanization and economic expansion. Therefore, the uses of all kinds of energy increase over time, especially uses of fossil fuels are expected to continue supplying much of the energy used worldwide (Karakurt and Aydin, 2013).

The world benefits from a plentiful supply of coal. It has many uses critically important to economic development and poverty alleviation worldwide with the most significant being electricity generation, steel and aluminum production, cement manufacturing and use as a liquid fuel (Höök et al., 2010). Almost every country worldwide has coal reserves, however, approximately 70 of those has recoverable coal reserves. It remains abundant and broadly distributed around the world (Mason, 2007). Proved coal reserves in the world at the end of 2013 were 891531 million tons (Table 1). It is seen from Table 1 that world coal reserves can be distributed in thirds; one is located in North America (28.5 %), dominated by the United States; other is located in Europe&Eurasia (35.4%), dominated by Russia and the last is located in Asia Pacific (30.9%), dominated by China and Australia.

Turkey being a developing country with respect to population, industrialization and the economy, is growing rapidly. Its energy demand is continuously increasing with its growth. Studies on forecasting future energy requirements have shown that these requirements will continue to increase in the coming years (Kabak and Dağdeviren, 2014).

Among many energy resources, coal is by far the most plentiful energy resource in Turkey. Domestically produced coal accounts for more than half of the country's total energy production. Coal has been consumed primarily for power generation, steel manufacturing, and cement production (Karakurt and Aydin, 2013). In 2013, coal has the second place among primary energy

consumption of Turkey (see Fig.1). Due to its importance in country's energy balance, coal covers an important place for government, energy sector investors and other corporations in Turkey. Therefore, this study focused on the coal consumption of Turkey. The coal consumption was forecasted using a Grey modeling (1,1) technique based on the data composed of the period between 1965 and 2013. Using these historical data, the coal consumption of Turkey was forecasted for the period of 2014-2025. Additionally, the performance of forecasting was tested using performance measures.

Table 1. Proved coal reserves of the world at the end of 2013 (BP, 2014).

Region	Reserves (million tons)			
	Bituminous and anthracite	Sub-bituminous and Lignite	Total	Share (%)
North America	112835	132253	245088	27.5
S. & Cent. America	7282	7359	14641	1.6
Europe & Eurasia	92557	217981	310538	34.8
Middle East	1122	-	1122	0.1
Africa	31600	214	31814	3.7
Asia Pacific	157803	130525	288328	32.3
World total	**403199**	**488332**	**891531**	**100**

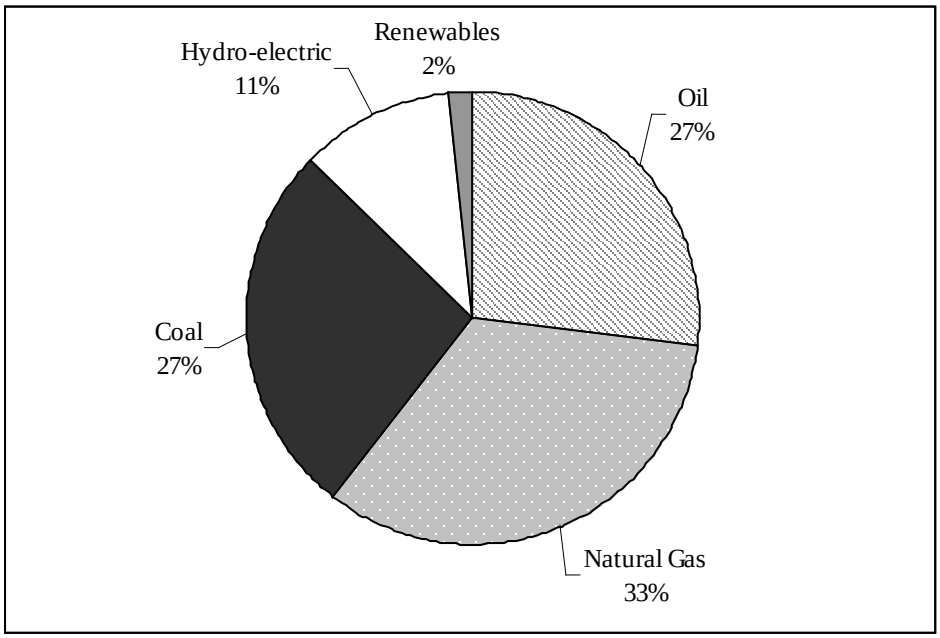

Figure 1. Primary energy consumption of Turkey by fuel type in 2013 (BP, 2014).

2 GREY PREDICTION MODELS

Grey prediction models such as GM(1,1), GM(0,N), and GM(1,N) are a part of grey systems theory (GST) proposed by Deng (1982). The GST has been successfully applied in many fields such as management, economy, engineering, finance, etc. There are three types of systems. One is called "white", other is called "black" and the last is called "grey". A system is called a white system when its information is totally clear. When a system's information is totally unknown, it is called a black system. If a system's information is partially known, then it is called a grey system (Pi et al., 2010).

In the real life, uncertain systems with small samples and poor information exist commonly (Liu et al., 2012). Grey prediction models are used both time series prediction,

and cause and effect type prediction. While GM(1,1) is used for prediction based on time series, GM(1,N) and GM(0,N) are used for prediction based on cause and effect relationships. Most widely used grey prediction model is GM(1,1).

2.1 GM(1,1)

GM(1,1) model can be used in circumstances with relatively little data, and it can use a first-order differential equation to characterize an unknown system. Therefore, GM(1,1) model is suitable for forecasting the competitive environment where decision makers can reference only limited historical data (Pi et al., 2010; Hamzacebi and Es, 2014). GM (1,1) is based on three essential steps: one is accumulated generation operation (AGO), other is grey modeling and the last is inverse accumulated generation operation (IAGO). The steps of GM (1,1) are shown below as indicated by Hamzacebi and Es (2014).

Step 1: For the initial time sequence

$$X^0=\left\{X_1^0,X_2^0,X_3^0,.....,X_n^0\right\}=(X_t^0;\quad t=1,2,3,...,n;n\geq 4) \qquad (1)$$

where X_t^0 is a non-negative sequence and n is the number of the data.

Step 2: is obtained after sequence is subjected to AGO.

$$X^1=\left\{X_1^1,X_2^1,X_3^1,.....,X_n^1\right\}=(X_t^1;\quad t=1,2,3,...,n;n\geq 4) \qquad (2)$$

where

$$X_k^1=\left\{\sum_{t=1}^{k}X_t^0,t=1,2,...,n;k=1,2,...,n\right\} \qquad (3)$$

Step 3: Setup grey modeling by establishing a first order grey differential equation

$$X_t^0+aZ_t^1=c,\quad t=2,...,n \qquad (4)$$

where

$$Z_t^1=\beta X_t^1+(1-\beta)X_{t-1}^1,\quad t=2,..,n \qquad (5)$$

β denotes a horizontal adjustment coefficient, $0<\beta<1$ and generally $\beta=0.5$. In equation (4), a is called the development coefficient and c is called driving coefficient. Applying least square method coefficients, can be estimated as

$$A=\begin{bmatrix}a\\c\end{bmatrix}=(B^TB)^{-1}B^TY_n \qquad (6)$$

where

$$B=\begin{bmatrix}-Z_2^1 & 1\\ -Z_3^1 & 1\\ .... & ...\\ -Z_n^1 & 1\end{bmatrix},\qquad Y=\begin{bmatrix}X_2^0\\X_3^0\\.....\\X_n^0\end{bmatrix} \qquad (7)$$

$$Y=BA$$

Step 4: The whitenization processes is defined as follows;

$$\frac{dX_t^1}{dt}+aX_t^1=c \qquad (8)$$

Hence, a using a and b coefficients the AGO grey prediction model can be obtained.

$$\hat{X}^1_{t+1}=\left[X_1^0-\frac{c}{a}\right]e^{-at}+\frac{c}{a},\quad t=0,1,2,.... \qquad (9)$$

Step 5: Obtain the prediction value of original sequence by IAGO operation. IAGO operation can be defined as:

$$X_{t+1}^0=X_{t+1}^1-X_t^1 \qquad (10)$$

If Eq. (9) is substituted in Eq. (10), then Eq. (11) is obtained as

$$\hat{X}^0_{t+1}=(1-e^a)\left[X_1^0-\frac{c}{a}\right]e^{-at} \qquad (11)$$

3 DATA AND METHODOLOGY

The data used in the forecasting models were obtained in an annual basis from BP (British Petroleum) Statistical Review of World Energy (BP, 2014). Figure 2 shows the used data graphically. As it is seen, the coal consumption of Turkey increased over the period of 1965 and 2013. The data from

$[a\quad c]^T$

1965 to 2008 was used for model fitting and the data from 2009 to 2013 was reserved for testing.

In order to forecast two or more future periods, iterative or direct forecasting approaches can be used. Hamzacebi and Es (2014) indicated that grey direct forecasting approach give better result over iterative approach.

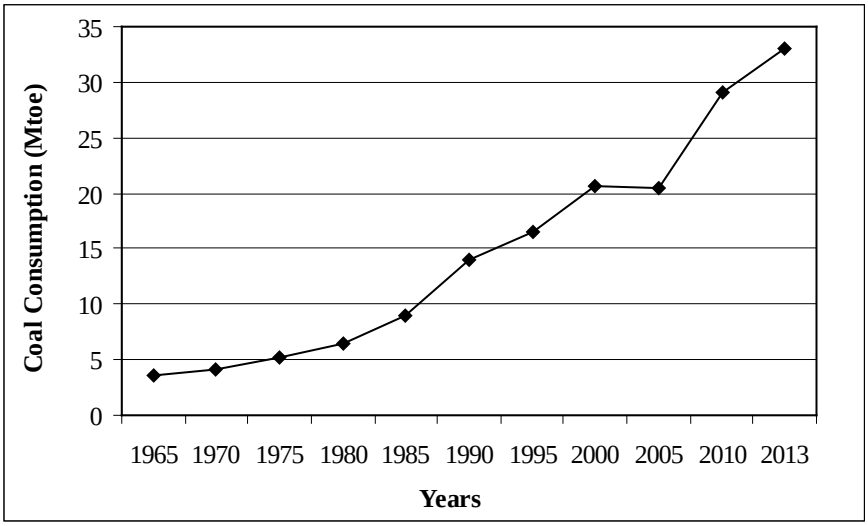

Figure 2. Coal consumption of Turkey over the period of 1965-2013 (BP, 2014).

Hence, grey direct forecasting approach was applied in current study. The following equations (Eq.12-15) illustrate how the grey direct forecasting method is applied to predict the value of p for future periods:

$$\hat{X}_{t+1} = GM(1,1)\left[X_t, X_{t-1},..., X_{t-(k-1)}\right] \quad (12)$$

$$\hat{X}_{t+2} = GM(1,1)\left[X_t, X_{t-2}, X_{t-4},..., X_{t-2(k-1)}\right] \quad (13)$$

$$\hat{X}_{t+3} = GM(1,1)\left[X_t, X_{t-3}, X_{t-6},...X_{t-3(k-1)}\right] \quad (14)$$

.....

$$\hat{X}_{t+p} = GM(1,1)\left[X_t, X_{t-p}, X_{t-2p},...X_{t-p(k-1)}\right] \quad (15)$$

The main advantage of grey direct forecasting approach is to use the past real observations as seen in Equations from 12 to 15. It selects the past observation values according to the value of *p*. For example, if *p=2*, the approach uses $\left[X_t, X_{t-2}, X_{t-4},...X_{t-2(k-1)}\right]$ subsequence to predict the next 2 periods. To forecast *p* for future periods ahead the approach selects the past observation values from the present time to *k* periods backwards by in every *p* periods. Thus, $\left[X_t, X_{t-p}, X_{t-2p},..., X_{t-p(k-1)}\right]$ subsequence is obtained to forecast $\hat{X}_{t+p}$

3.1 Performance Measures

In order to evaluate the forecasting capability of the prediction models, various performance measures are available in the literature. In this study, the mean absolute percentage error (MAPE) and , the mean absolute error (MAE) were used for evaluating the model performance. These are expressed as follows:

$$MAPE = \frac{1}{n}\sum_{i=1}^{n}\left|\frac{e_i}{Y_i}\right| * 100 \quad (16)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n}\left|e_i\right| \quad (17)$$

where e_i and Y_i are the error and observation values of the ith period. Lower values of all performance measures indicate the higher forecasting precision. Table 2 gives the reference values of the forecasting precision levels. Among these measures, Lewis (1982) interprets the MAPE results as the decisive factor since it is expressed in easy generic percentage term to judge the accuracy of the forecast.

Table 2. MAPE for model evaluation (Lewis, 1982).

MAPE (%)	Forecasting Power
>50	Weak and inaccurate forecasting
20-50	Reasonable forecasting
10-20	Good forecasting
<10	Highly accurate forecasting

4 FORECASTING RESULTS

The forecasted data, together with the actual data, were presented in Figure 3. The forecasting results showed that Turkey's coal consumption will increase in near future. The coal consumption will grow up to 47.73 Mtoe in 2025 which shows an increase of 1.31 and 0.64 growth rates when compared to that in 2000 and 2010 respectively. Additionally, the MAPE value for model fitting was found as 6.40%, while the MAPE value for testing was found as and 5.85% as given in Table 3. It is seen that both MAPE values are less than 10%. As indicated in Table 2, the GM(1,1) in this study was adequate to forecast coal consumption in Turkey with highly accurate forecasting power.

Table 3. MAPE and MAE values for model evaluation.

Criteria	Model fitting	Model testing
MAPE	6.40	5.85
MAE	1.07	1.92

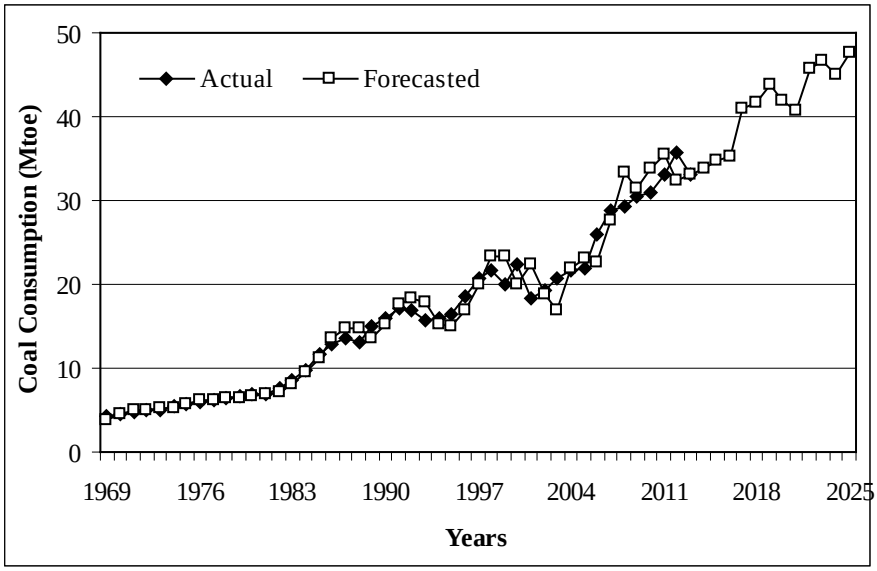

Figure 3. Actual and forecasted coal consumption of Turkey.

5 CONCLUSION

In this paper, Turkey's coal consumption was forecasted based on the grey system theory. In this regards, a GM (1,1) model was built and tested. The results indicated that grey system theory can be used to forecast the coal consumption in Turkey, and highly accurate forecasting can be obtained by the GM (1,1) model. Based on the forecasting model, the coal consumption of Turkey will grow up to 47.73 Mtoe in 2025 which shows an increase of 1.31 and 0.64 growth rates when compared to that in 2000 and 2010 respectively.

Due to the importance of forecasted values for both planning the countries' energy policy and maintain the international agreement on climate change mitigation, policy makers and related scientists should consider different forecasting techniques as well for the creation and effective implementation of energy policies in rapid growth market such as Turkey.

Modeling of Coal Consumption in Turkey: An Application of Trend Analysis

G. Aydin, S. Kaya, I. Karakurt
Karadeniz Technical University, Department of Mining Engineering, Trabzon, Turkey

ABSTRACT In the current modeling, trend analysis is used to model coal consumption (CC) and forecast the future coal demand in Turkey. The data is divided into two groups as the data for training the model (during the period 1970–2005) and the data for testing the model (during the period 2006–2013). The developed models are tested by the t-distribution, F-distribution and residual analysis. Additionally, the performance of the derived models are assessed using mean absolute percentage error (MAPE), root mean square error (RMSE) and means absolute error (MAE). The results show that the proposed models can be used for forecasting of future coal demand in Turkey.

Keywords: Coal, absolute percentage error, root mean square error, means absolute error

1 INTRODUCTION

A projection of future energy consumption is a vital input to many analyses of economic, energy, and environmental policies (Chang et al., 2012; Suganthi and Samuel, 2012). The decision on future energy investment requires an outlook on future energy consumption (Craig et al., 2002; O'Neill et al., 2005).

The experiences of the last five decades led to a blast in the number of energy supply/demand studies due to worries about the emissions of greenhouse gases (GHGs) from the combustion of fossil fuels (Yu et al., 2012; Aydin, 2014a; Aydin, 2014b). Therefore, since the early 1970s, various energy supply/demand studies have been carried out using various estimation methods. These methods can be classified as below.

i. Econometric approach: Linear regression (LR), partial least square regression (PLSR), and time series (ARIMA), etc.
ii. Artificial intelligence approach: Ant colony optimization (ACO), genetic algorithms (GAs), and particle swarm optimization (PSO) algorithm.
iii. Hybrid model.
iv. Grey theory forecasting model.
v. Long-range energy alternatives planning model.

In forecast modeling, various methodologies presented above can be used for energy forecasts. In the current modeling, trend analysis was used to model CC in Turkey. In the analysis, it was assumed that the future demand for coal will follow the historical trend observed in the past. The main advantage of this approach is its simplicity, and forecasts are based on whatever data are available (Kone and Buke, 2010; Aydin, 2014c; Aydin, 2015a). The study could be helpful for the energy planners and the policy makers of Turkey. They can get a general overview of future prospects for coal and its environmental affect.

2 DATA AND METHODOLOGY

The CC data for the study period were taken from British Petroleum (BP, 2014). The SPSS 17 statistical software which offers a choice of regression was used for the trend analysis. The data is divided into two groups as the data for training the model (during the period 1970–2005) and the data for testing the model (during the period 2006–2013). As can be seen from Fig. 1, the data for the CC appropriate for the linear regression

analysis (LRA). LRA is employed in two forms (Eq. 1-2) for modeling of Turkey's CC based on year.

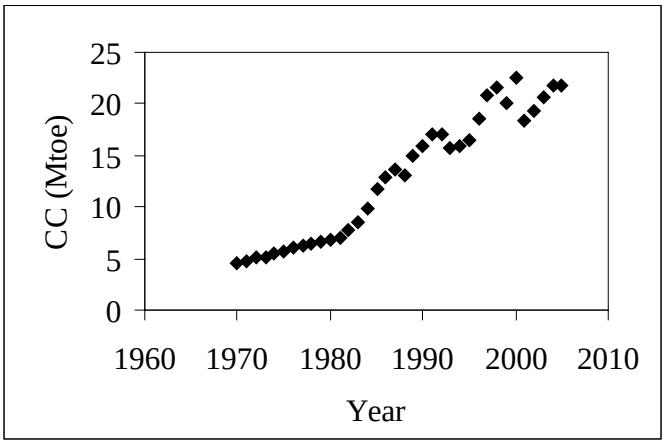

Figure 1. Turkey's CC during the period 1970-2005.

$$y = at + b \quad (1)$$

$$\ln (y) = a \ln (t) + b \quad (2)$$

where; y (*CC*), *t*: year, *b*: the intercept or the constant and *a*: the slope.

Once the model developed, confirmation of the goodness-of-fit of the models and the statistical significance of the estimated variable is done by considering the determination coefficient, F-test of the overall fit, followed by t-test of the individual variable (Mohamed and Bodger, 2005; Aydin, 2015b; Aydin, 2015c). The residual plots of the error are also studied to determine the appropriateness of the models. Moreover, the performance of the derived model for the testing data is assessed using the MAPE, RMSE and MAE.

3 MODELING OF TURKEY'S CC

Results of the trend analyses concerning the relations between Turkey's CC and the years are presented in Table 1. Statistically significant trends were indicated. As a result of analyses, following models (Eq. 3-4) were developed.

Table 1. Results of the trend analyses applied for CC modeling.

Depend. Variable	Coefficients	Unstandardized Coefficients		Stand. Coefficients	Std. Error of the Estimate
		B	Std. Error		
y	(Constant)	-1126.293	46.170		1.448
	T	0.573	0.023	0.973	
ln (y)	(Constant)	-758.670	32.848		0.136
	ln (t)	100.219	4.325	0.970	

$$y = -1126.293 + 0.573\, t \quad (3)$$

$$\ln (y) = -758.670 + 100.219 \ln (t) \quad (4)$$

The R^2 values for the models are 0.947 for Model I and 0.97 for Model II respectively, indicating a high degree of relationship between CC and t. The coefficient of determination also indicates that 0.053% of the variation in CC for Model I and 0.03% of the variation in CC for Model II is due to all causes other than the predictor. Equivalently, it can be stated that indicated variations in the models remains unexplained.

The generality and reliability of the model are further studied by examining the predicted trend versus the observed trend as shown in Fig. 2. It can be clearly seen that the predicted values of CC are very close to the actual ones for two models.

In this t test, a confidence level of 95% was chosen. As can be seen from Table 2, the computed t-values are greater than the tabulated t-values, suggesting that the developed models are statistically valid. Again at the 95% confidence level, valid for all the models, the computed F-values are greater than the tabulated F-values, indicating that the models are statistically valid (see Table 2).

The plots of the residuals against the predicted CCs by the proposed models are shown in Fig. 3. The figures indicate that the residuals appear to be scattered about x axis, confirming the accuracy of the models.

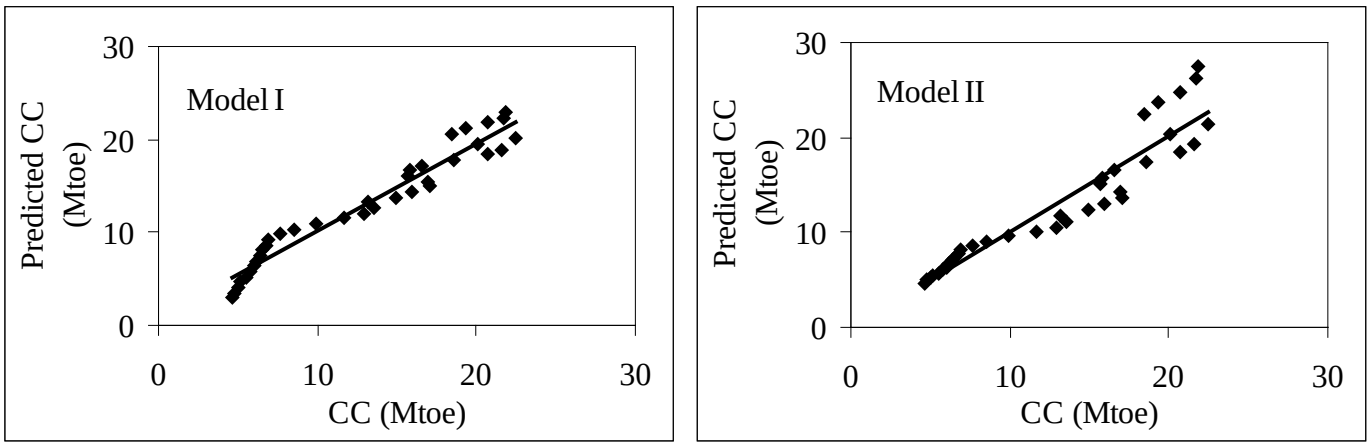

Figure 2. Comparison of the actual and predicted CC.

Table 2. Results of verification tests.

Dependent Variable	R Square	Adjusted R Square	t_{table}	t	F_{table}	F
Model I	0.947	0.946	1.690	-24.394 24.675	4.120	608.847
Model II	0.970	0.940	1.690	-23,098 23,171	4.120	536.913

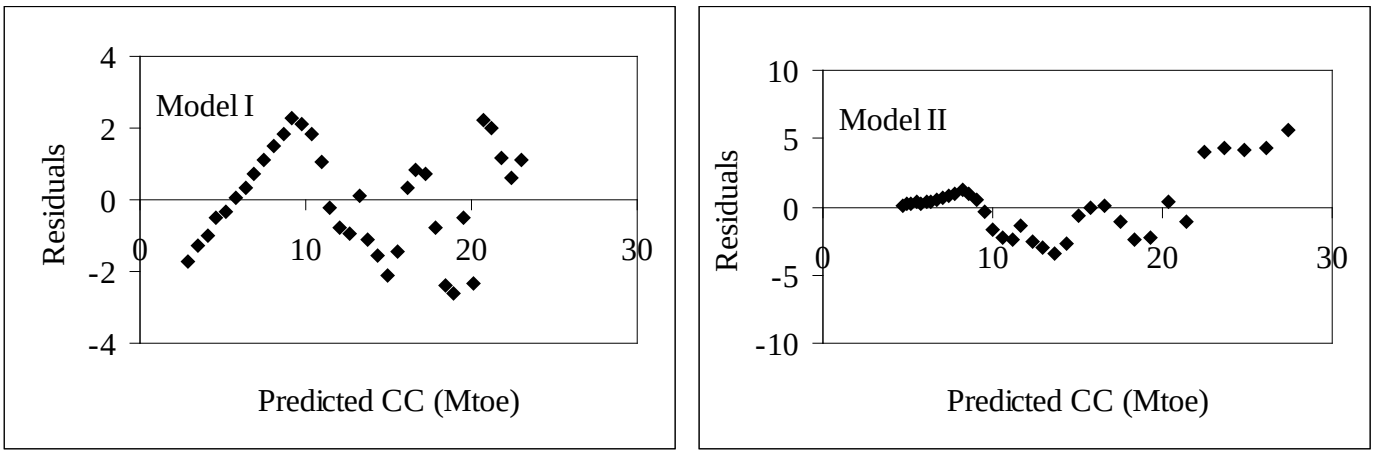

Figure 3. Residuals against the predicted CC.

The accuracy of prediction is evaluated based on the estimation of error. The smaller values of MAE, RMSE and MAPE indicate the better prediction performance. The equations of these performance criteria are given below.

$$MAPE = \frac{1}{n}\sum_{i=i}^{n}\left(\frac{|e_i|}{y_i}\right)100 \quad (5)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n} e_i^2} \quad (6)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |e_i| \quad (7)$$

where, n is the total number of measurements, e_i is differences between actual and predicted values, y_i is actual values.

As shown in Table 3, the MAPE value was determined as 16.9% for Model I and

11.9 Model II, while the RMSE value was determined as 5.608 for Model I and 4.122 for Model II. Similarly, the MAE value was determined as 5.339 for Model I and 3.715 for Model II. These results show the superiority of Model II over the Model I.

Table 3. Performances of the models.

Model	MAPE (%)	MAE	RMSE
I	16.9	5.339	5.608
II	11.9	3.715	4.122

MAPE is the decisive factor since it is expressed in easy generic percentage term. Table 4 shows the criteria of MAPE for model evaluation based on Lewis (1982). These results showed that the derived models can give adequate forecasting for Turkey's CC. The models can be also classified as good prediction model because their MAPEs are between 10% and 20%. Additionally, it can be clearly seen from Table 5 that the predicted CC values are close to the actual ones.

Table 4. Typical MAPE values for model evaluation.

MAPE (%)	Evaluation
MAPE ≤ 10%	High accuracy prediction
10% < MAPE ≤ 20%	Good prediction
20% < MAPE ≤ 50%	Reasonable prediction
MAPE > 50%	Inaccurate prediction

Table 5. Performance of the regression models.

Year	CC (Mtoe)	Predicted CC (Mtoe)	Predicted CC (Mtoe)
		Model I	Model II
2006	25.909	23.539	28.866
2007	28.855	24.112	30.344
2008	29.182	24.686	31.897
2009	30.440	25.259	33.529
2010	30.864	25.832	35.244
2011	33.086	26.405	37.045
2012	35.749	26.978	38.938
2013	32.989	27.552	40.926

Primary energy consumption in Turkey has increased rapidly due to social and economical growth in the past two decades As a results of the increase in Turkey's PEC, CC have increased recently. Future CCs calculated from the proposed models are presented in Table 6.

Table 6. Forecasts for Turkey's CC.

Year	Predicted CC (Mtoe)	
	Model I	Model II
2014	28.125	43.015
2015	28.698	45.209
2016	29.271	47.514
2017	29.,844	49.935
2018	30.418	52.478
2019	30.991	55.149
2020	31.564	57.955

Using Model I, Turkey's CC is forecasted to decrease from 32.989 Mtoe in 2013 to 31.564 Mtoe in 2020 with an annual percentage change of 0.55%. Additionally, Model II forecast Turkey's CC as 57.955 Mtoe in 2020, 75.68% higher than 2013.

4 CONCLUSIONS

In the current study, Turkey's CC was modeled and forecasted using trend analysis. Statistically significant trends were determined. It was concluded that the proposed models are statistically valid in terms of F-test, t-test and residual analysis. The results obtained from the trend analyses showed that the developed models can be used for forecasting of Turkey's CC into the future planning.

Modeling results showed that Model II presents good performance for forecasting of Turkey's CC. However, when the trend in the last decades is investigated, it is hard to come true the values obtained by Model II. High values of CC were forecasted with

Model II due to the equation form (ln). Therefore, Model I is recommended for forecasting of Turkey's CC.

Future CC in Turkey is affected by many factors, mainly economic growth, population growth, coal prices and its availability. Technologies that improve efficiency of power plants, decreasing the energy losses, environmental and emissions regulations and standards could also affect the CC in the country. For providing more successful results, forecasts should include some evaluations of these factors.

Modeling of Energy Consumption Based on Population: The Case of Turkey

G. Aydin, S. Kaya, I. Karakurt
Karadeniz Technical University, Department of Mining Engineering, Trabzon, Turkey

ABSTRACT In this study, Turkey's primary energy consumption (PEC) is modeled by linear regression analysis (LRA) based on population (P). The derived models are validated through some statistical approaches such as the determination coefficient, t-test, F-test, and residual analysis. For the performance assessment of the proposed model, three performance measures such as mean absolute percentage error (MAPE), root mean square error (RMSE) and mean absolute error (MAE) are used. Three scenarios are used for forecasting Turkey's PEC in the years 2013–2020. For each scenario, various assumptions are made considering different growth rate for P. Using the proposed model, Turkey's PEC is forecasted under different scenarios. The results show that the proposed model can be affectively used for forecasting of Turkey's PEC. The scenarios show that Turkey's PEC would vary between 135.523 Mtoe and 140.745 Mtoe in 2020.

Keywords: Energy consumption, population, modeling

1 INTRODUCTION

Turkey's energy demand has rapidly increased recently as a result of social and economic development (Tunç et al., 2006). Turkey's PEC increased from 13.07 Mtoe in 1970 to 122.79 Mtoe in 2013, representing an annual growth of 5.22% (see Figure 1). Figure 2 shows the share of energy sources in Turkey's PEC for the year 2013 (BP, 2014).

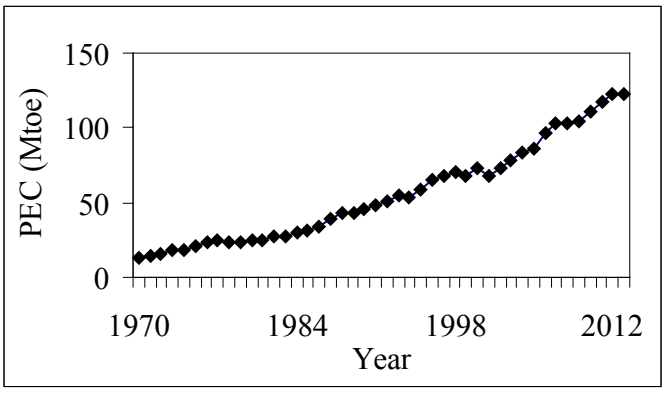

Figure 1. Turkey's PEC during 1970-2013.

The uses of all kinds of energy sources in Turkey have increased over time. The growth in global energy demand is estimated to rise over the coming years (Aydin, 2014a; Aydin 2014b). In 2013, about 90% of Turkey's PEC was supplied from fossil fuels (26.97% oil, 33.45% natural gas, and 26.87% coal), 10.92% from hydroelectric, and 1.79% from renewables (see Figure 2).

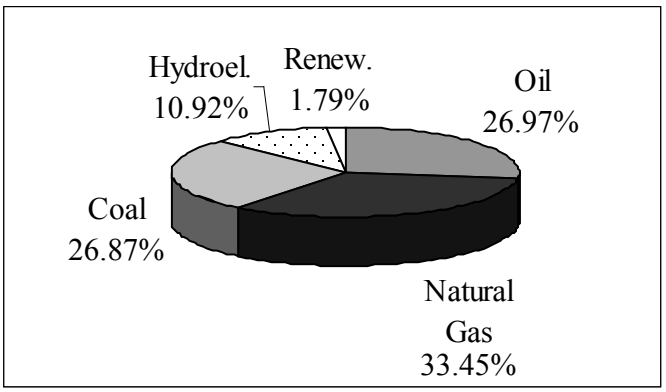

Figure 2. Share of energy sources in Turkey's PEC.

A projection of future energy consumption is a vital input to many analyses of economic, energy, and environmental policies. For example, the decision on future energy investment requires an outlook on future energy consumption (Chang et al., 2012; Suganthia and Samuel, 2012). Underestimation of the energy consumption would lead to potential greenhouse gases;

whereas overestimation would lead to unnecessary idle capacity. Therefore, it would be better to model energy consumption with a good accuracy in order to avoid the costs related to the errors (Kankal et al., 2011; Aydin, 2014c).

The scope of current study is to present a new model for forecasting of Turkey's PEC using LRA. The study is thought to be helpful for the energy planners and the policy makers in Turkey.

2 DATA AND METHODOLOGY

This study collects annual data on Turkey's PEC (Mtoe) and P for the period 1970–2013 from the British Petroleum (2014) and the World Bank (2014), respectively. The total data is used rather than per capita data as recommended by Friedl and Getzner (2003), Pao and Tsai (2011), and Aranda et al. (2012). The SPSS 17 statistical software which offers a choice of regression is used for the analysis. The data is divided into two groups as the data for training the model (during the period 1970–2005) and the data for testing the model (during the period 2006–2013). Presents the relationship between PEC and P in ln form. Figure 3 indicates that the data is appropriate for the LRA. Therefore, the LRA is employed for modeling of Turkey's PEC based on P.

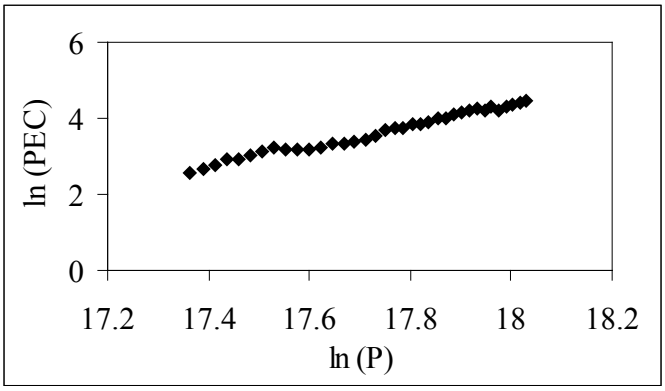

Figure 3. Relationship between ln (P) and ln (PEC).

$$ln\,(PEC) = a\,ln\,(P) + b \quad (1)$$

where; *PEC* (primary energy consumption), *P*: population, *b*: the intercept or the constant and *a*: the slope.

Once the model developed, confirmation of the goodness-of-fit of the model and the statistical significance of the estimated variables is done by considering the determination coefficient, F-test of the overall fit, followed by t-test of the individual variables (Mohamed and Bodger, 2005; Aydin, 2015a; Aydin, 2015b; Aydin, 2015c). The residual plots of the error are also studied to determine the appropriateness of the model. Moreover, the performance of the derived model for the testing data is assessed using the MAPE, RMSE and MAE.

3 MODELING OF TURKEY'S PEC

Results of the analyses concerning the relations between Turkey's PEC and the P are presented in Table 1. Statistically significant trends were indicated. As a result of analyses, the following model (Equation 2) was developed.

$$ln\,(PEC) = -44.789 + 2.730\,ln\,(P) \quad (2)$$

The R^2 value for the model is 0.984, indicating a high degree of relationship between the PEC and P (see Table 2). The coefficient of determination also indicates that 0.016 % of the variation in the PEC is due to all causes other than the predictors. In other words, it can be stated that 0.016 % variation in the PEC remains unexplained. Additionally, it can be clearly seen from Fig. 4 that the predicted PEC values are very close to the actual ones.

Table 1. Results of the trend analyses applied for modeling Turkey's PEC.

Depend. Variable	Coefficients	Unstandardized Coefficients		Stand. Coefficients	Std. Error of the Estimate
		B	Std. Error		
ln (PEC)	(Constant)	-44.789	1.053		0.071
	ln (P)	2.730	0.059	0.992	

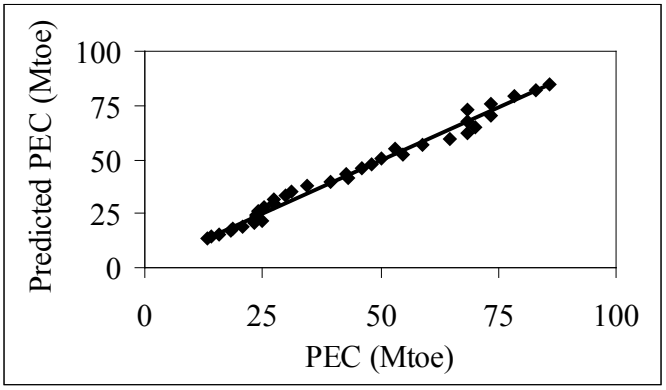

Figure 4. Comparison of the actual and predicted PEC.

As seen in Table 2, the critical value of F (4.120) is much smaller than the calculated F value. Therefore, it can be concluded that the Eq. 2 is significant at the 95 % confidence level. The t-test result for coefficient P is higher than the 95 % critical value of t (1.690). This means that P in Equation 2 is significant in its use in the model (see Table 2).

The plots of the residuals against the predicted PEC for the model case are also shown in Figure 5. The figure indicates that the residuals appear to be scattered about the x axis, confirming the accuracy of the model.

Table 2. Results of verification tests.

Dependent Variable	R Square	Adjusted R Square	t_{table}	t	F_{table}	F
PEC	0.984	0.984	1.690	$\frac{-42.542}{45.995}$	4.120	2115.498

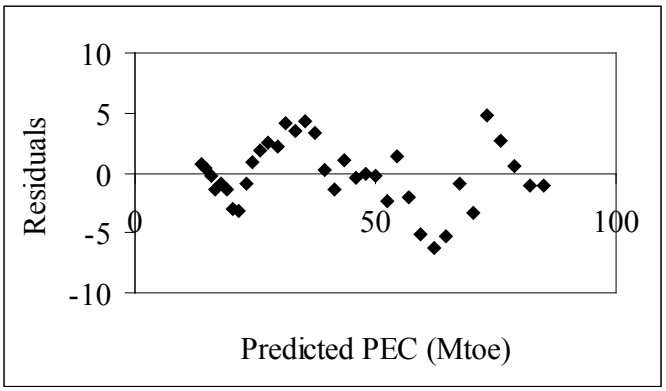

Figure 5. Residuals against the predicted PEC.

In order to assess the model performance, three performance measures such as MAPE, RMSE and MAE were used. The equations of these performance criteria are given below.

$$MAPE = \frac{1}{n}\sum_{i=i}^{n}\left(\frac{|e_i|}{y_i}\right)100 \quad (3)$$

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n} e_i^2} \quad (4)$$

$$MAE = \frac{1}{n}\sum_{i=1}^{n} |e_i| \quad (5)$$

where, n is the total number of measurements, e_i is differences between actual and predicted values, y_i is actual values.

The accuracy of prediction is evaluated based on the estimation of error, thus the smaller the value of MAE, RMSE and MAPE, the better the prediction is. The results are presented in Table 3.

Table 3. Performance of the model.

MAPE (%)	MAE	RMSE
9.2670	10.265	10.589

As shown in Table 3, the MAPE value was determined as 9.267%, while the RMSE value was determined as 10.589. Similarly, the MAE value was determined as 10.265. MAPE is the decisive factor since it is expressed in easy generic percentage term. Table 4 shows the criteria of MAPE for model evaluation based on Lewis (1982). These results showed that the derived model can give adequate forecasting for Turkey's PEC. The models can be also classified as high accuracy prediction model because its MAPE is below 10%.

Table 4. Typical MAPE values for model evaluation.

MAPE (%)	Evaluation
MAPE ≤ 10%	High accuracy prediction
10% < MAPE ≤ 20%	Good prediction
20% < MAPE ≤ 50%	Reasonable prediction
MAPE > 50%	Inaccurate prediction

Three scenarios were used for forecasting Turkey's PEC in the years 2013–2020. For each scenario, various assumptions were made considering different growth rates for P (see Table 5).

To forecast Turkey's PEC, P was initially forecasted using Equation 6. The forecasted results for P based on different growth rates are presented in Table 5.

Table 5. Forecasted P based on different growth rate.

Year	Scenario I G.R.* 1 %	Scenario II G.R.* 1.1 %	Scenario III G.R.* 1.2 %
2014	75681967	75756900	75831837
2015	76438787	76590226	76741815
2016	77203175	77432718	77662716
2017	77975207	78284478	78594669
2018	78754959	79145608	79537805
2019	79542508	80016209	80492259
2020	80337933	80896388	81458166

*G.R.: Growth Rate

$$V(t_n) = V(t_0)(1+CAGR)^n \quad (6)$$

where CAGR is compounded annual growth rate, $V(t_0)$ is start value, $V(t_n)$ is finish value and n is number of periods.

Based on these assumptions, Scenario I assumes that Turkey's PEC is projected to increase from 122.79 Mtoe in 2013 to 135.523 Mtoe in 2020, an increase of 10.37%, or 1.24% growth per year. According to Scenario II, Turkey's PEC increases to 138.110 Mtoe in 2020, 12.47% higher than 2013, and representing average growth of 1.48% per year. Turkey's PEC increases more quickly in the Scenario III, reaching 140.745 Mtoe in 2020, 14.62% higher than 2013, and representing average growth of 1.72% per year (see Table 6).

Table 6. Forecasted PEC under different scenarious.

Year	PEC (Mtoe)		
	Scenario I	Scenario II	Scenario III
2014	115.137	115.449	115.761
2015	118.308	118.950	119.593
2016	121.567	122.556	123.553
2017	124.915	126.272	127.643
2018	128.355	130.101	131.869
2019	131.890	134.046	136.235
2020	135.523	138.110	140.745

4 CONCLUSIONS

In this study, Turkey's PEC was modeled based on P. It was concluded that the derived model can be successfully used as a forecasting tool for Turkey's PEC. The results of forecasting scenarious showed Turkey's PEC would vary between 135.523 Mtoe and 140.745 Mtoe in 2020.

Forecasting of Turkey's PEC can be also investigated with other forecasting methods. The results of the different methods could be compared with the LRA to see the performance of the proposed model.

Recent Developments in Australian Mining Education

M. S. Kizil
The University of Queensland, School of Mechanical and Mining Engineering, Australia

ABSTRACT The Australian mining industry is responsible for more than 50% of the export revenues and is one of the top five largest exporters in the world. Graduating good quality engineers for such an important industry requires world-class education. Mining Education Australia (MEA) was established to deliver a common undergraduate curriculum in mining engineering across Australia. This unique initiative was developed in response to increased demand for mining industry professionals in an environment of limited funding within the traditional university environment and a critical shortage of suitably qualified academic staff. MEA is an unincorporated joint venture between The University of Queensland, The University of New South Wales and Curtin University in Western Australia. In 2009, The University of Adelaide that is the fourth biggest school of mine in Australia became a member of the MEA Program. This paper discusses the history and governance of MEA as well as the structure of the common curriculum and teaching innovations adopted.

Keywords: Australia, mining education, strategy, benefits

ÖZET Avustralya madencilik sektörü, ihracat gelirinin %50'den fazlasını karşılayan ve dünyanın en büyük beş üreticisinden biri olan önemli bir sektördür. Böyle önemli bir sektöre maden mühendisi yetiştirmek için, dünya kalitesinde bir eğitim gerekmektedir. 1996 yılında, Avustralya çapında standart bir maden mühendisliği eğitimi imkanı sunacak, orijinal adı Mining Education Australia (MEA) olan Avustralya Maden Eğitimi adı altında ulusal bir maden okulu kuruldu. MEA'ın kuruluş amacı, maden bölümlerine verilen maddi desteğin azalması, öğretim üyelerinin sayısındaki azalmaya karşın maden endüstrisinin artan mühendis ihtiyacını karşılamak ve daha kaliteli mühendis yetiştirmekti. Kurucu üyeler Queensland, New South Wales ve Curtin Üniversiteleriydi. 2009 yılında Avustralya'nın dördüncü büyük maden okulu olan Adelaide Üniversitesi de MEA'ye katıldı. Bu makale, MEA'nin kuruluş tarihçesini, oluşturulan ortak ders programını ve eğitim ve öğretimde getirilen yeni standartları ve metotları kapsamaktadır.

Anahtar Kelimeler: Avustralya, madencilik eğitimi, strateji, faydalar

1 INTRODUCTION

The global mining education institutions, especially in the developed countries, faced a number of challenges between 1985 and 2003. These included an acute shortage of talented academic staff, small number of student enrolments, high relative costs, making mining programs vulnerable to closures, when universities were under extreme cost pressures, and most importantly under-resourcing of mining departments because of their comparatively small size, making these departments incapable of delivering top class teaching in all aspects of their courses, despite being excellent in some areas. In Australia, this concern was felt more by the industry when it was realised that a number of mining departments across the world had already been closed down as shown in Figure 1 with exception of Chile, South Africa and Australia. The mining industry through its representative body, the Minerals Council of Australia (MCA) set up a task force to review the state of the

minerals education in Australia. The findings and recommendations from this review was published in a report called *"Back from the brink"* in 1998 (MCA, 1998). In response to industry's concerns the National Tertiary Education Taskforce established the following Mission.

"The Development of World-Class Education for a World-Class Minerals Industry"

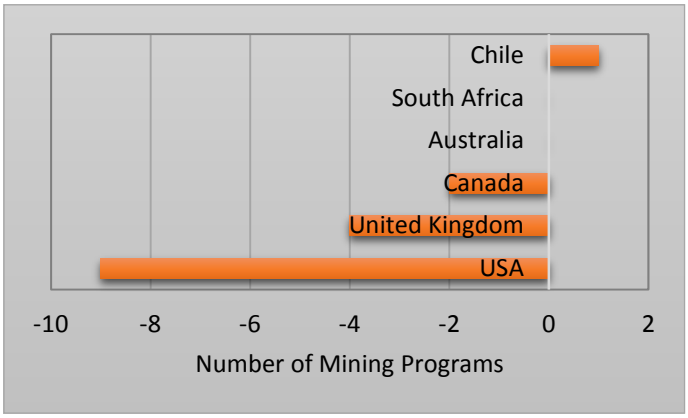

Figure 1. Change in number of mining programs between 1985 and 2003.

The Australian minerals industry's main concern was that, new industry professionals needed to be better educated to deal with emerging challenges of the industry such as globalisation, competition, and rapidly changing technologies. The industry was seeking to ensure that there were sufficient technically capable graduates available to meet its needs, that these graduates valued continuing professional development and that they had sufficient exposure to industry workplaces to ensure they were aware of broader issues such as safety, environmental care and commercial aspects of their work (MCA, 1998). This resulted in establishment of the Minerals Tertiary Education Council (MTEC) which is a division of the MCA in October 1999. Since this time MTEC has been a major driver in establishing three national higher education programs in Mining Engineering, Minerals Geoscience and Metallurgy across 15 Australian universities, which now produce the bulk of new, highly skilled technical professionals from those disciplines (MTEC, 2015). One of the MTEC initiatives was to support the establishment of Mining Education Australia (MEA).

2 MINING EDUCATION AUSTRALIA

Soon after establishing MTEC, the industry started supporting the mining schools by sponsoring two academic positions at each institution and financially supporting the key course development. While this support helped to sustain the minerals education institutions, it did not provide the kind of improvement in the education system the industry was hoping for. Therefore, the discussions for establishing a national mining school started in 2004 which resulted in the establishment of the Mining Education Australia (MEA). MEA was developed to meet the increasing demand for mining industry professionals in an environment where limited funding exists within the conventional university system and to maintain a critical mass of suitably qualified academic staff. The initiative was stimulated by support and funding from the MCA representing the Australian mining industry. The MCA remains committed to the on-going financial support of MEA to deliver a world class program of undergraduate education in mining engineering.

MEA was set up as a joint venture between three major mining education providers in Australia, namely; the University of Queensland, the University of New South Wales and Curtin University. In 2008, the University of Adelaide became a member of the MEA Program. MEA provides a common curriculum for 3rd and 4th year mining engineering students, as shown in Figure 2.

Figure 2. The University of Queensland's undergraduate Mining Program showing common 3rd and 4th year MEA courses *(MEA electives includes: Surface Mining Systems, Underground Mining Systems, Mining Asset Management and Services, Socio-Environmental Aspects of Mining, Advanced Mine Geotech Eng, Mining in a Global Environment and Advanced Ventilation).*

The development of MEA was supported by a $1.3 million grant from the Federal Government through the Collaboration and Structural Reform funding scheme. Funds from a government grant have permitted new mining courses and resource materials to be developed to a world class standard. Advanced tools and systems are being applied to the management and delivery of the Joint Venture's teaching resources and innovative delivery and assessment techniques have been developed and are being adopted in all courses. The experience gained from these activities is being shared with others through an active dissemination program including publications. These achievements have been undertaken in a strong interactive environment that forms a model for future cross-university collaboration.

The following is a chronology of the development of MEA.

2004 Initial discussions for MEA started.
MEA was established.
Identified common courses.
Established a common program structure.
Identified course convener and local coordinators.

2005 Established a common program.
Established new courses at local universities.
Detailed course content.
Developed course profiles.
Identified course delivery mechanisms.
Test run of some common courses.

2006 Inclusion of details in Universities' Handbooks.
Transition run.

2007 Australian undergraduate school of mining was fully operational.

2008 MEA produced first graduates.
Adelaide University joined MEA.

3 BENEFITS OF MEA

Mining Education Australia is a first and unique educational initiative in the world which standardised the mining education across the country through industry, government and university collaboration. It has provided many benefits to the universities, students and the industry, which includes (Tuckwell, 2004):

- improved quality of graduates;
- increased quantity of graduates;
- allowed sharing academic expertise;
- provided a common education standards (across universities);
- sustained viability of programs – opportunity for growth;
- increased the quality of teaching courses and materials;
- access to marketing strategies – broad and focused;
- international market; and
- new generation academics.

The major benefits MEA program provides for mining engineering students includes:

- a nationally recognized, comprehensive educational program covering all aspects of mining engineering, technical, operational and social/community issues;
- access to national group of mining academic staff with skills in all major areas;
- exciting new and innovative teaching and learning programs, including collaborative student activity across four member university nodes;
- opportunities to undertake exchange semesters among member universities; and
- a world-class degree and industry-supported national program.

Since the setup of MEA, the number of mining graduates produced by the member universities for the mining industry has more than tripled from 72 in 2007 to 250 in 2014 as shown in Figure 3. Today, MEA provides 90% of Australia's mining engineering graduates.

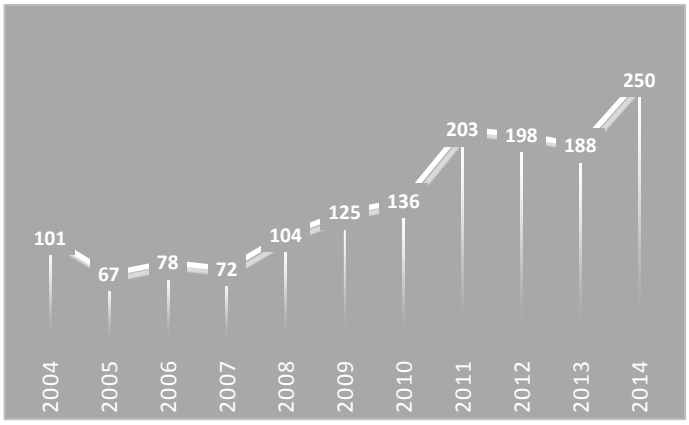

Figure 3. Total number of mining engineering graduates from the MEA member universities.

4 MAJOR CHALLENGES IN SETTING UP MEA

Mining academic staff at all four member universities played a major role in preparing for and establishing the MEA joint venture, aligning curricula among the MEA universities and developing courses to be taught at all four institutions. Major challenges and obstacles were identified and addressed during the establishment of MEA included different program structures at each university, variations in teaching styles, the need for specialised courses, the number of courses offered, course weightings, pre-requisites, time table incompatibilities, lack of commonality in delivery and assessment mechanisms, electives, and laboratory facilities. In order to overcome these challenges and develop a climate of collaboration, MEA developed and implemented a range of collaborative strategies. These include:

- a joint venture agreement between the four universities;
- collaborative course teams;
- implementation of tools to support cross university teaching and assessment;
- implementation of tools and processes for cross university student collaborative assessment, moderation and evaluation processes;

- program leaders committee, and
- twice yearly academic workshops.

5 MEA CORPORATE STRUCTURE

The corporate structure of MEA is shown in Figure 4. It has a governing board, executive committee, program leaders committee and course leaders and course coordinators.

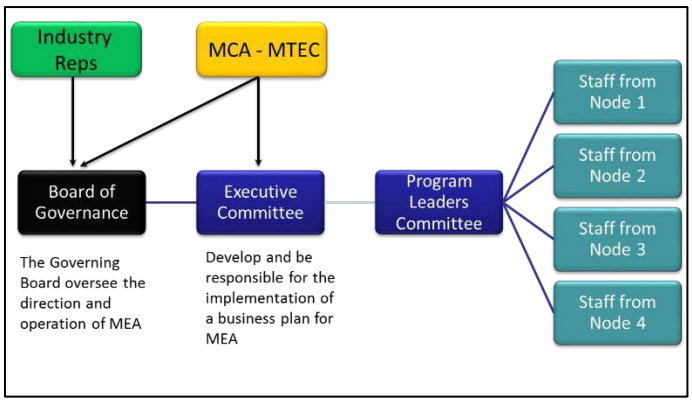

Figure 4. MEA Management Structure

5.1 Governing Board

The MEA Governing Board has a member from each member universities, three members from the industry, the MEA Director and the director of MTEC, meets once a year and oversees the direction and operation of MEA. In particular, it:

- sets the strategic direction of MEA;
- is responsible for the financial management of MEA;
- sets goals and key performance indicators for MEA;
- approves the annual operating plan and budget;
- appoints the Director;
- approves the curriculum and the program content and structure; and
- develops and oversights student recruitment.

The Governing Board appoints a Director who is a senior academic of one of the Members. As a general rule, the appointment will rotate between academics of the Member Universities. The appointment may be on a part-time basis and is for a three year term, which may be renewed.

5.2 Executive Committee

The Executive Committee is chaired by the Executive Director of MEA and comprises senior teaching nominees from each participating university and the Chairman of the Program Leaders' Committee. The committee meets at least four times a year and is responsible for implementing the business plan approved by the Board and pursuing the strategic objectives defined by the Board.

The MEA Executive Committee:

- develops and is responsible for the implementation of a business plan;
- implements the strategic directions and marketing plan;
- monitors and reports to the Board on the performance of MEA against the key performance indicators and goals set by the Governing Board; and
- considers recommendations brought forward by the Program Leaders Committee regarding academic matters.

5.3 Program Leaders Committee

Each university appoints a senior teaching academic as its Program Leader responsible for coordinating the undergraduate teaching program at that university. The Program Leaders are represented on the MEA Executive by their chairman and responsible for:

- designing and reviewing the program structure, content, delivery and resource requirements and allocation;
- approving course outlines, learning guides and assessment schedule;
- implementing and monitoring an assessment moderation process;
- approving the exchange of students between MEA partners;
- monitoring the level of collaboration within each of the course teams;
- reviewing and researching potential innovative teaching and learning technologies and encouraging their adoption in the MEA Program.

5.4 Course Leaders and Coordinators

The Program Leaders appoint Course Leaders at each university to be responsible for the development and delivery of each MEA course. For each course the Course Coordinators from each university work as a team under the leadership of the Course Leader.

6 MEA STRATEGIES/ACTIVITIES

6.1 Academic Staff Workshops

Twice yearly all academic staff of MEA come together for three day workshops. This workshop is held in Sydney, Brisbane and Perth (or Kalgoorlie) in a rotating fashion. This workshop enables all participants to discuss different aspects of the project, participate in staff development workshops, assess the progress of the project, deal with any issues that might be impeding the project and build an understanding of the common goals and values of MEA. This workshop is a major change management strategy (Andrews and Lind, 2007).

6.2 Course Development and Improvement

MEA currently supports 12 compulsory common courses during the final two years of mining engineering program at each member university complemented by a number of more specialised elective courses. Member universities continue to be responsible for the more general engineering education during the first two years of the degree.

MEA takes a collaborative approach to course development, delivery and assessment. Each course is developed by a team of academics consisting of a representative from each partner institution and includes a nominated course convenor and three node co-ordinators. Under the guidance of an educational consultant, a rigorous course development process ensuring alignment between course objectives, teaching and learning activities, graduate attributes and assessment was introduced and is an integral part of the development of all courses. This approach to course development was new to most of the academics in MEA and required them to build capacity to undertake the collaborative development essential for MEA's common curriculum and to design course that met industry requirements that specifically requested the development of workplace skills such as team work and communication.

In order to address regional differences and specialities, 80% of the content is core and 20% complimentary. Regular meetings occur between the course teams and the twice yearly workshops enable the course team members to work together to maintain high academic standards and implement any minor changes required. This rigorous approach to course design is now an integral part of MEA course development activities, with existing academics demonstrating high levels of expertise in the MEA curriculum design process and providing support in this regard to new academics coming into the program. This ensures the high standard of curriculum design implemented for the MEA course development process continues.

Course materials (learning guides, readers, slides, etc.) are professionally developed, reviewed by the industry and UQ's Teaching and Educational Development Institute (TEDI) and published for students. The materials are provided to students in the first week of each semester.

6.3 Course Evaluation and Improvement

MEA has implemented a comprehensive course evaluation and improvement process. Feedback is received from the students for every course through end of semester evaluations. Course leaders collect the survey results from all MEA universities and analyse the results to identify any issues, develop an action plan to resolve these issues and report back to the Program Leaders Committee for implementation.

6.4 Collaboration Process

MEA offers a unique opportunity for students at the partner institutions to access a

much larger pool of expertise than is available through single institution programs. Academic staff who are expert in their teaching areas are called upon by other MEA universities to give a set of lectures to share their expertise with all MEA students. Using a range of technologies, including collaborative teaching tools such as Moodle, video conferencing and SparkPlus™, staff are able to teach across the institutions providing access to a rich pool of expertise and addressing shortfalls in expertise at individual institutions. The collaboration also enables cross-institutional student projects and other learning activities.

6.5 Quality Assurance and Moderation Process

In order to ensure standardisation of assessment across the program, MEA developed standard criteria for projects, group work, presentations and assignments, with the ability to adapt for specific circumstances within the individual course. It was also recognised that is some cases course teams would need to develop criteria for specific assessment items not covered by the generic tools. This work was largely carried out by the program leaders committee with feedback from other staff. A moderation process for assignments and courses was also developed. It was decided that a sample of individual and group assessment items in three of the courses would be reviewed against the standardised assessment criteria developed for each assessment item. An individual assignment, a group assignment and an individual examination made up this process.

6.6 Student Conference

MEA holds a student conference each year which showcases the best of high quality research projects undertaken by students enrolled in MEA mining engineering programs across Australia. The location of this conference is rotated each year between members' universities.

Up to five students selected from each university who are sponsored by MEA and their home university to attend and present their paper at the conference. In addition to each student receiving a certificate of participation and their paper published in the MEA journal, the best three presentations are awarded. The judging panel comprises programme directors from each of the MEA universities for the selection of award winners.

The conference is telecast live and students at each university are encouraged to engage in the Conference. Students in Years 3 and 4 are particularly encouraged to view the telecast and participate during question time.

6.7 Journal of Research Projects Review

All papers presented at the MEA Student Conference are automatically eligible for inclusion in the journal of MEA Research Projects Review, following a peer review process. This journal is circulated to the industry and other stakeholders to highlight the quality of research projects undertaken by MEA undergraduate students by publishing a selection of only the best research papers.

The Course Convenor at each university may nominate up to two further papers for inclusion in the journal. Each submitted paper must be reviewed and co-authored by the student's supervisor.

6.8 Student Exchange Program

As 3rd and 4th year curriculum of every MEA university is the same, any student from an MEA university can study at another MEA university as an exchange student for a semester or two in their 3rd or 4th year of study program. As the offered courses are the same at each institution, students have no problems with course selections/ compatibility.

This exchange study program offers many benefits for students, including:

- spending one or two semester(s) at an MEA institution other than their home node;
- opportunity to meet and work with other student groups; and
- living and studying in different location;
- possibility to link in with summer industrial work experience.

7 CONCLUSIONS

Mining Education Australia was developed to meet the increasing demand for mining industry professionals in an environment where limited funding exists within the conventional university system and to maintain a critical mass of suitably qualified academic staff. The initiative was stimulated by support and funding from the MCA representing the Australian mining industry. The MCA remains committed to the on-going financial support of MEA to deliver a world class program of undergraduate education in mining engineering.

MEA is unique from a world-wide perspective. Approximately 30 academics across four institutions develop and deliver a common curriculum. Commonly, academics develop and deliver their programs either individually or in teams within their own institutions. Developing an environment that encouraged collaboration between the different institutions and enabled the development of an agreed curriculum has been essential to the success of MEA.

MEA has become a successful initiative with superior education outcomes, including:

- a comprehensive educational program covering all aspects of mining engineering, technical, operational and social/community issues.
- improved and enhanced student experience through access to a combined national cohort of mining academics at four institutions and alternative and innovative delivery and learning methods; and
- student access to well prepared, up-to-date and quality assured teaching materials including course profiles, learning guides, reading material, slides, videos, mining industry software packages, and laboratories.

The success of the MEA was commended in the recent Accreditation Report by Engineers Australia to the School of Engineering, citing *"Team skills, project management, sustainability and ethics are all well covered throughout the program, and the implementation of MEA has assisted in mapping graduate attributes well to course content"*. MEA provides industry with graduates equipped with professional skills, life-long learning capabilities and exposure to a standard curriculum.

Is Landfill Mining a New Prospect for the Mining Sector?

M. Menegaki, A. Benardos, D. Kaliampakos, K. Tsakalakis
National Technical University of Athens, Athens, Greece

ABSTRACT Sustaining the availability of resources is one of the major challenges that the future generations will face. Traditional mining approaches seem incapable of meeting such demands and new streams for materials need to be discovered. The utilization of municipal waste can develop into a promising solution for the recovery of valuable materials and energy while at the same time minimizing the environmental strains. The paper discusses the concept of landfill mining, analyses its characteristics and furthermore it presents the approach utilized for the pilot application of landlfill mining that is currently under way in Polygyros, Greece.

Keywords: Landfill mining, Polygyros, Greece

1 INTRODUCTION

The depletion of natural resources is one of the main challenges that the global economy in general and the mining sector in particular have to face, as the material extraction has been increased rapidly since the last century. The global extraction of material resources per year in 2007 was 60 billion metric tonnes (Gt), presenting an estimated 8-fold increase over the last century, when material extraction was less than 7 Gt per year (Krausmann et al., 2009). In the U.S.A., the material resources consumed from 1900 to 1995 have grown from 161 million metric tons to 2.8 billion metric tons respectively (Matos and Wagner, 1998). The last 25 years there has been an enormous increasing in the consumption rate. Only between the years 1970 and 1995 the worldwide consumption of raw materials (not including food and fuel) doubled (USGS, 2008). According to European Commission (EC, 2011), the use of resources at the current rate, will create the need by 2050, on aggregate, of the equivalent of more than two planets to sustain us. In the EU, each person consumes 16 t of materials annually, of which 6 t are wasted. The municipal waste generation exhibits significant fluctuations among the EU countries owing to consumption patterns, levels of economic development, and organization of municipal waste collection and management Eurostat (2011). For instance, in 2009, municipal waste generation ranged from 831 kg per capita in Denmark to 316 kg per capita in the Czech Republic. Waste generation generally increased between 1995 and 2009 for the majority of the countries, with half of the waste going to landfill (EC, 2011). Although the landfilling rate has been reduced the last twenty years due to strict regulations in order to reduce the amount of wastes, landfilling remains the prevailing solid waste disposal method in many countries (Eurostat, 2014). It is estimated that in the EU the total number of closed and active landfills ranges between 150,000 and 500,000 (Hogland et al., 2011; van Vossen, 2005).

There are several studies providing data with respect to the quantities of materials disposed of in landfills. Typically, besides organic matter municipal solid waste landfills contain significant amounts of paper, plastic, wood, rubber, glass, leather and other textiles, and earth construction materials and metals (e.g. Obermeier et al., 1997; Hogland et al., 2004; Kurian et al., 2007). For example, according to Kapur and Graedel (2006), the quantity of copper located in landfills and other waste repositories around the world is about 300 million tonnes, an amount corresponding to more than 30 percent of the remaining

reserves in known ores (Frändegård et al., 2013). These waste deposits could be the source of a significant stream of secondary materials and energy (Jones et al., 2013), that could comprise the "ore" of the future.

Besides municipal solid waste landfills, mine waste heaps may also constitute an important source of materials. This is especially the case with sites polluted with heavy metals, where on one the hand they can have a significant negative impact to the environment while on the other, materials can be recovered, proceeded and finally would re-enter the production cycle. For example, in the site of the Lavrion Technological and Cultural Park (LTCP), a special "dry tomb" landfill structure was constructed to dispose of approximately 115,000 m^3 of contaminated soil containing heavy metals and toxic metalloids, such as arsenic, lead, cadmium and zinc (Kaliampakos et al., 2007). It can be seen as a man-made orebody, which might be marginal or uneconomical to be exploited today, yet it may present a significant resource, for the future. It is estimated that approximately 17,000 t of metals are found in the repository, the value of which is estimated at around $US 41.4 million, in current prices with the most significant materials being Pd and Zn.

Under the pressure of resources deficiencies and environmental challenges, many countries have included resource productivity issues in their sustainable development strategies. To this end, they have introduced integrated waste and materials management policies such as sustainable materials management (SMM), 3R (Reduce, Reuse, Recycle) related initiatives or circular economy approaches (OECD, 2011). Materials management is a conceptual framework for systematically addressing the movement of materials through the economy and the environment from extraction to end of life (USEPA, 2009). As Jones et al. (2013) mention: "…*in a circular economy material loops need to be closed by direct recycling of pre-consumer manufacturing scrap/residues (e.g. steel slags), urban mining of post-consumer End-of-Life products (e.g. recovery rare earth metals from electronic waste), and landfill mining of historic (and future) urban waste streams*….". Figure 1 presents the different ways of closing materials loops in a circular economy.

Landfill mining is described as "*a process for extracting minerals or other solid natural resources from waste materials that previously have been disposed of by burying them in the ground*" (Krook et al., 2012). Thus, landfill mining could be the chance not only to transform landfills into the new "mines", but also to enhance the image of mining sector in society as a necessary partner in modern circular economy.

In the light of the above-mentioned remarks, this paper wishes to contribute to the discussion surrounding the landfill mining issue and the role of mining sector in supporting this concept. Towards this direction, the fundamentals of landfill mining are explored and the results from an ongoing research project carried out in Greece are discussed.

2 THE CONCEPT OF LANDFILL MINING

Technically, landfill mining (LFM) is the process of excavating from operating or closed solid waste landfills by employing the method of open cast mining, and sorting the unearthed materials for recycling, processing, or for other dispositions (Lee and Jones, 1990; Cosu et al., 1996; Hogland et al., 1997; Carius et al., 1999). The concept of LFM is not new. Examples have been cited since the early 1950s (e.g. Savage et al., 1993) and it is likely that earlier, unrecorded activities took place (Fisher, 2013).

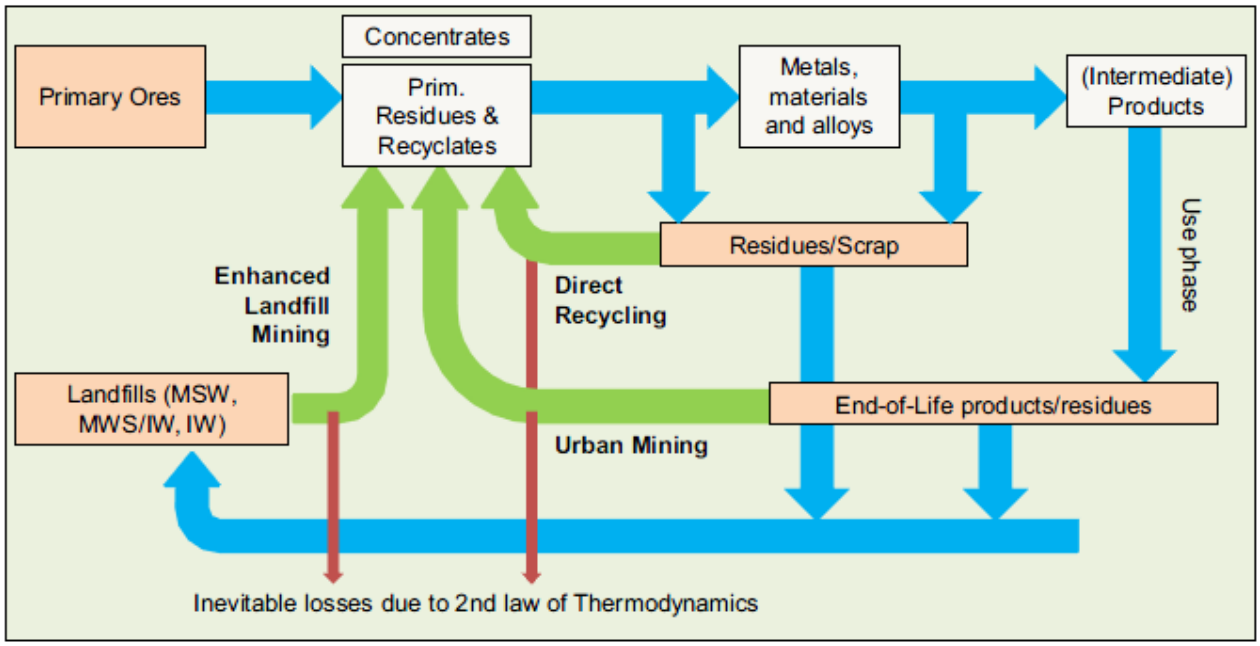

Figure 1. Different ways to close materials loops in a circular economy. Reproduced from Jones et al. (2011).

It is not a practice unique to one country, region or has any specific strategy. The initiatives for LFM are often unique to the site itself and include different objectives, such as: conservation of landfill space, reduction in landfill area, elimination of potential contamination source, rehabilitation of dump sites, energy recovery from recovered wastes, reuse of recovered materials, reduction in waste management costs (USEPA, 1997; Lee and Jones, 1990; Hogland et al., 1997; Cossu et al., 1996; Krook et al., 2012).

2.1 Considerations about Landfill Mining

There are three main strategic reasons for LFM operations, namely: (a) extraction for recycling of materials; extraction for energy recovery; and (c) extraction for the reclamation of land. These reasons may be independent drivers for LFM but may also be combined to deliver wider benefits and maximize the LFM opportunity. The third reason, however, has greater potential for considering environmental and wider sustainability drivers (Fisher, 2013).

The extraction of wastes for their recycling potential is driven by the material values in the market place. Recovered materials, such as ferrous metals, aluminum, plastic, and glass have the highest values, and are often cited as targets for LFM. Recovery of combustible materials for conversion to energy may be considered a 'renewable' energy source. Finally, landfill mining for reclamation (LFMR) for land reclamation may include one or a combination of the following:

- Landfill sites may be in locations that are ideal for other development purposes and may form a physical barrier to a development that is planned.
- Landfill sites may be a source of contamination that has to be removed.
- There may be a need to reuse the available landfill space at the site for different kinds of wastes more suitable to long-term disposal, such as non-reactive hazardous waste.

In this way, LFMR extends the life of the current landfill facility and reduces the size of the landfill "footprint". Hence, the facility operator may be able to avoid the cost and time to locate, design, permit, and construction of a new landfill; lower the cost of closing the landfill; or make land available for other uses.

So far, more than 60 LFMR projects are reported in the literature (van Vossen and Prent, 2011). Ford et. al. (2013) have

recorded 57 of them, shown in Table 1, describing also the principal project driver.

LFM, however, has certain limitations. Historic landfill sites have many unquantifiable variables and only in recent years it was made possible to assess the types of wastes a landfill site may contain (Fisher, 2013). Lack of knowledge about the nature of waste may generate safety issues. Other safety issues include physical injury from rolling stock or rotating equipment; exposure to leachate, and hazardous material or pathogens during mining or processing; subsurface fires and landfill gas emissions. Other limitations include odour and air emissions, increased traffic on roads between the landfill and resource recovery facility, extra mixing and handling of waste at the resource recovery facility, and the handling of additional inert materials.

Many of these risks are similar to traditional mining operations but are enhanced by the heterogeneous nature of the wastes in a landfill.

Table1. Principal drivers for historic and current LFMR projects worldwide

Principal project driver	Europe	North America	Asia	Total projects
Not specified	12	4	2	18
Void space recovery	3	4		7
To allow site redevelopment	5		1	6
To mitigate pollution	2	5	1	8
To improve landfill engineering (e.g. meet regulatory requirements)	4	2	1	7
Material reclamation for recycling or energy production	3	2	6	11
Total projects	29 projects across 9 countries	17 projects of which 1 in Canada and 16 in the USA	11 projects across 7 countries	57

Source: Ford et al., 2013

2.2 Landfill Mining Process

The first step in planning a LFM project involves a site survey to gather site-specific information such as its operating history, types of wastes present, dimensions, topography and physical characteristics (Salerni, 1995). Furthermore, this first step includes planning for preliminary excavation and obtaining the necessary regulatory approvals. According to Joseph et al. (2004), several factors should be addressed for planning an LFM project, e.g. proper time to begin extracting material from the landfill, taking into consideration the odour that will be produced, appropriate methodology in taking representative samples, expected quality of the recovered materials in terms of purity, variation of degradation with time, wastes and space, enhancement of waste stabilization and integration of landfill design and operation, environmental and health risks of landfill rehabilitation works, etc.

The operational phase typically consists of three primary stages: excavating, processing, and managing the excavated or processed material. The excavated waste can be processed to meet several objectives, including separating bulky materials, sorting hazardous material and other unidentified waste, screening soils from waste, and sorting materials for recycling or use as fuel. The objectives will determine at a great extent the selection of the appropriate equipment. To this end, several common mechanical processes (such as magnets for ferrous metal and eddy current separators for aluminum) can be used. Other major factors that influence the choice of processing methodology are the condition and properties of the excavated materials, as well as the cost and time for processing the

excavated material. Figure 2 presents a generalized flow chart of the process that LFM projects employed according to IWCS (2009).

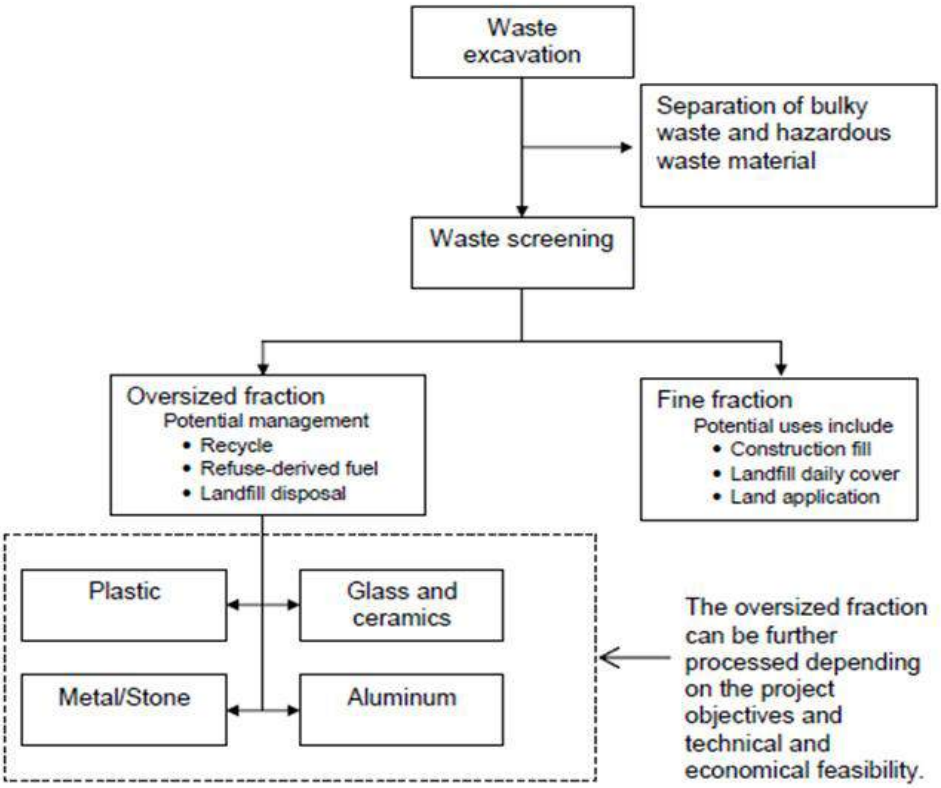

Figure 2. Landfill Mining Process (IWCS, 2009).

3 POLYGYROS LANDFILL MINING PROJECT

The mining activities in the Polygyros Landfill (PL) are part of the "LIFE-RECLAIM" research project co-funded by the EU-LIFE. The project aims at exploring both technical and social aspects of landfill mining. Thus, it will be possible to demonstrate potential environmental and economic benefits, fulfilling sustainability needs that are present not only in Greece but in many other European countries as well.

Apart from the above, the project includes the development of a demonstration waste processing and sorting unit that will serve as a pilot-scale application capable of analyzing techniques for the separation of mixed MSW.

At the current stage, the project is focused on the design of the mining scheme to be used in the facility as well as on the design of the sorting and separation unit. Also, a sampling campaign has been implemented to further analyze the nature of the waste materials in the Polygyros landfill and to provide inputs for the aforementioned design studies.

3.1 Basic Data

The Polygyros Landfill (PL) is located in Northern Greece, in the Chalkidiki area, approximately 3.5 km northwest (NW) of the Polygyros town. The PL site is developed at that hilly terrain at an elevation between +580m, at the northwestern part, and +680m, at the southern part of the area. The geology of the area is consisted mainly by phyllites and quartzites, while at places quartzite shales and quartzite sandstones are found.

The facility is operational from 2008 and covers a total area of 9.3 ha, from which the disposal area is around 2.6 ha (Figure 3).

The disposal area is developed with the use of HDPE membranes along with leachate collection pipes and pond, biological treatment plant as well as biogas active pumping.

Figure 3. General layout of the Polygyros Landfill site.

The PL is designed to hold a total of 266,000 m^3 of municipal solid waste (MSW) that will be disposed in two phases, namely A and B that have a maximum design capacity of 6,000 and 8,100 m^3 per annum, respectively. The main disposal area is located in the western part of the site and at the moment, the landfilling operations are taking place as part of the 1st phase, located at the lower part of the area.

With the maximum disposal capacity of PL set at about 8,100 m^3 per annum, its service life was estimated at around 21 years. Nevertheless, an increase in quantities of the waste brought at the PL site has been experienced in the last 2 years. This is mainly derived from the increase in the touristic volume at the area, as well as from the delays in the development of additional landfill facilities in the Chalkidiki area. Thus, the PL facility is now receiving waste streams from an area greater than initially projected, narrowing down its projected life. It is now estimated that its useful life is less than 12 years.

Thus, the development of a successful waste mining scheme apart from the recovery of materials can also lead to the extension of the service life of the facility, or in other words the recovery of valuable surface space.

3.2 Mining Plan

The mining plan provides the necessary information regarding the extraction of the HSW material from the landfill body. With respect to the project's requirements the waste materials to be mined and processed reaches a volume of approximately 1,000 m^3.

3.2.1 Sampling campaign

At first, a sampling campaign took place in order to obtain information that would be used to design the main excavation scheme. Its main purpose is to identify the type and characterization of waste in terms of content. Furthermore, it could be used to get insight regarding the physical characteristics of the waste and assess its geotechnical properties.

In the case of PL the most appropriate method is the development of sampling trenches as the depth of the landfill is relatively low. Two sampling areas were selected and their excavation took place using a typical backhoe excavator. The materials were processed using a custom made screening equipment with a sieve opening of 15 cm. The materials identified were mainly rock and soil materials (50%) while metal content (ferrous and non-ferrous) ranged from 1-1.5% and the plastics were about 4%.

3.2.2 Mining area selection

The target area for the development of the mining scheme should be (a) representative of waste content, (b) easily accessible to the equipment and (c) appropriately located in areas where the extraction works could not interfere with the daily waste disposal operations. The best possible arrangement, given the current state of the PL site, is to designate the mining area at the elevation of +620 m, at the central part of the disposal area, approximately 30 m eastern from the toe area of the current working cell.

In there, the mining could take place almost independently from the disposal operations. At the same time, the waste material found there covers a significant part of the PL's working life, from almost 2008 to 2012. Another advantage of the position is the minimization of the development works required for the setting up of the haulage road. The main internal access network of the PL will be used, while only limited new road development is required at the level of +620. The area where the processing unit will be installed is located at the entrance point of the disposal area, and thus, the total haulage length from the designated mining area to that point is almost 125 m. The proposed arrangements, the designated mining and processing areas along with the proposed haulage access road are presented in Figure 4.

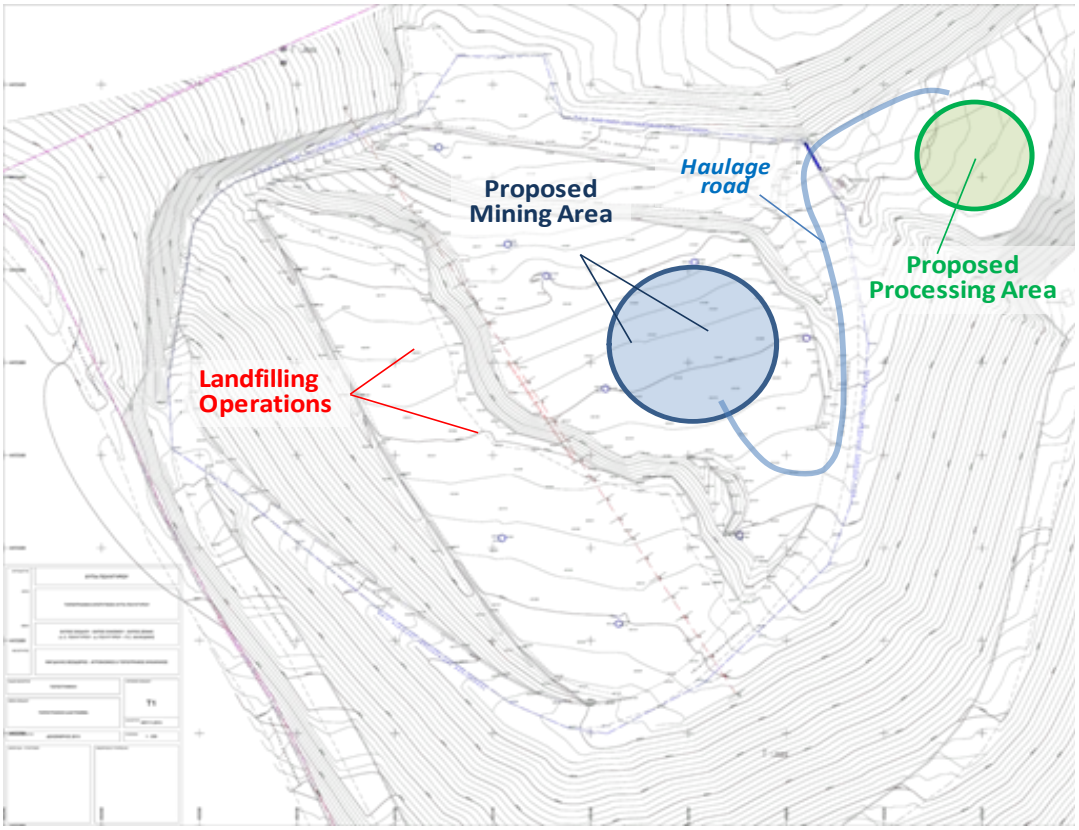

Figure 4. Proposed location of the landfill mining area, with respect to the current landfilling operations and the proposed processing area.

3.2.3 Mining process

The mining of the waste will be made with conventional surface mining equipment. At this stage the whole process is designed so that the work can commence at the start of the spring of 2015, taking advantage of the favorable weather conditions. The PL mining scheme proposes the excavation to take place from the top (+620 m level) using a hydraulic excavator at the crest area, rather than making the extraction from the toe using front-end loaders and by scraping the wastes. The excavator can perform quite well with high productivity, extracting the loose waste found below, up to a depth of 4 - 5 m. The other alternative would require the

development of an initial trench excavation and then the moving of the equipment (front loader and bulldozers) at the lower extraction level. This method could be applied successfully to a large scale mining scheme, but in the current mining application the development of the initial trench alone can provide the required waste volume. Therefore, the direct mining approach selected for the Polygyros pilot LFM is more simple, straightforward and therefore less risky and more productive.

Based on the proposed mining plan, the waste will be mined using 3 - 5 m wide and 3 - 4 m deep trenches, aligned in the NW-SE direction. Special attention will be paid to the gas extraction wells found in the area or other fixed infrastructure so as not to disturb them. The trench excavation will start from one end (the SW - or the NE one) having a length of about 20 m. At the end of the section the next cut will start. The excavation will continue to develop towards the NE (or SW) direction, until the target volume of 1,000 m^3 is reached. It is estimated that finally a "box cut" of about 20 x 20 x 4 m will be developed, at the end of the operations.

In terms of stability, the relatively shallow excavation is expected not to create strains or problems to the slope. Yet, special attention needs to be paid with a constant careful assessment of the waste condition directly below the excavator. Caution is to be paid in cases of extreme rainfalls that could deteriorate the stability conditions. In those events the possibility of the temporary suspension of the excavation will be considered.

As a general rule, the final slope of the mined area should not exceed the 1:3 limit. Furthermore, a buffer distance of around 5 to 10 m is required between the mined area and the adjacent southwestern landfilled slope. A safety distance should be kept between the loading trucks and the trench's crest, with each truck stopping at least 2 - 3 m away from the working face.

The rate of excavation will be directly linked with the feeding capacity of the processing unit, as the possible temporal stockpiling of the waste material needs to be minimized for environmental reasons. Thus, the excavation will be taking place at intervals but no apparent problems or other issues are anticipated, as long as a constant flow of materials can be maintained. However, for flexibility reasons, the possibility of developing a small stockpile near the processing unit will be considered. However, the proper design of the unit in terms of feeding rate can ensure the smooth operation in both the mining and the screening process. Based on preliminary estimations the whole mining and waste processing phase can be completed in about 25 working days.

At the start of the operation, the soil cover will be carefully removed and stockpiled for further reuse. The mining face need to be covered with soil so as to minimize odour issues, reduce windblown litter, etc. This can be done on a daily basis, at the end of the working shift. To facilitate the whole process, having also in mind the excavation rate, it is recommended that the exposed working face should be kept to a minimum. Further issues to take into account are the problems related to storm water and runoffs after heavy rainfalls. It is recommended that a surface water drainage system (e.g. diversion berms, grading of the surface adjacent to the excavation) could appropriately address such issues. For the case of the exposed face in the trench excavation a geomembrane cover will be applied, so as to minimize waste and water interference.

The haulage of the material will be performed using standard dump trucks. Their capacity is quite adequate to cover the capacity of the excavator and the processing unit, given the relatively small transport distance. The road network should be periodically inspected and properly maintained. Also in case where dust problems are expected, water spraying can be applied in the road surface with the use of tanker trucks.

Finally, the environmental monitoring of the site will take place, identifying critical

conditions and safeguarding the compliance with the environmental standards.

4 CONCLUDING REMARKS

The depletion of the mineral resources, together with the environmental footprint of former and operating mining sites, puts a lot of stress in mining companies. To deal with the challenges of the new era, a lot of discussion is being made for re-exploitation of low grade resources, underwater mining or even extraterrestrial mining. Technological evolution may allow these types of exploitation in the near future. Nevertheless, in terms of sustainability, the sector should look into the opportunities they appear today in order to continue not only to be competitive but also to respond to the increasing social requirements.

To this end, a number of individual companies have started to develop a better understanding of the full life-cycle of minerals and metal products, so as to maximize societal value and minimize impact on human health and the environment (USEPA, 2009). To this end, urban mining has become a familiar term describing different types of materials recycling potentials (i.e. electronic waste, demolition waste). As Krook and Baas (2013) mention, although landfill mining could be considered as a subcategory of urban mining, it contains features making it somewhat different, since landfill mining originates from the waste sector associated with serious problems. Moreover, there are significant uncertainties with regard to the composition of waste in each site. The objects of the majority of projects that have been carried out until today, were mainly the conservation of landfill space, the remediation or the solving of other traditional waste management issues (Frändegård et al.; 2013). There is an emerging approach, however, presented in several studies (e.g. Baas et al., 2010; Jones et al., 2010; Krook et al., 2012) of landfill mining as a strategy to recover deposited materials and energy resources by employing more advanced, up-to-date material separation and processing technologies (Krook and Baas, 2013). This approach is the result of the outcomes of a lot of studies showing that in many regions of the world massive amounts of metals have accumulated in landfills (Lifset et al., 2002; Kapur and Graedel, 2006; Müller et al., 2006; Krook et al., 2012).

In the light of the above, it is evident that the mining sector could have a key role in landfill mining, provided that it has the state of the art technology for mining and material processing. At the same time, the mining sector has an opportunity to improve its environmental performance and its poor public image. The landfill mining concept, however, is quite new in general and for the mining sector in particular. The uncertainties involved in this process are much alike the uncertainties involved in the potential exploitation of a new ore. Each potential "ore" coming from both natural resource reservoirs and landfills is unique. Composition of the extracted materials, market variability, financial, environmental and social costs and benefits should be estimated for each project individually. But, this is what the mining sector has been traditionally doing. After all it is another "dirty job but somebody has to do it".

ACKNOWLEDGEMENT

This work was supported by the LIFE+ financial instrument of the European Community in the context of LIFE RECLAIM "Landfill mining pilot application for recovery of invaluable metals, materials, land and energy" (www.reclaim.gr), Grant: LIFE12 ENV/GR/ 000427. The coordinating beneficiary is ENVECO S.A. and the associated beneficiaries are the Municipality of Polygyros, School of Mining & Metal Engineering NTUA and HELECTOR S.A.

Occupational Health and Safety

A Review of Preconditioning and its Influence on Mining Conditions with Particular Emphasis on Health and Safety

S. Modisha and T. Zvarivadza
School of Mining Engineering, University of the Witwatersrand, Johannesburg, SA

ABSTRACT The basic premise of any mining operation is to be profitable. In light of this, there should be a balance between safety and maximum extraction. Current gold mining in the Witwatersrand occurs at depths that are in excess of 3 kilometres. At such great depths, stress conditions are increasingly high and seismicity is also widespread. The success of any operation at these depths thus depends on the efficient negotiability of these high stresses. These stresses are capable of inducing violent ejection of rock from the faces which is detrimental to the workmen in the vicinity of the face area. Preconditioning as a means to ameliorate rockburst conditions in deep level gold mining complexes was introduced and it has since proven to be beneficial at various experimental sites.

The primary objective of this research was to conduct a review of preconditioning as a means to mitigate face bursts and its influence on mining conditions with particular emphasis on the Health and Safety aspects. The investigation process to complement this review was undertaken at one of the deep hard rock underground mines in South Africa. An extensive review of the current state of preconditioning and the advances thereof was conducted to unfold the techniques and mechanisms involved in preconditioning. The detailed investigation at the South African deep hard rock mine established that preconditioning, if applied correctly as per well informed mine standards, can be used as a tool to combat face bursts.

The authors observed that the correct application of the technique is the most important factor in order to ensure the effectiveness of this tool. The research also noted that well preconditioned stopes are generally safer than those that are incorrectly preconditioned or not preconditioned at all. It also follows that incorrect preconditioning is worse than not preconditioning at all. It is a recommendation of this paper that the importance of preconditioning, its operational benefits and correct application should be reiterated to stoping crews to ensure that stopes are safe for the workmen in the vicinity.

Keywords: Preconditioning, mitigate face bursts, health and safety

1 INTRODUCTION

Mining in the Witwatersrand Basin currently occurs at depths greater than 3000 metres and at vertical virgin stress levels which are in excess of 79MPa. Relatively high mining induced stresses are also inevitable under such conditions. The mine studied in this research is located in a seismically active and geologically complex deep level mining area. At such great depths the Ventersdorp Contact Reef (VCR) and the Carbon Leader Reef (CLR), which host most of the remaining gold resources becomes prone to rock bursting conditions due to the increased stress profile which then poses a significant safety risk to the workforce in the vicinity.

A rock burst occurs when the stored strain energy is abruptly released resulting in a violent ejection of the highly stressed rock from the mine workings (Eberhardt, 2014). Rock bursts are therefore associated with mining in high stress areas which is prevalent in the current South African gold mining landscape. A violent failure of a mining face results in a faceburst. This has become a widespread problem in deep level gold mining due to the presence of the hard and brittle quartzite rocks and relatively high stress regimes imposed on the rock mass.

Fatalities, possible stope closures hence lost production time; equipment damage and loss of mineral resource are inevitable from these conditions if there are no control measures in place to mitigate the effects thereof. Owing to this, the mining industry was prompted to conduct extensive underground investigations in the 1950s which then led to the implementation of preconditioning as a tool to ameliorate face burst conditions in deep level gold mining industry.

The research investigates and reviews different issues with regards to preconditioning as a means to ameliorate rock burst damage in underground gold mining and its influence on mining conditions. The effects of incorrect or not preconditioning and the consequences thereof with regards to safety of the workers are determined and reviewed. The study also compares preconditioning as it is applied at the face with the set out preconditioning standard.

1.1 Seisimicity Challenge and the Need for Effective Preconditioning

The VCR and CLR of the Witwatersrand basin are faceburst prone and as such, this poses a significant risk to people working in the vicinity of the stope areas. Face bursts and falls of grounds are the major causes of fatalities and injuries in narrow reef mining. Rock bursts and rock related accidents reportedly account for some 25% of all reportable injuries and more than 50% of all fatalities in the gold mining industry.

Preconditioning the stope face has been implemented as a technique to alleviate these risks thereby providing a safe working environment for the workmen in the stopes. It is therefore imperative to review the application of this technique with regards to its success and associated shortcomings in order to recommend appropriate corrective measures which effectively improve current practices which are widely applied in narrow reef gold mining.

2 PRECONDITIONING BACKGROUND

2.1 The Development of Preconditioning

The management of the East Rand Proprietary Mines (ERPM) along with the Council for Scientific and Industrial Research (CSIR) introduced preconditioning, then referred to as de-stress blasting in the 1950s, as a means to mitigate the effects of face bursting conditions in deep level gold mining (Roux et al, 1957 as cited in Lightfoot et al, 1996). Since then, a wealth of knowledge on this technique has been gathered and compiled to provide guidance on how to negotiate such dangerous conditions. Between 1990 and 1996, there were 214 fatalities that were a result of 134 face burst incidents across the South African gold mining industry (Toper et al, 1998). The basic premise on which preconditioning was based at that time was that the effects of face bursts can be reduced by increasing the depth of the fracture zone. Albeit the damage resulting from face burst incidents is only local, that is, events with a magnitude less than 2, it still poses a significant risk to the workers as stopes would typically have a concentration of eight to ten workers at any one time.

This then led to the undertaking of the Gold and Platinum (GAP)030 and GAP336 projects by the Rock Engineering programme of the CSIR to develop and implement preconditioning techniques that will effectively control face ejection rock bursts to allow safer mining in seismically hazardous areas. These projects have led to some of the major developments on de-stress blasting which include two preconditioning techniques namely; face parallel and face perpendicular preconditioning both of which have practical limitations in terms of the mining environment in which they can be applied. Some of the major recommendations from these projects were to include preconditioning in the mine's code of practice so as to enable the mine's safety personnel to follow up on compliance and to also educate the production personnel and train stoping crews on implementing

preconditioning which then changed the safety landscape of deep level gold mining.

2.2 The Mechanism of Preconditioning

Pre-conditioning, previously referred to as destressing is a means of reducing the potential for rock burst damage by extending existing fractures ahead of faces and thus moving the high concentration of stresses away from the immediate face area into the solid rock. The potential for faceburst is reduced by remobilising existing fractures into the rockmass thereby preventing the accumulation of strain energy ahead of the working face (Venter, 2008). Preconditioning mitigates the effects of a seismic event by acting as a cushion between the seismic event and the working place. Figure 1 illustrates an idealised model of how preconditioning moves the peak stresses that has accumulated in the rock mass further away from the face such that the inevitable bursting that would happen could occur within the fractured zone, with fractures acting as a cushion to reduce the consequent effects of such bursting.

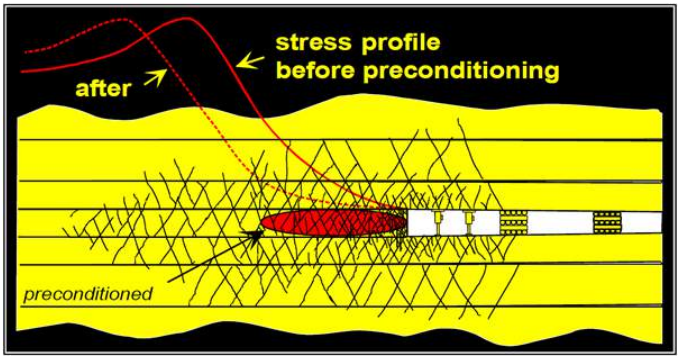

Figure 1. Stress redistribution due to preconditioning (Venter, 2008)

A preconditioning blast, after being set off, pulverises the rock in the immediate vicinity of the blast hole. This pulverisation is a result of the high compressible stresses acting on the wall of the preconditioning hole. As a result, the hole is pressurised thus generating stress waves capable of creating an intense radial fracturing zone close to the preconditioning hole (Toper *et.al*, 2003). The gases originating from the explosives in the preconditioning hole extend radially outwards from within, into the surrounding rock mass thereby extending the existing fractures by forcing apart the sides of the existing fractures to reduce any clamping stresses present in the rock. This would then encourage slip across factures and will ultimately relieve the stresses acting on the immediate face.

2.2.1 The GAP030 Project

The GAP030 project provided guidelines on optimal parameters and the actual methodology for the implementation of the various preconditioning techniques (Lightfoot et al, 1996). Some of the parameters proposed include the optimal spacing of 3m between preconditioning holes and offsetting of holes 50cm from the previous day's holes. Figure 2 illustrates the basic outline of the three day cycle preconditioning technique as was proposed in the GAP030 project report.

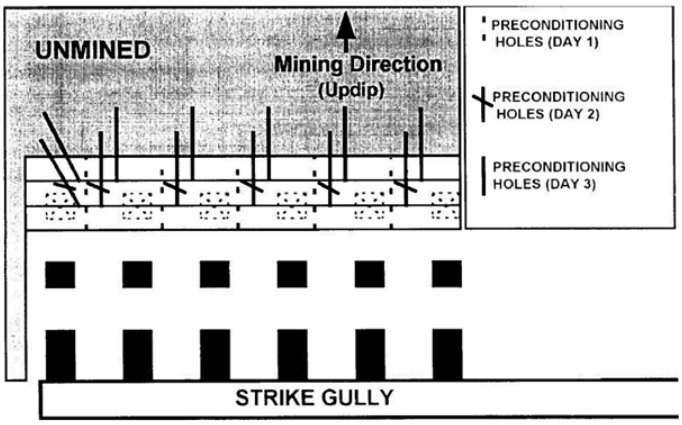

Figure 2. Layout of the three day preconditioning cycle (Lightfoot et al, 1996)

Lightfoot et al (1996) further postulated that stress transfer is a dynamic process that is a response to mining and preconditioning, as such it should be amalgamated into the mining cycle in a controlled and sequential manner. Also, based on the preconditioning experimental site, it was established that the effects of preconditioning are local and temporary in both space and time. It followed that every production blast must be carried out concurrently with a preconditioning blast to ensure maximum

face stability. The GAP030 project established that preconditioning works on the mechanism of slip on existing fractures rather than the generation of complete new fractures, the cause of slip at that stage, with the then available body of knowledge was however not known. Lightfoot et al (1996) also proposes that as an additional benefit, preconditioning can be seen to trigger larger seismic events.

2.2.2 The GAP336 Project

The GAP336 project was aimed at informing the practicing engineer about the importance of correct application of the technique chosen. The findings of this project included the specifications of conditions under which the various preconditioning techniques can be implemented i.e. face parallel preconditioning is widely used in pillar and remnant extraction. The advantages and disadvantages of each technique were also weighed out as shown in table 1.

Table 1. Comparison between face perpendicular and face parallel preconditioning techniques

Perpendicular face drilling	Parallel face drilling
Primary mining	Secondary mining
Ideal for deep level mining and up dips	Ideal for extraction of stability pillars
No special equipment required	Special equipment required
Integrated into the existing mining cycle	Requires a special production cycle
No limit on face length	Limits face length

Also, assessing the effectiveness of each technique was an important recommendation of the GAP336 project. Because this project was based on an experimental site, individual mines might have different conditions and as such practicing engineers were advised to optimise or adjust preconditioning parameters such that they would suit the specific site conditions of that particular mine.

2.2.3 The GAP811 Project

Further works done by CSIR Miningtek for the Safety in Mines Advisory Committee (SIMRAC) involved determining the criteria for preconditioning at high stoping widths in the research project GAP811 which involved the establishment of various high stoping preconditioning experimental sites. It was recommended that the preconditioning holes must be drilled at 60cm from the hanging wall to avoid over hanging faces. This project further established that training of mining personnel on the correct implementation procedures of preconditioning was an essential component of its success in mitigating the effects of rock burst damage (Toper et al, 2003).

2.2 Quantifying the Effects of Preconditioning

Research was further undertaken by Grodner (2001) to effectively establish an optimal method of preconditioning; Ground Penetrating Radar (GPR) was used to quantify the effects of preconditioning on the fracture patterns. This was an essential undertaking as it affirmed the initial hypothesis formed regarding fracturing of rock ahead of the stope face. The radial zone of influence of each preconditioning hole was also established which then allowed the optimisation of preconditioning. Assessing fracture patterns was also essential for understanding whether precondition blasts result in the development of entirely new fractures or the extension of pre-existing fractures which is essentially the framework of the mechanism by which preconditioning occurred (Grodner, 2001).

Mitri (2000) as cited in Saharan and Mitri (2011) postulates that even though preconditioning can be used to contain the effects of strain bursting, measures like using alternative methods and appropriate rock support systems such as back filling were necessary to reduce the damaging effects of excessive stresses. This is a particularly important realisation because depending on preconditioning to remedy all rock related problems underground might deem it ineffective to a certain extent. It is also worth noting that preconditioning is only a tactical measure while a change in mining layout can be incorporated in the

mine design and should therefore be planned in advance and as such it is a strategic measure.

Saharan and Mitri (2011) state that a major challenge with preconditioning is that the source that is responsible for initiating rock bursts is yet to be known. The fact that the timing of these events cannot be predicted regardless of the scientific and technological advances made in mining poses a persistent risk to future mining. This poses a significant problem such that a proactive technique which could entirely alleviate rock burst damage cannot be implemented without the understanding of the genesis thereof. This is also a challenge to researchers as rock burst might increase despite the application of preconditioning (Saharan and Mitri, 2011).

A case study done at Mponeng mine affirms that there is a decrease in the occurrence of face bursting during effective shift times and the frequency of injuries associated with seismicity (Viljoen, 2003). This is attributed to the improved hanging wall and face conditions and as such, this technique is seen as the only tool to ameliorate face bursts (Viljoen, 2003). In this case study, it was established that drilling of preconditioning holes at 60cm from the hanging wall has some practical implications such that it necessitates the establishment of two preconditioning standards for high and low stoping widths respectively. This led to a conclusion that preconditioning holes must be drilled in the middle, between the hanging and footwall to produce one preconditioning standard so as to avoid confusing the stoping crews (Viljoen, 2003).

3 RESEARCH OBSERVATIONS

3.1 Utilised preconditioning approach

Panels that are situated in highly stressed grounds are preconditioned in order to alter the behaviour of the overstressed rock and thus minimise the hazards and risks that are associated with these stress levels. The mine uses a face perpendicular preconditioning technique which was decided by weighing it against the face parallel technique which cannot be incorporated in the current mining cycle. Four underground working places were investigated

3.1.1 The Preconditioning Cycle and Drilling

Using drilling machines that are used for normal production holes, 2.4m preconditioning holes (twice the production hole length) are drilled at 90 degrees to the face, spaced 3m apart. There should thus be enough spacing between the last line of support and the face to accommodate the use of these 2.4m drill steels. These holes are drilled in the middle of the face between the bottom and top holes in the channel of the reef and must be drilled at least 60cm below the intended hanging wall so as to not compromise the stability of the hanging wall.

Lightfoot *et al* postulated that the effective area of a preconditioning hole is indeed 1.5m in radius after assessing Giltner (1992)'s assumption and as such these holes are drilled at 3m spacing. However, observations made at the study working places have shown that rock drill operators (RDOs) have a proclivity to drill these holes at distances that are either shorter or greater than the prescribed distances.

This technique is cyclic and each cycle consists of 3 days. Consistent with the findings by Toper *et al* (2003, 71-72), preconditioning holes are offset at 50cm from the sockets of the previous day's preconditioning holes along the strike of the reef. The panel face is advanced almost 2.7m (0.9m advance/day) in three days and as such the holes of the fourth day are drilled on the same position as the one for the first day. Also, with such an advance rate, there should not be sockets remaining at these positions because three production rounds would have been blasted. Figure 3 shows a typical layout of the 3 day cycle face perpendicular preconditioning technique.

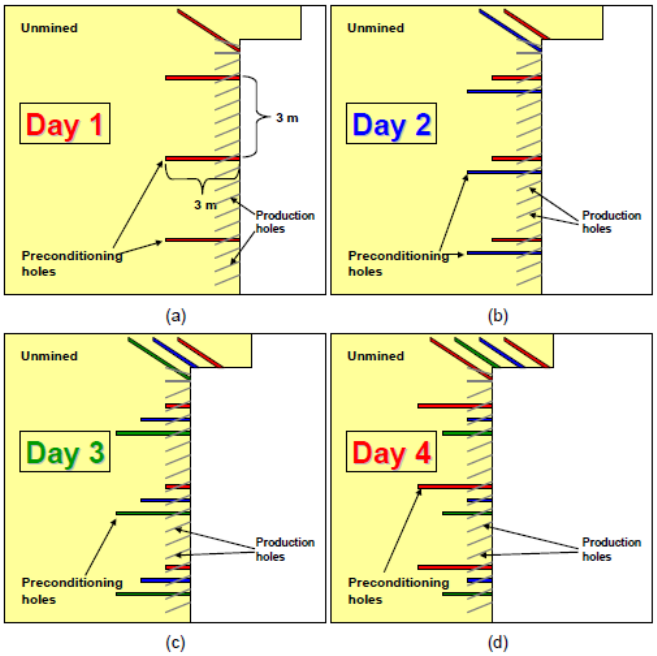

Figure 3. Layout of the three day cycle preconditioning technique (Toper *et al*, 2003)

3.1.2 Charging and timing

Preconditioning works by allowing shearing along pre-existing fractures in the rock mass so as to redistribute the stresses in the immediate face area to the solid rock ahead of the face and as such large volumes of gas are required to extend these fractures. The same explosives that are used to charge up the production round are used for preconditioning hole. The 34mm diameter preconditioning holes are charged from the bottom with a water based gel and top primed for 1.4m. The remaining 1m of the hole is stemmed with tamping clay to retain the maximum explosive energy thus achieving efficient fracturing. 2.4m long fuses are used to time the preconditioning holes. These holes are timed such that they have a four-hole burning front; this ensures that they detonate four holes before the normal production holes could detonate. An illustration of the charging up of preconditioning holes is shown in figure 4.

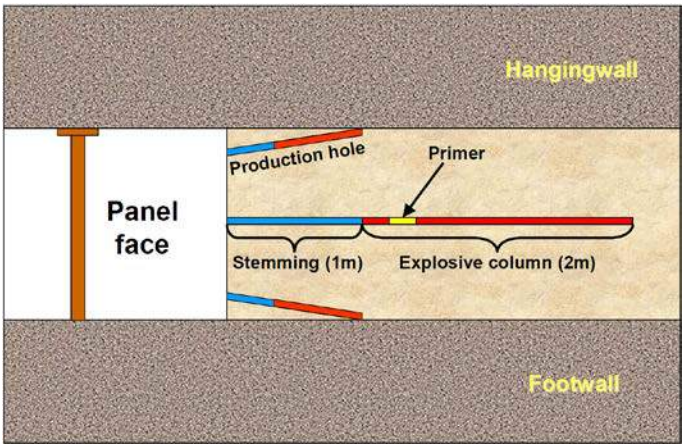

Figure 4. Illustration of charging up of preconditioning holes (Toper *et al*, 2003)

3.2 Preconditioning Human Factor Observation

Some stope crew believe that drilling preconditioning is extra work and as such, they should be paid for it. In some stopes, stoping crew believe that the night shift did not clean the panel and as such, the RDOs could only start cleaning late in the shift, production holes were therefore prioritised over preconditioning holes. It is crucial to note that pressure from management wanting production may lead production crews to focus more on drilling production blast holes. Behavioural change amongst all interested parties is needed in order to facilitate improvements in the preconditioning technique.

4 Evaluation Of Reseach Observations

4.1 Preconditioning Parameters

4.1.1 Hole length

This is sometimes not done completely to standard. This is evidenced by preconditioning holes that are shorter than the specified length of 2.4m in the preconditioning standard. Although the variance between the specified hole lengths and the ones measured is not grossly disproportionate, if the hole length is shorter or longer than 2.4m, there may be grave consequences. Drilling of short holes may render preconditioning ineffective resulting in misfires and under breaking of the face.

Excessive stresses would be placed in the rock ahead of the face should over breaking occur.

Drilling of longer holes also has detrimental consequences in that it will result in fracturing of the block too far ahead of the face. This will essentially leave a slightly fractured area between the previously fractured area and the newly preconditioned area. A highly stressed block ahead of the face will then be created leaving an area which could potentially result in face bursting.

4.1.2 Spacing

The radius of influence of each preconditioning hole was found to be 1.5m on either side which translates to spacing between preconditioning holes of 3m. Holes that are spaced at a distance greater than the prescribed spacing result in a stress amplification between these holes. The stresses become concentrated in the portion of the area between these holes that did not fall into the area defined by the radius of influence of each hole. This causes stress concentrations between holes. The increased stress levels between these holes thus increases the chances of instability.

4.1.3 Charging and Timing

Preconditioning holes should be charged as per specified mine standard. A common misconception that overcharging of holes would result in maximum stress transferal was noted, instead this gives similar effects to that of drilling short holes in that it results in under breaking of the face. This then places excessive stresses ahead of the face which can be detrimental to the workmen in the vicinity once this position of the face area is encountered. While over charging of the holes is detrimental to the safety of the workers, under charging will render preconditioning ineffective by resulting in misfires. Misfires are time consuming to clean and may potentially lead to lost blasts which are detrimental to production and the total mine productivity.

4.2 Preconditioning and seismicity

Scattered mining configuration as is practiced at the mine often necessitates creating reef and off-reef pillars for regional stability which can induce seismicity. The scattered mining configuration is largely due to the fact that the mining complex is highly faulted. Seismic events associated with these pillars do not only occur while active mining is taking place in their vicinity but after a considerable amount of time Van der Heever (1998). The relatively high frequency of seismic events in the mining complex can, in part, be attributed to the scattered mining configuration. Also, the load on these pillars increase as more areas are being stoped out; pillars also deteriorate in terms of strength and stability over time. Although preconditioning does not reduce the likelihood of a seismic event, it mitigates the effects of such an event by acting as a cushion between the seismic event and the working place, thus preventing the face from bursting and the consequent risk of injury to the people in the vicinity. Preconditioning offers protection against face bursting but it cannot influence the source of the events causing the face to burst. Also, preconditioning can be seen to induce seismicity, such that the fractures allow a controlled release of strain energy in the highly stressed areas.

4.2.1 Preconditioning Judgement

The checklist provided in Table 2 was used by the authors for an objective judgement of the preconditioning blasts that were recorded during the research. This was done for each of the four working areas investigated.

The approach takes the approximate amount of explosives used and the subsequent seismicity recorded into account so as to minimise the subjectivity in the judgement.

Table 2. Example checklist for first working area

Preconditioning Checklist	
Day 1	
Average spacing between holes	3m
Average Length of holes	2.2m
Average Inclination to the hangingwall	85°
position of the holes on the face	middle
Day 2	
Condition of the face (blocky, fractured or smooth)	fractured
How many holes detonated?	all
Are there any misfires?	no
Average Length of day 1 sockets	1.9m
Average spacing between holes	3.4m
Average length of holes	2.3m
Average inclination to the hangingwall	75°
position of the holes on the face	middle
Day 3	
Condition of the face (blocky, fractured or smooth)	smooth
How many day 2 holes detonated?	5
Are there any misfires?	Yes (3)
Average length of day 1 sockets	1.2m
Average length of day 2 sockets	1.8m
Average spacing between holes	3m
Average Length of holes	2.2m
Average Inclination to the hangingwall	80°
position of the holes on the face	middle
Day 4	
Condition of the face (blocky, fractured or smooth)	fractured
How many day 3 holes detonated?	all
Are there any misfires?	no
Average length of day 1 sockets	0.3m
Average length of day 2 sockets	0.9m
Average length of day 3 sockets	0m
Average spacing between holes	2.9m
Average Length of holes	2.1m
Average Inclination to the hangingwall	85°

4.3 Operational Benefits of Preconditioning a Stope Face

Preconditioning has certain operational benefits when done correctly. Some of the benefits observed by the authors during the study include:

- Improved ground conditions and consequently a smoother hanging wall and stope face. These conditions result in better stoping width control.
- In a less stressed face, the face advance per blast tends to increase which therefore results in greater productivity.
- Consistent and better fragmentation resulting from efficient drilling and blasting.
- Safer working environment for the workers in the vicinity of the face area due to a smoother hangingwall and a less stressed immediate face area.
- Easier cleaning (scraping) made possible by improved fragmentation.
- Reduced stoping costs due to a better stoping width control.
- As an additional benefit, preconditioning can also serve to trigger larger seismic events in that it encourages a controlled release of stored strain energy.
- The summed effect of a safer working environment, easier workload and more production resulting from improved face advances equals increased stoping team confidence due to safety and production incentives.

4.4 Strategic and Tactical Measures to Supplement Preconditioning

Preconditioning, if employed correctly can significantly alter the behaviour of overstressed rock by mobilising the fracture zone ahead of the advancing stope thus forcing it to dissipate the stored strain energy as well as reducing its load carrying capacity. This technique has proven to be effective and as such it can prevent fatalities and ore reserve abandonment due to stope closures or ultimate mine closures by the issuing of penalties from the department of mineral resources. However, to adequately improve some problems underground, a change in mining method or stope layout may be necessary and as such, it should be done rather than depending on preconditioning in its entirety to remedy all rock related problems (Toper et al, 2003). Also, efficient support systems can go a long way in supplementing preconditioning.

4.4.1 From scattered to sequential grid mining

The mining configuration employed at the mine shaft is scattered mining which involves leaving of strike pillars. In face burst prone areas, it is quite evident that strategic measures included in mine design such as a properly sequenced stoping process as opposed to the scattered mining configuration currently employed can minimise the rockburst damage. One such

strategic measure would include the switch to sequential grid mining in all the stopes which is capable of capping the Energy Release Rate (ERR) in the mining front by limiting the mining span

Sequential grid mining is characterised by leaving systematic dip pillars for regional support as opposed to strike pillars left during scattered mining and as such, this makes the mining layout more orderly due to the predetermined grid of mining. Because the current mining is occurring at a geologically complex district characterised by faults and dykes near the stopes and it is at depths in excess of 2000m where there are a lot of remnant areas left between stopes, mining induced seismicity and rock bursting pose significant risks to the workmen. Sequential grid mining method is an ideal strategy for reducing the number of remnants being formed and the associated seismicity generated on these geological features would be kept at a minimum (Handley et al, 2000).

4.4.2 Support systems

The use of elongate support and in-stope roof bolts to minimise the effects of seismicity has proven to be successful as a tactical measure to complement preconditioning and as such, the correct implementation has to be reiterated to the workforce. Back filling to fill out mined out areas reduces the occurrence and the effects of large seismic events thus reducing rock bursting conditions.

5 CONCLUSIONS

An efficient preconditioning methodology relieves stresses on the immediate face area thus providing a safe working area to the workmen in the vicinity.

To mitigate the effects of face bursts, a face perpendicular preconditioning technique is used at the mine shaft. This was on the basis that this technique does not pose any significant disruption in the mining cycle and can easily be integrated into the existing mining. The technique offers some operational benefits when carried out properly on top of the main benefit of ameliorating face bursts, this gives more impetus for the workmen to precondition the face with every blast.

Preconditioning involves stress redistribution from the immediate face area back into the solid rock ahead of the mining face, existing fractures are remobilised. It is localised in both space and time and as such it has to be carried out with every blast because its benefits are temporary. This technique is a proactive tool in combating face bursts incidences and providing a safer working environment.

The summed effect of a safer working environment and increased throughput due to improved advance rates leads to increased worker morale.

The authors recognise that there is still room for improvement in the application of this technique at the mine and give the following recommendations to facilitate the improvement.

• The importance of preconditioning has to be reiterated to the stoping crews to ensure maximum adherence to the mine standard thus achieving the desirable results. It is also worth reiterating that incorrect preconditioning can exacerbate the stress conditions on the face by inducing face bursts rather than the prevention thereof, as such, if preconditioning is to be done, it has to be done correctly.

• Regular training needs to be carried out to ensure that workers adhere to the standards. Training of newer employees and re-training older employees on the importance of preconditioning is also imperative. Preconditioning depends largely on correct application and as such, its success lies in ‘on the job’ training and coaching of employees to ensure that preconditioning standards are thoroughly adhered to.

• If maximum results are to be achieved, some sort of a compliance incentive has to be introduced. The mine can adopt the same system of incentivising the workmen for installing in-stope rock bolts. This will encourage the workers to correctly precondition the panels on a daily basis.

• Dynamic or rapid yielding support systems such as pre-stressed elongates and hydraulic props in faceburst prone areas still prove to limit the extent of rockburst damage as such, they must be installed correctly as per mine standard on support systems.
• Alleviating safety problems should be done as a holistic approach, mine design and planning strategies that can effectively reduce or expose workers to rock bursting conditions should be taken rather than the utter reliance on preconditioning to alleviate all rock bursting conditions. This would ensure that a proactive approach of risk amelioration is adopted in a bid to reach the resilience stride of the risk maturity journey model.

A Risk Assessment Approach to Achieving Mining Safety Goals

D. Kent
Mine Site Technologies, Sydney Area, Australia

ABSTRACT Given the recent focus on mine safety in Turkey, and the role of technologies to support these initiatives this paper discusses the two differing approaches to mine safety that have developed over the years in the USA and Australia. Though the outcomes can be similar, the approaches are from two different viewpoints; one being prescriptive based (USA) and the other being risk assessment based (Australian).

A key difference is one vests the control, and hence responsibility, with the mine operator and workers, whilst the other approach vests much of the responsibility with the government authorities to police mine operators to ensure they follow the legislated rules. Focus will be placed on the outcomes that result, in that similar systems and technologies may be deployed, but the actual quality of the total safety systems can vary quite significantly.

This paper discusses these approaches to improving safety and some of the key technologies, including tracking and communication systems, that provide the engineering controls to key mining risks as well as meet stringent mine safety laws.

Keywords: Risk assesment, mining safety, tracking, communication systems, mine safety laws

1 INTRODUCTION

There is a striking difference in the approach different countries around the world take in addressing safety and management processes of their respective industries. This paper will focus on the US and Australian mining industries, as they are both well regarded internationally and represent first world mining.

Stepping back to 2006 the coal industry in the US was jolted by the tragic explosion at Sago Mine that resulted in the death of 12 miners. Mine Site Technologies was pulled into the subsequent analysis and media frenzy because some of our equipment got into the hands of government authorities and was waved around in Senate hearings.

What became apparent was a fundamental difference to how safety was managed and implemented between the US and Australia mining industries.

The difference is the one that really interested me. It was best summed up by a common question, that was almost an accusation, I was asked when discussing our communication and tracking technologies at industry forums and presentations in 2006.
When I mentioned how 90% of the underground coal mines in Australia had a certain one of our technologies installed, the common remark was: ’”Yeah, yeah that’s because *the regulations say* they must have it”.

My response was “No, our technology was installed because it was the best available device to *manage a risk they had identified*”.

Then the common comeback was along the lines of: “Yeah, yeah, that’s because the *law says they have to install it*”. As if the “it” was specified precisely.

And around it went.
These exchanges kept me thinking for a long time and have resulted in this paper.

2 WHAT WILL WORK?

Australia had their “Sago” in 1994 when 11 miners we killed in an explosion at Moura No.2 Mine in Queensland. It really stunned the industry, particularly the Queensland

industry including both the mining companies and government authorities.

Here we were in 1994, improved laws, inspections and equipment, and yet this happened again. Over the preceding 20 years there had been major explosions at Kianga, Appin and Moura No.4 mines resulting in a total of 39 deaths.

To the industry's credit the mine operators, government authorities and unions stood back and realized there had to be a better way to improve safety, just implementing new rules or regulations did not get to the heart of the problem.

Taking a lead from the chemical and the oil & gas industries, a safety system was developed around risk management principles.

As previously mentioned, up to now safety was driven by new rules and regulations, forcing miners to install better equipment, specific back-up devices, etc. But this hadn't worked as effectively as hoped.

What was needed was a change of process, and that process driven by all involved, being the unions, mining companies and government. Plus the responsibility and control rests with those directly involved in its use – the mine management and mine workers.

Basically there was a duty of care to every employee to be able to arrive at work, complete their shift and go home safely to their families. All well and good, but how to achieve it?

So over a number of years this new approach to safety was developed and the trust between parties was established that allowed the benefits of this new way of safety to be realized.

The result? The following two Figures show the dramatic reduction in Fatalities and Lost Time Injury Frequency rates (LTIFR) since 1980.

Balanced against this is another interesting statistic, Figure 3 shows the productivity of Australian coal mines over a similar period.

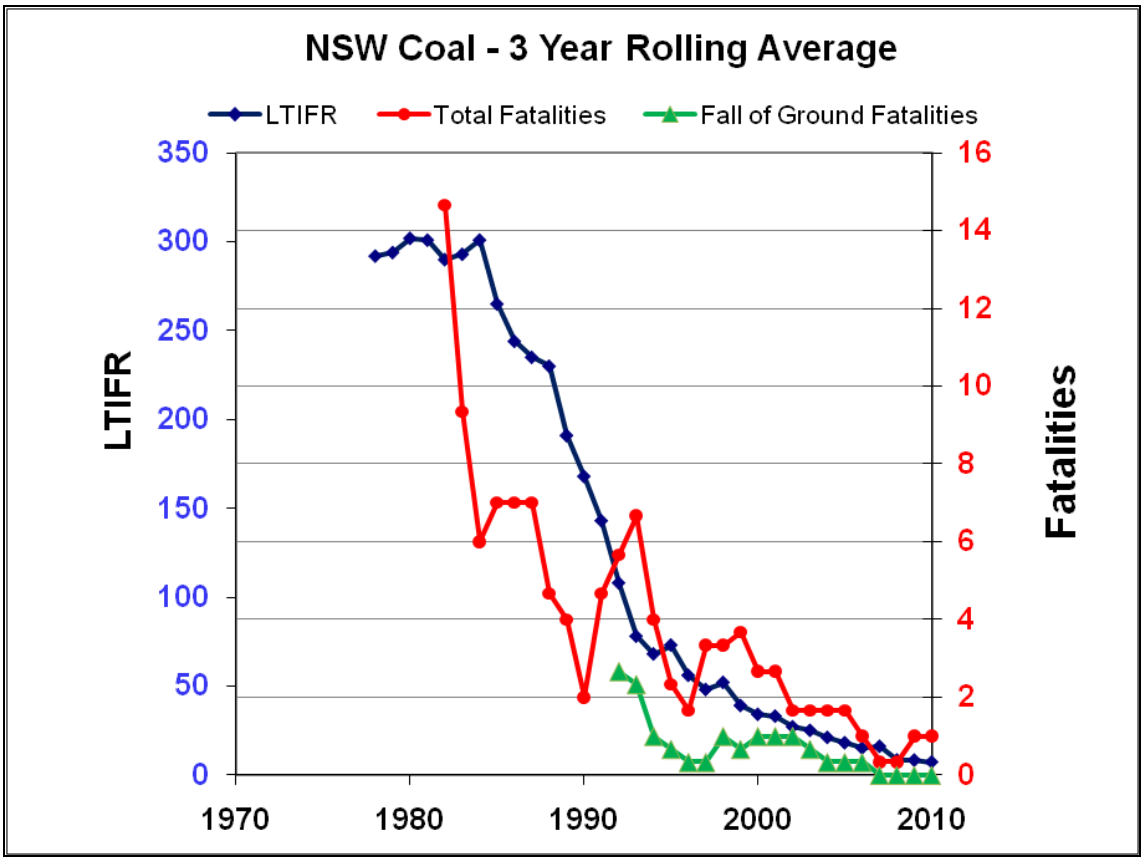

Figure 1. Fatalities & LTIFR in NSW Coal Sector (from Galvin 2011).

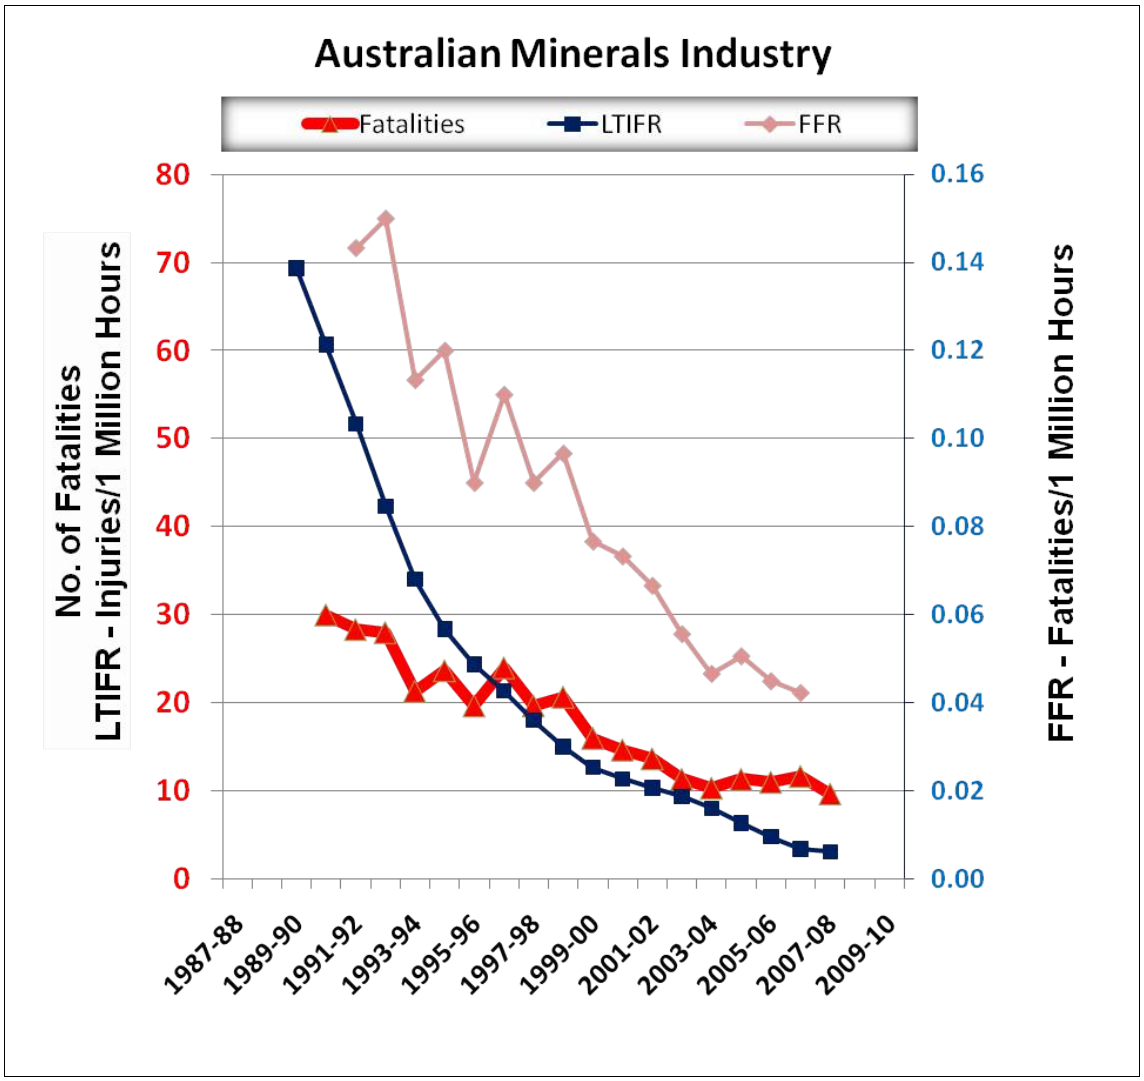

Figure 2. Fatalities & LTIFR in Australia Minerals Industry (Galvin 2011)

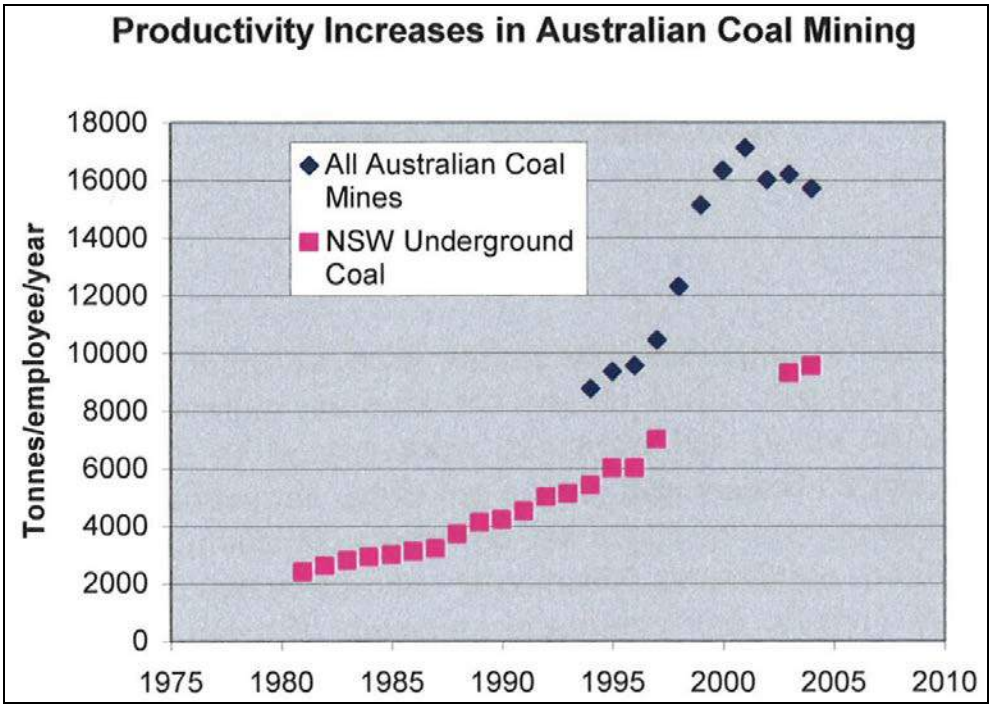

Figure 3. Productivity Increase in Australian Coal Mining since 1980 (Galvin 2005)

Over this same period there had been excellent improvements in the US industry as well, where a more traditional prescriptive approach dominates.

Though flattening over the last few years, the US industry has had major advances in mine safety, as demonstrated by the fall in the number of fatalities over the years as shown in Figure 4.

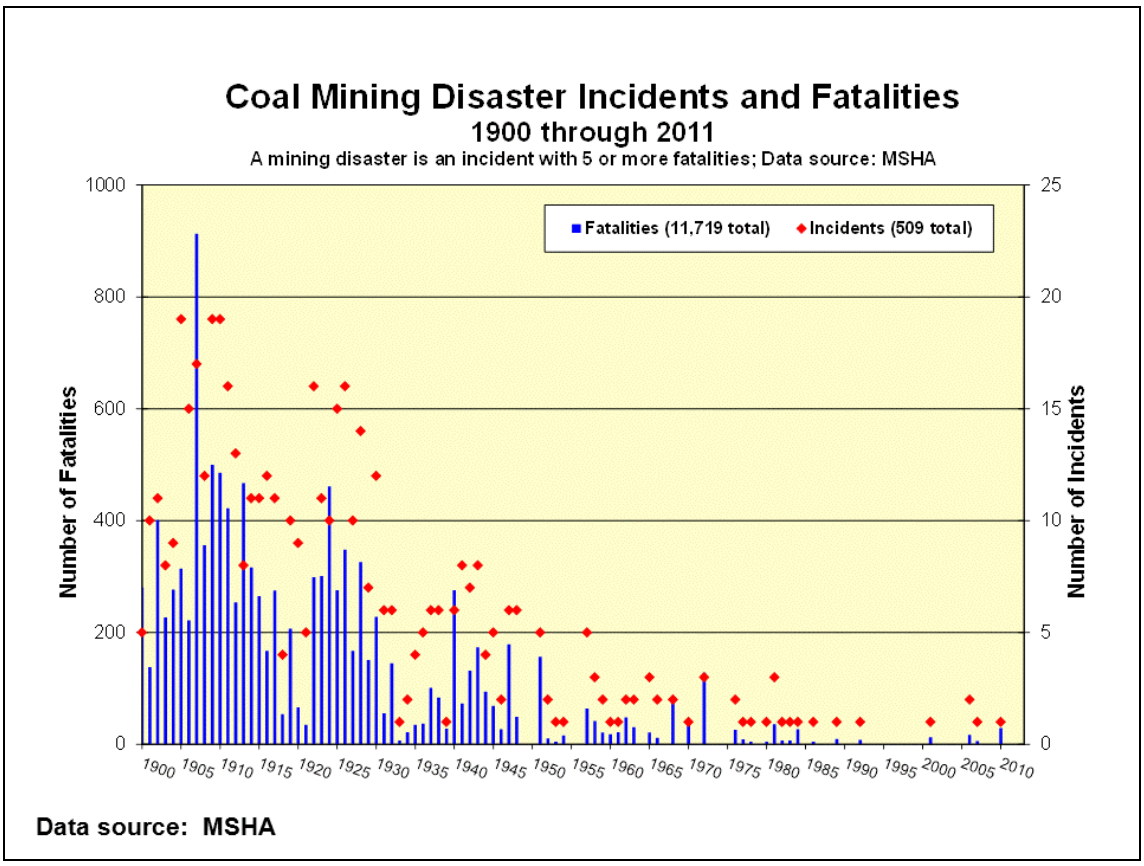

Figure 4. Coal Mining Fatalities 1900 to 2011 (MSHA)

3 THE PROCESSES BEHİND THE SAFETY IMPROVEMENT

The end result between the US prescriptive approach and the Australian risk assessed approach is often remarkably similar in what ends up being implemented at the individual mine sites.

Given the investigations and analysis that goes on after a mining disaster, this is not surprising. However, having been witness to, and involved in both industries for considerable time, I would contend the risk assessed approach is more proactive as opposed to the more reactive, prescriptive approach.

Basing your safety systems on a risk assessment approach, means that as each aspect of the operation and its safety systems are analysed in a risk assessment, there is an immediate responsibility to address the issues identified in that risk assessment. The responses being:

- Eliminate the risk if possible.
- Put engineering controls & barriers in place to minimise the risk,
- Put controls in place should an event occur to minimise the impact of the event on the people and the mining operation.
- Develop procedures to reduce risk

The classic Bowtie Diagram in Figure 5 illustrates this very well

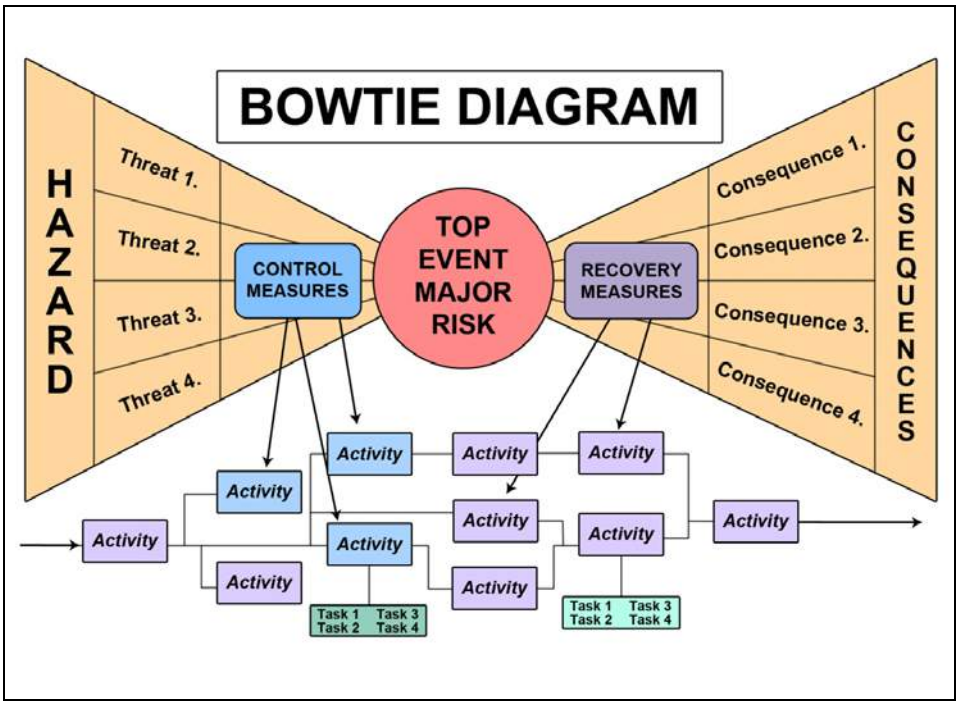

Figure 5. Bowtie Diagram

This is not new to many people, but to implement it properly throughout an operation is a significant task. Good miners anywhere have always done their own "mini risk assessments" every time they start their day at the face. When I started on the face the older, experienced miners I was with just didn't leap onto machines and start cutting coal, they spent a minute or two looking around. Basically, it was a long entrenched, albeit brief, private risk assessment process.

What the modern risk assessment processes of today are doing, is allowing the individual experience and ideas to be gathered and shared in a formalized process.

This entails the involvement of the mine workers and operators, as well as management, as a single team. This reinforces a critical element in a successful risk assessment – the shared responsibility and commitment to implement the recommendations.

And for someone who has straddled the older prescriptive system in Australia to the newer proactive approach, success can only be achieved in the latter by a cultural change in the attitude to mine safety. When I worked underground we lost about one guy every year or two at the operations, and twice it was a co-worker in the crew I worked in.

It was shattering, it was sad, BUT in some way there was a tacit assumption by everyone that it was "expected", after all "mining is a dangerous game". That attitude has completely changed and I can stand here today and say I do not believe that there is one person in the Australian or US mining industry that would consider a fatality as inevitable. That is a considerable change and it did take time.

So what are the processes behind the improvements? Apart from individual assessments on new equipment or situations, the process began with a foundation of each mine required to manage their core risks and develop Safety Management Plans for all aspects of the operation. Core Risks for underground coal mines were identified and the Safety Management Plans had to address them. The generic core risks are shown in Table 1.

Table 1. Core Risks

Core Risk	Related Risks & Items
Ground Control	Strata Stability: -Local -Regional
Ventilation	-Gas -Fires & Explosions -Dust
Spontaneous Combustion	Related to ventilation & design, but categorized separately
Water Inrush	
Failure to Isolate	-Electrical -Mechanical, including hydraulic & pneumatic
People/Vehicle Interaction	Most recent of what is a general core risk
Other Mine Specific Risks	Such as: -Lightning & extreme weather

Managing Core Risks through risk assessments can have many paths leading to the Safety Management Plans. A typical process can be seen in the development of TARPs (Trigger Action Response Plans) in Queensland, Australia.

As an example of this process a key risk is identified at a high management or Board level. This in turn leads to a risk assessment or assessments at each operation exposed to the risk, out of which a number of controls and procedures are identified to eliminate or reduce the risk and any consequences should they occur.

Then this flows into the so called TARPs for the practical implementation and management of the controls at the mine site. The TARPs are designed to allow for a simple flow of actions that can be easily followed, even under the stress of a major incident.

Diagrammatically the process is shown in Figure 6 below.

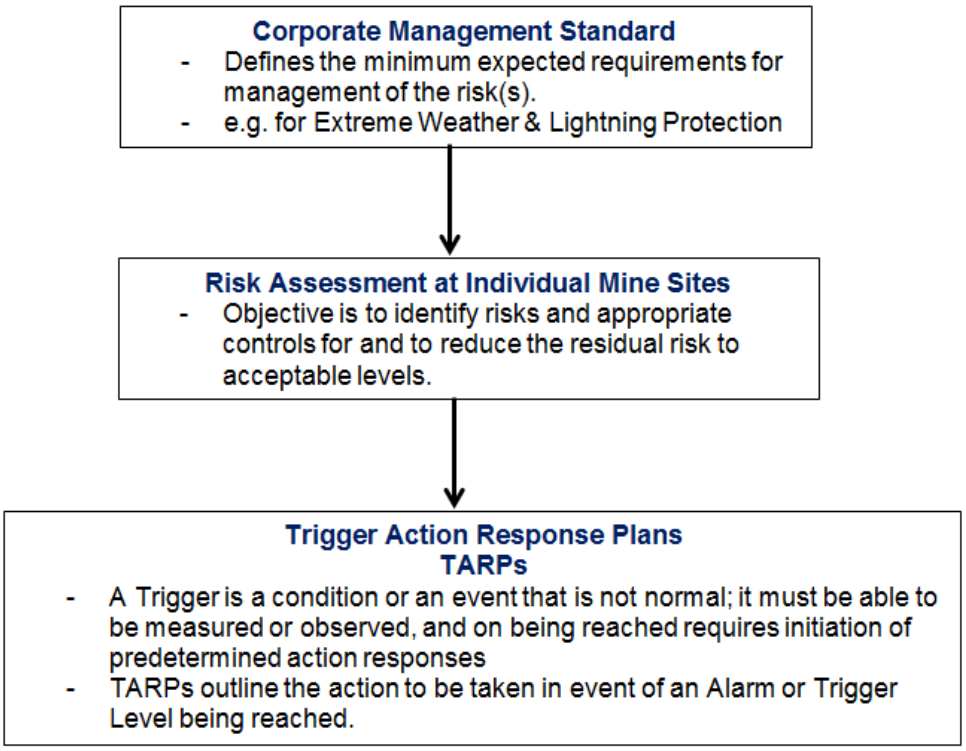

Figure 6. Simplified TARP Development Diagram

So, again, what is the difference in the end result between the two approaches adopted by the US and Australia – sometimes very little. Similar equipment and systems are in place trying to control and manage risks.

But the timing of implementation and on-going reviews and improvements do seem to vary.

For example in the area of communications in which we are closely involved, once the risk assessment methodology started to be taken up, companies identified risks in the lack of communications in emergencies, so we found from the mid to late '90's mines in Australia were equipping all miners going underground with our Personal Emergency Device (PED) pagers, rather than just 20% to 30% of the workforce.

The process to get to this decision was started with the requirements of the Safety Management Plans, one of which being the Emergency Management Plan (Emergency Preparedness Plan). The following Figure shows the overall plan structure, and in this case also shows the role of emergency exercises that are conducted in Queensland coal mines.

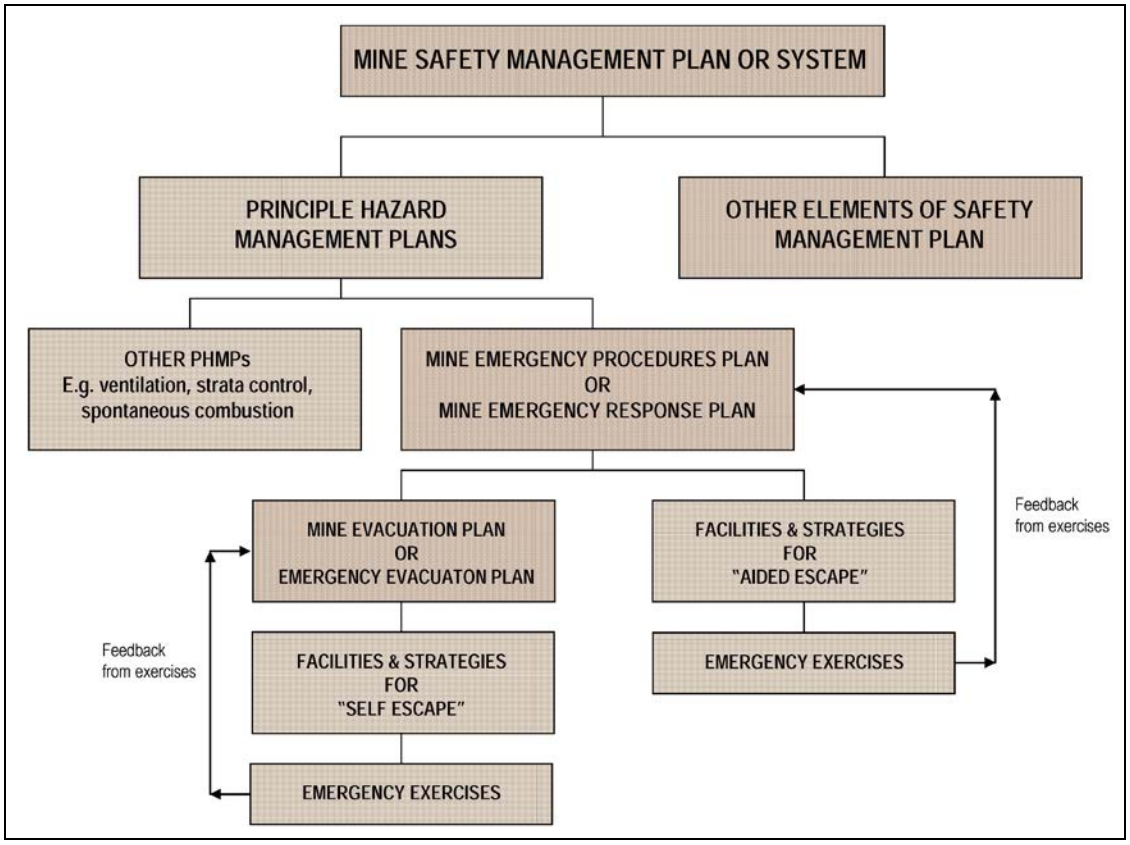

Figure 7. Emergency Management Plan

During the risk assessments for this plan it was identified that a key element was ensuring you were able to contact personnel and issue specific evacuation instructions as quickly as possible should an incident occur, such as a fire. PED was available and judged the best control for that risk at the time; in fact PED is still used in this role in about 70% of underground coal mines in Australia.

Similarly, as the importance of knowing who is underground and which areas underground they are located became identified of critical importance to managing emergency responses, our tracking systems have become widely deployed.

There was no law saying you must "install a through-the-earth emergency warning system" or "track people at a minimum of 2,000 feet spacing", or whatever. The mines had complete control in selecting what to implement. If a better solution came along, they would assess it and deploy it if it was deemed to be a better control. For example, today we see mobile, two-way communication and tracking systems, such

as the ImPact Digital Network, being installed. Mostly these are in addition to PED, to complement its functionality rather than replacing it.

This is the process I referred to earlier that many of the US miners did not understand back in 2006.

Another aspect worth noting is the Australian mining industry is overwhelmingly export driven, so they must be cost competitive on a worldwide basis. So there has been a long history of technology adoption to improve efficiencies in the mining operations, which is why high bandwidth communication systems are now integral to many operations.

One final point on this risk assessment approach is that it does require considerable commitment from all levels of an organization and more specifically, significant investment – that is, hard dollars.

This investment along with general consolidation in mine ownership has seen many of the smaller operations disappear in Australia. Inevitable, but as a person that loves mining and mining history it is not without some regret.

4 MANAGING ALL THIS

As mentioned, to establish these systems does take a considerable effort in time and money. Then there is an on-going requirement to maintain, review and improve what is inherent in the process, to deliver long term results.

All this responsibility on the mining companies does give them control over their choices, but certainly doesn't eliminate government mining authorities and regulations.

The Australian equivalents of MSHA are more about setting the safety framework in place that the mines need to work within, but the mines do have considerable flexibility in how they meet the ultimate requirements for safety at their operations.

Zeroing in on one aspect of the two countries' authorities is the role of government inspectors. Because of the prescriptive approach, MSHA inspectors could be seen more like policeman, investigating and issuing fines. In contrast the Australian inspectors are more like auditors, coming in to review the processes. Certainly fines can be issued and operations ordered to stop, but that is rare as their role is more about mentoring and ensuring the established procedures are being maintained and reviewed.

5 CONCLUSİON - WHAT NEXT?

Not over doing it! The risk assessments and documentation could be seen as getting out of control in Australia and has the potential to actually reduce the effectiveness of what is intended. So reviews are now beginning to take place into how to streamline what has become, quite a complex system.

Another aspect of the safety drive in Australia that is seen by many as hindering the progress to zero harm is the prosecution mentality, particularly in NSW. This view is shared by a number of internationally recognized mine safety experts, such as Prof Jim Galvin. No one disagrees that the blatant disregard for someone's safety, requires punishment under law, as long as it does not lead to a "guilty until proven innocent" mentality and methodology

The risk is that focus has to be given to anticipating the potential legal ramifications of any decision through to a possible reluctance to openly raising and investigating high potential incidents. The latter is a real concern, as the high potential incident is an enormous opportunity for free learning. However the risk of it potentially being used in evidence against someone in some possible, future event, may actually cause hesitation amongst some to raise such things.

But this is only one negative, in what has overwhelmingly been a successful transition in safety methodology in Australian mining from reactive to proactive.

This has taken a lot of commitment and trust from all parties involved. In particular the mining companies have invested a lot of money into implementing the recommendations from the risk assessment,

in terms of equipment, additional controls, training and personnel to manage the whole process. Compared to the personal and financial consequences of serious injuries and fatalities in this day and age, it really is a sound investment.

There is no doubt that momentum is growing in the US for a more proactive approach to safety. Like Australia, after dramatic reductions in fatalities and injuries over the decades, the accident statistics are flattening out and the difficulties associated in achieving the ultimate zero harm remain a challenge.

From "a few to zero" is the hardest, and no industry is yet to achieve it – but I'm confident that Australia and the US will be amongst the first to do so.

Analysis Factors Influence To Mining Accident Using HFACS-MI Frameworks (A Study at Underground Coal Mining of CV. ABC)

A. Yulianto, M.N. Haramaini, S.M. Siregar
Balai Diklat Tambang Bawah Tanah – Kementerian ESDM, Sawahlunto, Indonesia

ABSTRACT: Underground coal mining of CV. ABC has 14 mine tunnels. The risks of underground mine accident are high, more depth of mining will increase the amount of gasses, more complex underground mining technology is applied. Based on data from the Office of Mines, Industry, Trade, and Cooperatives (Disperindagkop) Sawahlunto, during 2010 – 2012, CV. ABC reported that there were 4 cases of mine accidents with severe injury categories. And based on data from CV. ABC, in 2013, there were 9 cases of mine accidents with minor categories. Mining accidents must be prevented and must not to be happen again. The aim of research was analyzing the factors influence mine accidents using Human Factor Analysis and Classification System in Mining Industry frameworks. This was a cross sectional analytic survey research. The method of research used mixed methods, which combine qualitative and quantitative. Analyzing quantitative data by using *Chi-square* and logistic regretion test, firstly to analyze the correlation between all independences variable with mining accidents, and then to mapping factors influence mining accidents. The logistic regretion result as multivariat that there were contextual relationship where (P<0,05) for the characteristics are unsafe acts, mining technology, communication personnel, and physical readiness before work. The result of quantitative compared with the result of qualitative to know the difference or a combination. The recommended that the efforts to control mining accidents include : providing additional knowledge and attitude improvement work to employees, conducting for analyzing and technical improving to the application of mining technology, pushing the head of the tunnel and employees to create a climate conducive communication without any distinction, providing direction to all employees as well as campaigning for quality sleep.

Keywords: HFACS-MI frameworks, CV. ABC, mine accidents, coal mine

1 INTRODUCTION

Underground mine accident risk is still high, refer to several cases of underground mine accidents in Indonesia, as example underground coal mine explotion in Sawahlunto at 2009 which caused 33 mine worker died (Disperindagkop Sawahlunto, 2009), then at May 14, 2013 the collapse of tunnel roof at underground training site of PT. Freeport Indonesia (Esdm, 2013).

Many accident theories try to analyze the factor that influence of mining accident. Theory of *Human Factor Analysis and Classification System in Mining Industry* (HFACS-MI) is developed by Jessica Marrie Patterson (2009) from the *Human Factor Analysis and Classification System* (HFACS) which is announced by Wiegmann dan Shappell (2003). This theory studies and analyzes accident at working not only from the direct cause, but also from the other factor as a latent cause. Cause factor analysed using HFACS-MI are *Unsafe Acts Factor, Precondition for Unsafe Acts Factor, Unsafe Leadership Factor, Organizational Influences Factor,* and *Outside Factor*.

According to data from Office of Mine, Industry, Trade and Cooperatives Sawahlunto, at the periode 2010 - 2012 there were 4 cases of high injuries mining accident reported by CV. ABC. That is low quantity accident, but we must aware that there are

some cases of light injuries do not reported. Studied by Franks E. Bird, Jr. (1969), from 1.753.498 accident happened at working area, that for every seriously accident reported, there were 9,8% light accident, 30,2% accident that caused properties damage, and 600 accident without financial losses. That is proven in CV. ABC, from the 2013 accident report, there were 9 case of light accident.

From that description, it is necessary doing some research to analyse what are the factor that influence mining accident in CV. ABC using HFACS-MI framework.

2 RESEARCH METODOLOGY

Observational research using *mixed methods* approach to combine or using together quantitative method with qualitative method to analyse factors that will influence mine accident in CV. ABC, so the data collected are more comprehensive, valid, reliable and objective.

Table 1. Summary of *Crosstabs* Experiment Significansy On Variabel Correlation of HFACS-MI Framework with Mine Accident in CV. ABC at 2014

3 RESULT AND DATA ANALIZATION

Table 1 shown about Summary of *Crosstabs* Experiment Significansy On Variabel Correlation of HFACS-MI Framework with Mine Accident in CV. ABC at 2014.

3.1. Factor Influenced Mine Accident In CV. ABC

3.1.1. Correlation of Unsafe Acts with Mine Accident

According to statistical experiment, unsafe acts variable had value , p = 0,000. This is indicated a significant correlation of unsafe act variable with mine accident.

From interview with mine workers, some examples of unsafe acts done :

a) Don not follow procedure, as if do not install temporary roof support after develop tunnel as far 1 m, or do not install permanent support after 1,5 m development, or do not *scalling* (clearing of hanging coal).
b) Do not use personel safety device, like helm, or do not use helm properly.
c) Use uncorrect equipment, like using axe or crowbar for digging.

3.1.2. Correlation of Precondition for Unsafe Action Factor with Mine Accident

According to statistical experiment, variable of mine working environment, mining tehnologies, worker exhaustion, and physical readiness had value p < 0,05. This is indicated a significant correlation of that variables with mine accident.

Observation show that all mine tunnels of selected sample *culster* already do effort to control physical mine working environment, that is to measure mine gases as monitoring to anticipate the increase of mine gas that could triggering mine explotion and to neutralize methan gas detected.

For mining technologies, observation show that all mine tunnel of selected sample *culster* already try to improvised technologies used, like as maintening the rotten and broken support, or repairing damage electrical installation. But at the field observation, still found supporting system, or electrical equipment, and ventilation system that not conform with standard regulated by government.

Interview with mine workers, the management in all mine tunnel of selected sample *culster* are already do some persuasive talk with modest spirit worker, caused by individual problem..

Interview result also show that all mine workers of all mine tunnel of selected sample *culster* already got health treatment for sick worker. And for physical disabilities, there are some worker had decreasing of sighting fuction because of age condition.

Interview result also pointed that there some efforts to give communication opportunity for all workers, if they have problem with mining operation.

For physical readiness, from health examination of all workers, resulted that almost all worker of mine tunnel of selected sample *culster* do not have physical disabilities.

3.1.3. Correlation of Unsafe Leadership Factor with Mine Accident

According to statistical experiment, variables of Tunnel Chief leadership, mining operation planning, problem solving abilities, and obedience of Tunnel Chief had value p < 0,05. That is indicated significant correlation of that variables with mine accident.

From the interview with Tunnel chief, got explaination that in all tunnel of selected sample cluster, the chief has responsibilities to all mining operation, from mine planning, equipping mining and supporting equipment, completing self protection devices of miner, and fulfilling production target. Tunnel chief alsao communicated the daily development plan with miner everyday at the safety talk time.

Tunnel chief also explained that they all have abilities in problem solving of mining operation, and they all obedience to mining operation procedure.

3.1.4. Correlation of Organizational Influences Factor with Mine Accident

According to statistical experiment, variable of management commitment, organizational working environment, application of safety procedure had value p < 0,05. That is indicated significant correlation of that variables with mine accident.

Interview with tunnel chief, understood that duty to equipped miner tools for running of mining operation already done by management dengan kepala terowongan. That is agree with the result of field observation, That the company equipped all resources, like gas measurement instrument, supporting material, ventilation equipment, electrical equipment, self protecting devices, miner tools, and health care in company clinic.

Interview result also so that all tunnel chief of selected sample cluster, give wide opportunities to miner to create in working and discussion.

Observation show that CV. ABC already have some work procedure regulated to all tunnel without exception. The chief said that all operation activities must refered to the safety procedures.

3.1.5. The Influence of Mine Inspector Report to the Organization role on Mine Safety

Layer number-5 on HFACS-MI are *outer factors*, that is influence from outside that influences organization on the application of mining safety. Inspection doing by mine inspector from the government expected to improve safety in mining industry. There are some excerpt from the interview with mine inspector according to the purpose of inspection.

"The principle things of our inspection in underground mine are to observe support.... then... electricity.... and ventilation..." (Informan AW, Mine Inspector)

"Because the risk of underground coal mine are the collapse of tunnel roof.... danger of gas.... and explotion cased by electric spark..." (Informan AW, Mine Inspector)

According to that excerpt concluded that some purpose of mine inspection are to develop safety in coal underground mine operation.

Inspection by mine inspector has an object. To understand the object of the inspection, there are some interview excerpt like below.

"One of our inspection object is mine safety...." (Informan AW, Mine Inspector)

"That is regulated in Minister Mining and Energy Act No : 2555 year 1993 and Act No : 555 year 1995" (Informan AW, Mine Inspector)

"All of object in details are.... inspection to the suitable of infrastructure, installation infratructure, and mining equipment.... and then tehe competence of mine worker.... then.... the evaluation of technical studies of mining operation...." (Informan AW, Mine Inspector)

So can summarized that the inspection object already regulated by the government.

The result of their inspection to the company are descripted as below.

"For CV. ABC the most crusial note are the concentration og methane gas...." (Informan AW, Mine Inspector)

"The measurement approximately 0 LEL – 3 LEL.... this value is below the limitation regulated... but if we don't continuely monitoring the accumulation will increase very fast....." (Informan AW, Mine Inspector)

According to that excerpt concluded that the result of inspection are based on field observation and report from the companies to the mine office.

Below the explanation of the result found by mine inspector.

"From several inspection by mine inspector since my carrer here.... I as myself and also as person who have responsibilities of mining operation in this CV. ABC... there are many benefit we got..." (Informan AA, KTT)

"Some of inspection found all are carryon to us....." (Informan AA, KTT)

"Explaining all found in inspection... then discussing with us.... many valuable suggestion to us." (Informan AA, KTT)

According to that excerpt above, can concluded that the result of the inspection are for the safety f mining operation so they must be presented and discused.

Below are description of the benefit obtained by the company on the result of the mine inspection.

"That time...when mine inspection... on one of our tunnel there are very much water leakage on the wall and roof of tunnel... that water makes the floor muddy... and slipery... The report recommended to make drainage, and then the watershould be pump to outsite the tunnel" (Informan AA, KTT)

"We get benefit directly.... after proposed to the mine director.... he is very responsive... and then the tunnel where the water leak already not muudy and slippery..." (Informan AA, KTT)

According to that interview can conclude that the report of inspection by mine inspector have benefit directly to underground coal mine operation safety.

3.2. *The Mapping of Factors that Influence Mine Accident in CV. ABC*

To mapping the factor that influence mine accident in CV. ABC, we must conduct statistical analysis using statistical experiment logistic regretion to find the influence of several variables on the HFACS-MI frameworks simultanously.

The result of analysis Logistic regretion on tabel show that from all variables of HFACS-MI frameworks, only variable of unsafe acts, mining technologies, personel communication, and physical readiness before works that has influence to mine accident ($p < 0,05$). Value R square (correlation coefisien) obtained is 0,678, That means variables of unsafe acts, mining technologies, personel communication, and physical readiness before works could explained or predicted Value of **variabel terikat,** that is mine accident in the value of 67,8% and the remaining 32,2% influenced by the other factor.

The Probability of mine accident happened could counted by test the logistic regretion model using equation below :

$$Prob.(Y = 1) = \frac{1}{1 + e^{-(\beta 0 + \beta 1 X1 + \beta 2 B2)}}$$

That means the probability of mine accident is caused by worker do unsafe acts, the worst personel communication, and physical unreadiness before works is valued P (Ever Accident).

Table 2. Final Result of Logistic Regretion Experiment on The Factors Influenced to Mine Worker Accidents in CV. ABC Year 2014

Variable	β	Df	P	OR	R
Unsafe Acts	-2,710	1	0,010	0,067	0,678
Mine Physical Environment	-1,151	1	0,141	0,316

4 DISCUSSION

4.1. Correlation of Variable on HFACS-MI Frameworks with Mine Accident

4.1.1. Correlation of Unsafe Acts with Mine Accident

The significant correlation among unsafe acts with mine accident are indicated by some mine workers of CV. ABC still doing unsafe action because of carelessness, as like forgetting self protection device (safety shoes, helmet), using unproper tools, not installing temporary roof support after 1 m development or not installing permanent roof support after 1,5 m development. According to Kletz (2001) on Fikie (2004), one of classification human error that influence ansafe cation is forget, this error happens to sameone that already understand, able and want to do rightly and safely and already customary practiced.

4.1.2. Correlation of Precondition for Unsafe Act Factor with Mine Accident

The significant correlation among mine physical environment with mine accident indicated by the worker are not allowed enter the mine tunnel when daily measurement show that the consentration of mine gas are high or some of roof supporting are broken so could trapped the miner. According to Wignjosoebroto (1995), one of outside factor is physical condition of working environment, that are including temperature, humidity, air circulation, lighting, noise, mechanical vibration and the others. They could influence significantly to the human work result.

The technologies of underground coal mine are very complex, so the proper technologies used are useful to do the works, but also could cause failure to the works. Although already use the right technologies, the danger from nature of underground coal mine could sometime influence the worker. Coal underground mining activities, according to Saepulloh (2011), could not liberated from tunneling on the earth, and the rock will expanded because of earth pressure make some fault and *stress relief* zone which could cause the rock fall or callapse, so that tunnel developed must supported.

No significant correlation among worker worrieness with mine accident are explained by some low spirit (bad mood) workers, Directly persuaded by tunnel chief. According to Geller (2001) descripted that individual personel, behaviour and environment lingkungan are have interaction to build what called by *The safety triad* that consist of safety culture inside.

The significant correlation among worker exhaustion with mine accident is explained by some medical treatment to exhausted or unhealthy mine workers from company medic representative. Nurmianto (1998) said that basically all works produce exhaustion or fatigue. Exhaustion will decrease productivity and increase works error. The increasing error could product opportunity of work accident in industries.

No significant correlation among worker's physical limitation with mine accident show that there were no workers wit physical disabilities. Budijanto (2003) said that physical limitation (disabilitas) is the lack of abilities or deterioration or decreased

individual function to do daily activities which preceding by condition of impairment, that the activities previously could done without difficulties or with the others help..

No significant correlation among personel communication with mine accident could explained by the giving of daily works plan every morning at the time of safety talk, so the personel communication become very friendly. That is not appropriate with the research by Senjaya (2011) in Plantation PT. Gunung Sejahtera Dua Indah Astra Group Kalimantan, the conclution is there were correlation among information from supervisor to worker with level work accident with significant value p = 0,000.

The significant correlation among physical readiness with mine accident explained by majority of mine worker do not have physical disablities according to montly examination at campany clinic. According to widodo (2009), the work readiness is readiness of all person condition to preparing himself physically, mental, and experience to do some works.

4.1.3. Correlation of Unsafe Leadership Factor with Mine Accident

The significant correlation among tunnel chief leadership with mine accident is explained by the responsibilities of tunnel chief to plan mine operation and to fullfil the safety equipment of all worker. That is match with Mabruri (2010), on his research in Machine workshop PT. DOK and Shipyard of Surabaya at 2010, achieved that there were correlation among leadership style with works accident with significancy value p = 0,041.

The significant correlation among mine operation planning with mine accident is explained by the full responsibilities of planning by tunnel chief. According to Sudrajat (2010), Mining operation is activities that against nature, which makes destruction, caused soil or rock movement and environmental pollution. So the mining activities have opportunity produce danger without carefully planned.

The significant correlation among problem solving abilities with mine accident is explained by the abilities of tunnel chief to solve problem on mining operation, like like handling rock fault, or the increasing of methane concentration. Levine on Prihartini (1994) said that somebody could have good *problem solving* ability, if that person could solve problem efectively , that means affected the target and minimalize negative effect, for himself and other person.

The significant correlation among obedience of tunnel chief with mine accident explained by the responsibilities of tunnel chief to make sure the condition of tunnel are safe enough for the workers and operations. According to Suma'mur (1985), the leader must make every effort seriously on safety because he would become example of safety act by his workers on his responsibilities.

4.1.4. Correlation of Organizational Influences Factor with Mine Accident

The significant correlation of management commitment with mine accident is showed by fullfiled of gas measurement equipment, ventilation machine, medical clinic, etc. Reason (1997) said safety work program must start from begin, at this case from company top management.

The significant correlation of organization working environment with mine accident is showed by management effort to create good environment for worker to do the work creatively. Working environment begin with daily practice on organization and influence behavior of members positively like productivity, satisfaction, and motivation, or negatively like absent, turnover and work accidents (Furnham, 2003; Gillies, Franks, & Child, 1990; Runtu & Widyarini; 2009).

The significant correlation of application of safety procedures with mine accident is explained by applied safety procedures appropriate to company standard. Sitrisni and Kusmawan (2007) said that the procedures to works safely and orderly are regulated on every industries, usually on the form like regulation or behavior act.

4.1.5. Influence of the Report of Mine Inspector to Organization participation on Mine Safety

On Ministry of Energy and Mineral Resources Act No. 02 Tahun 2013, the responsible to inspect of mine industries are minister, governor, and city or municipal major helped by functional officer of mine inspector. The job of mine inspector basically to inspect mining industrial safety.

Consequence of publication of Mine Permit is inspection. Inspection on mining sector principally to make sure the holder of mine permits are more directed on their mining activities, so will not deviate from the regulation. Theoritical George R. Terry (2001) have opinion that the inspection are aimed to definite what are want to achieve, evaluate and do corrective effort if necessary, to make sure the result as needed.

4.2. Mapping the Faktor that Influence Mine Accident in CV. ABC

Mapping the factor that influenced mine accident in CV. ABC doing by statistical analysis using logistic regretion statistical experiment with the purpose to found influence of several variables on HFACS-MI frameworks Simultanously.

The result of the mapping concluded that the independent variables which had influence to the mine accident are :

4.2.1. Unsafe Actions

Unsafe action example doing by underground coal mine worker of CV. ABC are forget using self protection device (safety shoes, helmet), using unproper tools, not installing temporary roof support after 1 m development or not installing permanent roof support after 1,5 m development. According to Kletz (2001) on Fikie (2004), one of classification human error that influence ansafe cation is forget, this error happens to sameone that already understand, able and want to do rightly and safely and already customary practiced.

4.2.2. Mining Technologies

The Effect of tunneling on earth, according to Hartman (1987), there are some pollutant gases on the mine, as the result of mining process or from the rock or mineral mined. So Prata (2006) said underground mine should use ventilation system to supplying fresh air, good enough in quantities and quality, then supply it and devide it to the mine tunnels so there is safe working condition for the miner and mining proceses.

4.2.3. Personel Communications

Daily works plan of the mine operation are communicated from the tunnel chief to the workers, supported by newest physical condition of tunnel give certainity to the workers that they could work safely and comfortable. Comfortable working evidence worker satisfaction because the good communication are the activity that integrated worker by the behavior.

If the working condition uncomfortable, like difference treatment among the workers, unfulfilled equipment to work, that will make uncomfortable conditions that make the worker anxious and stressed. That is appropriate with judgement of t Chen et al., (2006) on (Wahyuni, 2009) that said the organization communication have positive correlation with organization commitment and productivity , and have negative correlation with working stress.

4.2.4. Physical Readiness Before Works

Mine worker who are not ready physically will not allowed to do works, because that will be dangerous to them. According to Robbins (2006), he said that abbilities of individu basically consist of two factor : intelectual ability nad physical ability. Physical ability is his ability to do work that wants stamina, adroitsness, strength and skill.

5 CONCLUSION

According to research result and discussion, can conclude as:

1. There is correlation of *unsafe* actions with mine accident.
2. *Precondition for unsafe acts* factors which has correlation with mine accident are : mine physical environment, mining technologies, exhaustion of workers, and physical readiness before works.
3. *Unsafe leadership* factors which has correlation with mine accident are: tunnel chief leadership, mine operation planning, abilities of problem siolving, and obedience of tunnel chief.
4. *Organizational influences* factor which has correlation with mine accidents are : management commitment, organization working environment, and application of safety procedures.
5. *Outside factor* which has influenced organization partipation to the mine accident is the report of mine inspector.
6. The result of mapping to the factors that influenced mine accident are: unsafe acts variable, mining technologies variable, personel communications variable and physical readiness variable.

6 SUGGESTION

Suggest to the company from this research are :

1. To increase the awareness and discipline, and to improve mine worker to do safe acts during work, the company should do education and training about safety operation and supporting system of underground mine.
2. To increase communication on the work, the company should do education nad training about effective communication.
3. To anticipate risk cause by roof tunnel collapse, the company should studies and maintenances the supporting system.
4. To decrease the risk of gas pollution on mining which danger to the miner, the company should studies and repairs ventilation system of underground mine.
5. To decrease the risk of mine explotion by spark of electrical equipment, the company should studies and repairs the electrical system of underground mine.
6. To increase the awareness and readiness of mine worker according to the the physical readiness before work, the campany should campaign program of the benefit of quality rest**.**

ABSTRACT: Underground coal mining operations continue to increase production as mining equipment and practices are improved. Unfortunately, increased production also results in the potential for increased Respirable dust generation and worker exposure. In response, operations are applying basic controls at elevated levels and looking to emerging technologies in an effort to better control Respirable dust levels. Ventilating air and water sprays remain the basis of dust control strategies for both longwall and continuous mining operations, and the level of application for these controls continued to increase. In addition, new technologies are emerging that have the potential to further reduce dust levels. In this Paper an attempt is made to study the Stresses Produced and its Influence on Dust generation at different Attack angle and force applied on the cutting material.

Keywords: Dust generation, rock cutting, sieve analysis, finite element analysis

1 INTRODUCTION

The high demand for coal production has increased the need for mechanical coal cutting in underground coal mines. On the other hand our coal reserves are shrinking, forcing operators to mine thin coal seams and subsequently to cut roof/floor rocks in order to maintain sufficient clearance for equipment. Enormous miles of entries are developed by these continuous miners for long wall operations as well as bord & pillar mining [12]. The amount of repairable dust generated by excavating coal and cutting roofs with continuous mining machines is the major concern to the mining industry. Dust is an inevitable product of mining, given by the nature of mining operations such as cutting/drilling, loading and transportation of coal. It is dispersed into the mine atmosphere by the ventilating air current, and travels downwind. Once airborne, the Respirable dust particles are difficult to capture and remove as they fall very slowly because of associated aerodynamic properties. As a result, miners are exposed to high Respirable dust concentration levels. Respirable dust is a continuing problem in the mine environment, where it adversely affects the safety and productivity of a miner. In underground coal mining, dust particles ranging from 1to10 micron sizes (Respirable particulate matter ranges from 1-5µm & greater than 5µm are suspended particulate matter as per ISO 7708, 1995), In addition, dust also results in obscuring visibility and affects general mobility of the miners, and may also lead to sudden catastrophic incidences of explosion. During last three decades with the introduction of the mechanization, i.e. Road header, Continuous Miner and Double Ended Ranging Drum Shearer in the underground coal mining, it has become a greater menace than ever posing threat to the health and safety of miners. The majority of Respirable dust generated by mechanical miners is the result of material that is crushed directly under the individual bits/cutters on the cutter head. Figure .1 shows the crushed zone underneath a bit and the resulting fractures in the rock

that lead to production of Respirable dust. Reducing the amount of dust produced will reduce the risk of dust getting airborne in the working area [2].

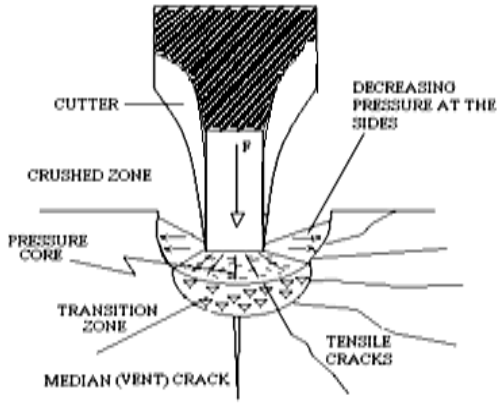

Figure 1. Crushed zone where dust is generated [2].

The main machine parameters that influence the cutting efficiency of a continuous mining machine include bit spacing, depth of cut and bit geometry. Through a correct combination of bit spacing and depth of cut, two adjacent grooves start interacting and the land/ridge between the two cuts can be removed which will result in large chip formation and less dust generation.

1.1 Objectives

The main objectives of this research study are:

- Fabrication of experimental set up of rock cutting machine with necessary arrangement like holding the rock specimen, for changing Cutting drum, RPM and thrust applied and the effect of Physico-Mechanical properties and mineralogical composition of samples on cutting rate and dust generation and also the effect of operational parameters of RPM and thrust and torque on cutting rate and dust generation

1.2 Literature Survey

The mining industry has centered its attention on mastering the goal in decreasing the amount of respirable dust generated during the cutting process. A better understanding of the influence of several parameters, including both machine-controlled and operator-controlled, during the rock cutting process is required. Important parameters affecting coal cuttability rate are physical and mechanical properties of coal/rock such as: density, uniaxial compressive strength, tensile strength and shear strength etc. Chemical composition of coals may directly or indirectly affect the coal cuttability. Increasing of 27% and 22% in moisture and volatile material respectively in coals may cause decrease in strength of coal, but less than these values, coal strength may increase [18]. Some of the minerals like Quartz can play a major role on erosion of cutter of coal winning machines, affecting the cutter life considerably. In the past, much research has been carried out to select the design parameters for cutting tools on a trial and error basis. The mining industry is yet to receive a solution, which could provide optimum parameters like type of bit, bit angle and angle of attack etc, for coal/rock cutting in underground coal mines. [17].

While mechanical coal cutting is a relatively well-understood topic, the technique has changed little in recent years. Primary enhancements have tended to centre on metallurgical improvements and advancements in the manner in which the tools engage the face. This, as a general observation, indicates that the understanding of the involved mechanics and technology is optimal, although a cautionary note must be sounded from the preceding section, which examined the generic or petro graphic content related mechanical properties of South African coal. In general, it can be concluded that several authors [14], [15] and [16] have alluded to differences between South African coals and those of Europe or America, that inherently make South African coal more difficult to cut.

Mechanized coal cutting traditionally makes use of tools that are dragged across the face, typically driven by a rotary drum, in order to liberate the coal. These tools are commonly described as either point attack or radial drag bits, so named as these terms best describe their generic method of engaging

the coal. The mechanisms of cutting using drag bits are well understood, and whilst there have been advances in cutting methods in recent years, the generic tool shapes have changed little.

2 CUTTING PARAMETERS

The influence of common parameters on drag tool cutting, such as geometry and speed, is depicted in Figure.2 and Figure.3 which graphically summarizes the different cutting parameter.

The following parameters commonly influence the cutting tool operations

2.1 Rake Angle

The angle of the cutting face relative to the work. There are two rake angles, namely the back rake angle and side rake angle, both of which help to guide chip flow.

2.2 Back Clearance Angle

The angle between a plane containing the end surface of a cutting tool and a plane passing through the cutting edge in the direction of cutting motion. The back clearance angle should not be less than 5° and not greater than 10°.

2.3 Attack Angle

The attack angle is the angle between the axis of the tool and the surface being cut. The attack angle is usually between 45° and 55° for rocks of lower strength. The most common tip angle is 75°. The preferred rake and back clearance angles should not be less than 25° and not more than 10° for conical bits.

2.4 Cutting Speed

Cutting speed has no significant influence on the magnitude of the pick forces provided the wear effect has been discounted.

2.5 Line Spacing

Line spacing is the distance between adjacent tools or picks in the axial direction, on the cutter or shearer drum. If the line spacing is too close, the cutting is inefficient due to over-crushing of the rock, and if it is too wide, the tool cuts in an unrelieved mode (tensile fractures from adjacent cut cannot reach each other to form a chip), creating a groove-deepening situation, resulting in the formation of a rib between cuts.

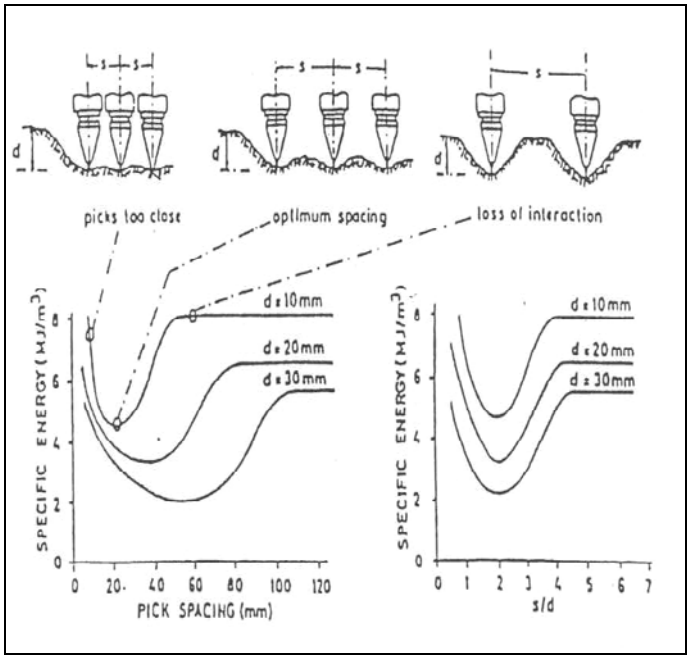

Figure 2. Line spacing is the distance between adjacent tools or picks [10].

The minimum specific energy is obtained with an optimum spacing to depth ratio has indicated to be in the region of 2:1.

2.6 Depth of Cut

It is the thickness of material removed by one pass of the cutting tool. It can be seen that the Specific energy improves substantially as the depth of cut is increased. This result has been proved both in the laboratory and by in-situ testing of an instrumented continuous miner

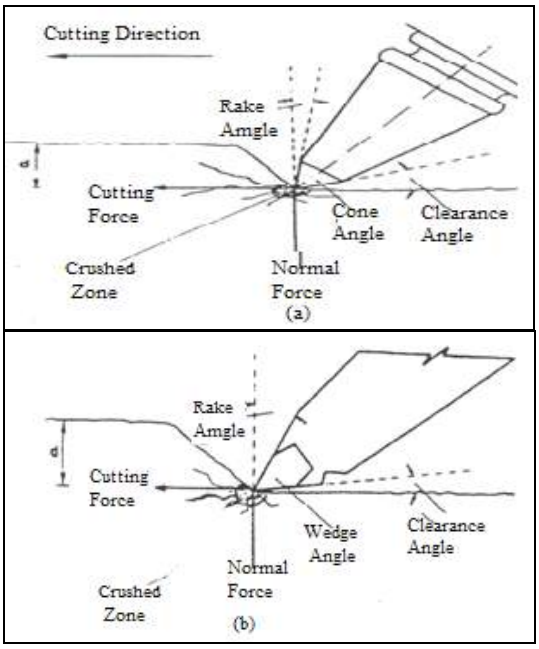

Figure 3. Interaction of bit with rock and bit geometry [10]

3 MECHANICAL PROPERTIES

3.1 Uniaxial Compressive Strength

Compressive strength is the capacity of a material to withstand axially directed compressive forces. The most common measure of compressive strength is the uniaxial compressive strength or unconfined compressive strength. Usually compressive strength of rock is defined by the ultimate stress. It is one of the most important mechanical properties of rock material, used in design, analysis and modeling.

3.2 Young's Modulus

Young's Modulus is modulus of elasticity measuring of the stiffness of a rock material. It is defined as the ratio, for small strains, of the rate of change of stress with strain. This can be experimentally determined from the slope of a stress-strain curve obtained during compression or tensile tests conducted on a rock sample.

3.3 Poisson's Ratio

Poisson's ratio measures the ratio of lateral strain to axial strain, at linearly-elastic region. For most rocks, the Poisson's ratio is between 0.15 and 0.4. As seen from early section, at later stage of loading beyond linearly elastic region, lateral strain increase fast than the axial strain and hence lead to a higher-ratio.

Table 1. Mechanical properties of Rocks (10 rock samples)

Rock	**Sample Collected**	Density (Kg/cm^2)	Compressive strength (MPa)	Young's Modulus (GPa)	Poisson's Ratio
Coal	5 Incline Mines, SCCL,AP	2.2	23-60	2.65-3.63	0.32
Sand Stone	MOCP 1, SCCL,AP	2.5	27 – 170	9-15	0.26
Limestone	JK cements, Mudhapur, Bagalkot	2.3	30 – 200	20-55	0.30

3.4 Description of Rock Cutting Machine

Figure 4. Rock cutting machine

Rock cutting machine is a prototype model of a Road header, Continuous Miner or Coal Shearer used for cutting coal/ rock in underground mines/tunneling which is installed at NITK, Suatkal as shown in Figure 4.

Rock cutting machine consists of a firm base with two parts protruding: one of the part has a prime mover (motor) mounted on it. A base plate attached to the motor has guide ways, which helps in moving to and fro movement and sideways also. A Motor is in turn is attached to a shaft pulley by belt drive. The cutter head will be attached to the shaft by a flange. Cutter head consists of a drum head with number of bits mounted on it.The other part of rock cutting machine has firm sample holder, in turn connected to a hydraulic cylinder, which can provide sideways movement during cutting operation and a dust collecting bin.

3.5 Sieve analysis

A **sieve analysis** (**gradation test**) is a practice or procedure used (commonly used in civil engineering) to assess the particle size distribution of a granular material. The size distribution is often of critical importance to the way the material performs in use. A sieve analysis can be performed on any type of non-organic or organic granular materials including sands, crushed rock, clays, granite, feldspars, coal, and soil, a wide range of manufactured powders, grain and seeds, down to a minimum size depending on the exact method. Being such a simple technique of particle sizing, it is probably the most common.

Procedure:

1. Arrange the nest of Sieves starting from 0.3, 0.212, 0.18, 0.15, 0.106 mm (0.3 mm sieve at the top and 0.106 mm sieve at bottom),
2. Place the sample material at the top most sieves that is on 0.3 mm sieve.
3. Place the sieve set on the sieve shaker and allows the machine to run for 5 min.
4. Weigh the material which is retained in each sieve and the bottom most pan to the most nearest of 0.1 gm. Tabulate the results in the standard form of sieve analysis shown in Table 2 and Table 3.

Table 2. Sieve Analysis data for 45°

Sample	Coarse (gms)	Medium (gms)	Fine (gms)	TOTAL (gms)
Coal	239.4	2.4	1.7	243.5

When the rock was cut with a cutting angle of 45°, the stresses induced is less and the dust generated is more. But, when the rock was cut with a cutting angle of 55°, the stresses induced is more and the dust generated is less. Hence, we got good results. At an angle of 55°, it is very effective and best suited for Rock Cutting.

6 CONCLUSION

1. The Experiment was conducted on 45° & 55° Attack angles and the results were found good in **55°**. Both the strength implied is more and dust generated is less.
2. By using this method, we are able to reduce the dust generation in coal mine, experiment was conducted on Sand Stone and Lime Stone also, the results are positive and the dust generation is less.
3. Due to the less dust generated, workers efficiency will increase and can reduce the occupational health diseases..

Determination of ^{222}Rn, ^{220}Rn and Their Decay Products in Natural Ancient Mine Measured with Nuclear Track Detectors: Radiation Dose Assessment

L. Oufni, M. Amrane
Department of physics, Faculty of Sciences and Techniques (LPM-EIRM), University Sultan Moulay Slimane, B.P. 523, 23000 Beni-Mellal. Morocco.

ABSTRACT Radon (and thoron) is a naturally occurring radioactive noble gas, having variable distribution in the geological environment. The exposure of human beings to ionizing radiation from natural sources is a continuing and inescapable feature of life on earth. Radon, thoron and their short-lived decay products in the atmosphere are the most important contributors to human exposure from natural sources. The aim of this study is to determine alpha-and beta-activities per unit volume of air due to radon (^{222}Rn), thoron (^{220}Rn) and their progenies in the air of ancient mine of Aouli in which there is no working activity is situated at approximately 25 km north of the city of Midelt (Morocco), by using LR-115 type II and CR-39 solid state nuclear track detectors (SSNTDs). Equilibrium factors between radon and its daughters and between thoron and its progeny were evaluated in the studied atmospheres. The committed equivalent doses due to the ^{218}Po and ^{214}Po radon short-lived progeny were evaluated in different tissues of the respiratory tract of the visitors of the considered ancient mine.

Keywords: Radioactive noble gas, radon, thoron, alpha- and beta- activities in air

1 INTRODUCTION

Due to its long half-life time relative to other isotopes, radon (^{222}Rn, $T_{1/2}$ = 3.82 d) which is a descendent of uranium-238 (^{238}U, $T_{1/2}$ = 4.5×10^{9} y) is considered to be the most significant isotope of radon problem in the environmental studies. It's well known that the radiations emitted from the primordial radionuclide originating from the Earth's crust are the major contributors to the total background exposures to the human populations. The include external gamma exposures and inhalation exposures, approximately in equal measure, the latter being due to radon (^{222}Rn), thoron (^{220}Rn) and their progenies in the indoor environment. ^{222}Rn, a progeny of uranium-238 (^{238}U), is a colorless, odorless, noble and radioactive gas. Its half-life is 3.82 days and its decay with the emission of 5.48MeV α particles. Radon and its short-lived decay products in dwellings present the main source of public exposure from the natural contributing to nearly 50% of the global effective dose to population.[1] Lung cancer pathologies caused by inhalation exposure to radon is due to alpha-dose deposited by short-lived radon decay products. It's well known that exposure of population to high concentrations of radon and its daughters for a long period leads to some pathological effects like the respiratory functional changes and the high occurrence of lung cancer.[2] Radon appears mainly by diffusion processes from the point origin following α-decay of ^{226}Ra in underground soil. Radon diffusion and transport through different media is a complex process and is affected by several factors.[3,4] It is well known that for material medium, the porosity, permeability and the diffusion coefficient are the parameters which can affect directly the capacity to hinder the flow of radon soil gas.

In the present work, we used a technique based on using CR-39 and LR-115 type II SSNTDs for measuring the concentration of radon, thoron and their progenies in different ancient mines. We also determined annual committed equivalent doses due to the inhalation of radon short- lived daughters by

the members of the public. This technique has been previously used to study the indoor radon level in different dwellings [1-3].

2 MATERIALS AND METHODS

2.1 Studied Area

Morocco with its large number of metalliferous sites is considered a traditional mining region since antiquity. One of these sites is the Upper Moulouya lead district which contained one of the largest concentrations of lead in Morocco. The former lead mine of Aouli is located about 26 km north of Midelt, at the junction of chains of medium and upper eastern Atlas (Figures 1 and 2).

2.2 Determination of Alpha Activities per Unit Volume due to Radon, Thoron and Their Decay Products in the Air of Ancient Mine

Square shaped Pershore Mouldings CR-39 (500µm thickness) and Kodak LR-115 type II (12µm cellulose nitrate on 100 µm polyester base) solid state nuclear track detectors (SSNTDs) of surface equal to 9 cm^2 have been placed in different locations inside t ancient mines for one month. During the exposure time, a-particles emitted by radon, thoron and their progenies bombarded the SSNTD films. After the irradiation, the exposed films were etched in two NaOH solutions at optimal conditions of etching, ensuring good sensitivities of the SSNTDs and a good reproducibility of the registered track density rates: the first solution of 2.5 mol L^{-1} normality at 60°C for 120 minutes for the LR-115 II films and the second solution of 6.25 mol L^{-1} normality at 70°C for 7 hours for the CR-39 detectors. After this etching treatment the track densities registered on the CR-39 and LR-115 II SSNTDs were determined by means of an optical microscope of magnitude 40x. For our experimental etching conditions, the residual thickness of the LR-115 type II SSNTD is 5 µm which corresponds to the lower (E_{min} = 1.6 MeV) and upper (E_{max} = 4.7 MeV) energy limits for the registration of tracks of alpha-particles in the LR-115 II films [4]. All a-particles emitted by the radon and thoron series that reach the LR-115 II detector surface under an angle lower than its critical angle of etching, with a residual energy between 1.6 MeV and 4.7 MeV are registered as bright track-holes. The CR-39 detector is sensitive to all a-particles reaching its surface under an angle smaller than its critical angle of etching.

The rate of track density (tracks cm^{-2} s^{-1}), due to α-particles emitted by the radon, thoron and their decay products in the outdoor air of a location, registered on the LR-115 II and CR-39 detectors, after subtracting the corresponding backgrounds, are given by :

$$D(LR) = \frac{\Delta R}{4}\sin^2\theta_c\left[\sum_{i=1}^{3} A_c(i)K_i + \sum_{i=1}^{4} Ac(i)K_i'\right] \quad (1)$$

$$D(CR) = \frac{1}{4}\sin^2\theta'_c\left[\sum_{i=1}^{3} A_c(i)K_iR_i + \sum_{i=1}^{4} Ac(i)K_i'R_i'\right] \quad (2)$$

where:

A_i ($Bq.cm^{-3}$) is the α-activity of the i^{th} α-emitter, and are the ranges in air of an α-particle of index i and initial energy E_i emitted by the nuclei of the radon and thoron series in the outdoor air of a location, respectively,

K_i and K'_i are respectively the branching ratios corresponding to the disintegration of the nuclei of the radon and thoron groups and,

R_i and R'_i are the α particles ranges in air which correspond to the lower (E_{min}) and upper (E_{max}) ends of the energy window. The ranges of the alpha-particles emitted by the radon and thoron series in air were calculated by using a TRIM program [5].

θ_c, θ'_c are the critical angles of etching for LR-115-II and CR-39, respectively. (the critical angle for a detector is defined as the angle between the direction of the projectile and the normal to the detector surface under which no track can be revealed by etching).

The activities of a i^{th} nucleus $A_c(i)$ and its (i + 1)th daughter $A_c(i + 1)$ of the radon and thoron series are related by Jacobi, 1972 [6]:

$$\frac{D_T}{\lambda_i}\frac{\partial^2}{\partial z^2}A_i(z)+A_{i-1}(z)-A_i(z)=0 \qquad (3)$$

$A_i(z=0)=0$ for i= 1, 2, 3 and 4 and $A_i(z=+\infty)=0$ for i = 0, 1, 2, 3 and 4, that is, far from the ground.

2.3 Evaluation of Annual Committed Equivalent Doses due to the Inhalation of Radon Decay Alpha Products in the Respiratory Tract of the Members of the Public in Ancient Mines

By using the ICRP model [7] the human respiratory tract is divided into two major regions: the thoracic TH and extrathoracic ET regions.

The thoracic region is divided into four sub-regions (alveolar interstitium AI, Bronchioles bb, bronchi BB and Lymphatics LN_{TH}) and the extrathoracic region is divided into three sub-regions (anterior nasal ET_1, posterior nasal passage, larynx, pharynx and mouth ET_2 and lymphatics LN_{ET}).

There are ten compartments in the thoracic region respectively numbered from 1 to 10: AI_1, AI_2, AI_3, bb_1, bb_2, bb_{seq}, BB_1, BB_2, BB_{seq} and LN_{TH}. The extrathoracic region contains four compartments respectively numbered from 11 to 14: ET_2, ET_{seq}, LN_{ET} and ET_1.

The rate of change of a j'th radon decay product α-activity in a compartment i of the respiratory tract (ICRP, 1994) at any time is given by:

$$\frac{dA_c^i(j')}{dt}=F_d(i)I_0(j')+\sum_n \lambda_{n,i}A_c^n(j')-\left(\sum_n \lambda_{i,n}+\lambda_{j'}\right)A_c^i(j') \qquad (4)$$

where F_d (i) is the fractional deposition in the compartment i of the respiratory tract of different members of the public (ICRP, 1994), $I_0(j')=BA_C(j')$. B is the average breathing rate for different members of the public. $A_c(j')$ ($Bq.m^{-3}$) is the α-activity of the j' th radon decay product in the atmosphere ancient mine, $\lambda_{n,i} = m_{n,i} + S_s$ where $m_{n,i}$ is the clearance rate from region n to region i due to particle transport and S_s is the clearance rate due to particle absorption into blood (ICRP, 1994). The rate of absorption of a material into blood is the same in all regions of the respiratory tract, except in the anterior nasal passages (ET_1), where no absorption occurs (ICRP, 1994). $\lambda_{n,i}=0$ for i=1,2,3,5,6,8,9,12 and 14 (ICRP, 1994), $\lambda_{i,n} = m_{i,n} + S_s$ where $m_{i,n}$ is the clearance rate from region i to region n due to particle transport [7] and $\lambda_{j'}$ is the radioactive constant of the j'th radon decay product.

Alpha activities corresponding to the j' radon decay product in each of the 1-14 compartments of the respiratory tract as functions of time are obtained by solving Eq.(4).

3 RESULTS AND DISCUSSION

The activities per unit volume air due to the radon and their progenies have been measured in different locations of the studied ancient mine. Data obtained are shown in Table 1. From the statistical error on track counting one can determine the error on track density rate and then evaluate the relative uncertainty of the radon and their progenies determination which is about 8%. The radon alpha-activity per unit volume increases with the distance from the entrance of the studied ancient mines. This is due to the fact that the ventilation rate decreases when penetrating inside the ancient mine studied. Values obtained for the alpha-activity per unit volume due to radon P7 and P8 places of the Aouli ancient mine (Table 1) are clearly higher than the 400 Bq.m-3 concentration limits for the members of the public. We notice that alpha activities due to radon and its decay products are higher than those due to thoron (Table 2) and its daughters for the ancient mine which is the subject of our study. This is due to the fact that thoron (^{220}Rn) half-life is too short (55s) compared to the exposure time (30 days) of the SSNTD films inside the ancient mine whereas radon (^{222}Rn) has a half-life of 3.82d. The average values of the alpha-activity due to ^{218}Po and ^{214}Po were found to be (190.60±12.86) Bq.m-3 and (121.30±8.47) Bq.m-3. Equilibrium factors between radon and its progeny F^{222} and between thoron and its daughters F^{220} were

evaluated for the studied ancient mine (Tables 1-2). The F^{222} and F^{220} factors decrease when the ventilation rate V increases. These factors do not depend on the nature of the rocks forming the studied ancient mine.

Annual committed equivalent doses per hour of exposure due to the ^{218}Po ($H_T(^{218}Po)$) and ^{214}Po ($H_T(^{214}Po)$) radon short-lived alpha emitting daughters have been evaluated in the respiratory tract of male and female adult from the inhalation of air in the studied ancient mine. Data obtained are shown in Table3. After inhalating air, amounts of ^{218}Po and ^{214}Po are deposited in the extrathoracic region ET and thoracic region TH. According to the ICRP compartmental model (ICRP, 1994) a quantity of ^{218}Po is transferred from the TH region to the ET region. As a consequence, we found that annual committed equivalent dose due to ^{218}Po is higher in the ET region than in the TH region. We notice that annual committed equivalent doses due to the ^{214}Po are smaller than those due to ^{218}Po in both ET and TH regions. This is due to fact that ^{214}Po has a very short half-life ($1.64.10^{-4}$s) compared to the exposure time of the tissues. Annual committed equivalent doses due to ^{218}Po and ^{214}Po in the respiratory tract of the members of the public increase when alpha-activity due to radon increases in the air of the studied ancient mine.

4 CONCLUSION

Using CR-39 and LR-115 type II SSNTDs we can evaluate the concentration of radon, thoron and their progenies in the environment air in the studied ancient mine. Alpha activities per unit volume air due to the radon and thoron inside the studied ancient mine depend on the ventilation rate. It has been shown that annual committed equivalent doses due to the radon alpha – emitting short- lived decay products (^{214}Po and ^{218}Po) increase when the radon concentration inside the considered ancient mine increase. We noted that the annual committed equivalent doses due to ^{218}Po and ^{214}Po in the bb and BB tissues is significantly higher than doses in the thoracic region. Similarly, we note that the dose in the ET_2 tissue is much higher than that calculated in the extrathoracic region

Physiological Effects of Dust on the Human Body

B. Plush
PM_{10} Laboratories - Particulate Matter Management, Somersby, NSW, Australia

ABSTRACT Lung diseases such as Coal Workers' Pneumoconiosis (CWP), also called black lung disease, develop when respirable coal mine dust (PM10 – 10 micron or smaller sized particles) is inhaled during the normal mining operation. Once inhaled, PM10 sized particles deposit and remain in the lungs forming the foundation for this deadly disease. It is a chronic, fibrotic, and irreversible disease that robs miners of their breath and eventually their life. CWP is a wholly preventable disease with the diligent use of best practice dust control measures including adequate ventilation, water sprays, water pressure and water flow, dust collectors and scrubbers and a quantifiable process for dust measurement to ensure compliance to statutory requirements (Davitt, 2011).

Keywords: Lung disease, dust classification, physiological effect

1 INTRODUCTION

The Upper Big Branch (UBB) disaster in April 2010, a mine owned by Massey Energy, in Raleigh County West Virginia, killed 29 men as a result of a massive dust explosion. It was subsequently found that 17 of the 24 victims' autopsied (71%) had CWP. This compares with the national prevalence rate for CWP among active underground miners in the U.S. of 3.2%, and the rate in West Virginia of 7.6%. The ages of the UBB victims with CWP ranged from 25 to 61 years (Davitt, 2011).

According to Davitt, of the 17 UBB victims with CWP, five of them had less than 10 years of experience as coal miners, while nine had more than 30 years of mining experience. At least four of the 17 worked almost exclusively at UBB. All but one of the 17 victims with CWP began working in the mines after the 2.0 milligram coal mine dust limit was put in affect in 1973. This was an exposure limit that was believed at the time sufficient to prevent black lung disease. It has since been determined ineffective to protecting miners' health and recommendations have been made to lower the exposure level for workers (Davitt, 2011).

Further, the victims of the UBB disaster constitute a random sample of miners on which autopsies were carried out. The fact that 71% of them show evidence of CWP has been seen as an alarming finding given the ages and work history of these men, and the fact that the disease was far more advanced than industry average indicated it should have been (Davitt, 2011).

Respiratory problems caused by exposure to dust are among the oldest identified industrial diseases. Early medical opinions in the 1920's, suggested that only hardrock workers were exposed to potential lung diseases from dust. It was identified at the time that silicosis from hardrock mining led to tuberculosis and eventual death (McPherson, 2009). During that time coal dust was not regarded as particularly harmful. However, during the 1930's, the number of recognized cases of pneumoconiosis increased dramatically resulting in the British Medical Research Council initiating an investigation into respirable disease within the black coal workers of South Wales. Europe and the United States had previously identified the hazards of dust in coal mines and by 1950 it was confirmed that workers in bituminous coal mines were also exposed to potential dust diseases, particularly pneumoconiosis (McPherson, 2009).

However, it took many years for a definitive association to be established between the atmospheric contaminants in an operating coal mine and respiratory dysfunction of coal workers exposed to these atmospheric contaminants. McPherson suggests that there were three reasons for this delay in recognising the association between airborne contaminants and lung disease. Firstly, it takes years of exposure to coal dust before the coal mine worker shows signs of lung disease and suffers significant breathing impairment whilst performing normal activities. Secondly, the onset of lung disease often presents symptoms similar to those of naturally occurring ailments such as coughing, wheezing, shortness of breath and flu like symptoms. Thirdly, at the time, the commonly used method for determining the dust concentration level in the atmosphere was to measure the number of particles in a unit volume of air. However, the relationship between dust levels measured as a particle count in a unit volume of air and the incidence of pneumoconiosis in coal workers was not completely understood (McPherson, 2009).

During the International Pneumoconiosis Conference held in Johannesburg, South Africa in 1959, a re-direction of pneumoconiosis studies was recommended, with particular focus being directed at the limitations to the existing methods of dust sampling. Studies had identified that those particles of equivalent diameter less than 5μm were the particles most likely to be retained within the lungs and create lung disease in coal mine workers. These size particle fractions were named respirable dust. Studies further established that the mass concentration of respirable dust in any given atmosphere, over the period of a shift (usually 8 hours) was a much better measure of the potential health hazard to a coal mine worker than the existing particle count methods. (McPherson, 2009).

It was from this point forward that the TWA method of determining exposure levels was implemented and statutorily enforced. It was also at this time that equipment capable of measuring TWA's in the atmosphere was developed.

2 LUNG DISEASE

Lung diseases caused by the inhalation of coal dust are known by the general term pneumoconiosis. This is often referred to as dusted or black lung.

The changes which occur in the lungs vary with the deposition of the different dust fractions. For example, the inhalation and subsequent deposition of coal dust in the lungs can initially cause symptoms such as:

- coughing;
- wheeze, or worsening of asthma;
- increased need for medications (eg: puffers, antibiotics);
- increased breathlessness; and
- flu like symptoms.

Continued exposure and inhalation of coal dust can then lead to pneumoconiosis, Coal Workers Pneumoconiosis (CWP) and Progressive Massive Fibrosis (PMF).

In contrast, lung disease caused by exposure to silica is much more severe and identified by areas of scar tissue surrounded by normal lung tissue. Because the injured areas are separated from each other by normal tissue, the lungs do not completely lose their elasticity. Some particles are dissolved in the blood stream and then carried around the body where it may affect the brain, kidneys and other organs (CCOHS, 2012).

Health effects resulting from exposure to pneumoconiosis may not appear for many years and may in fact only appear after exposure has ceased. This delay in the production of symptoms from this exposure may then be mistakenly attributed to non-occupational conditions such as smoking. Another more serious example is the identification of the fatal lung disease mesothelioma. Mesothelioma results from exposure to asbestos fibres and cases of the disease have appeared over 40 years after actual exposure to the asbestos have occurred. It is important for hygienists, and other professionals in this field, to consider the fact that although exposed workers may

not display any symptoms of lung disease, it should not be assumed that significant lung damage has not already occurred. It is now recognised that shorter exposures to higher concentrations of pneumoconiosis-producing dusts, has produced cases of acute lung disease. (WHO 1999, USDOL, 2010).

2.1 Dust Classifications

Within the alveoli are cells called *macrophages* (i.e., scavenger cells*)* that are released by the stimulus of foreign bodies, such as dust. The macrophages engulf the dust particles deposited in the lung. Some of the dust-laden macrophages, which have the ability to move freely within the air spaces of the lung and alveoli, are removed from the lung by two different pathways (WHO 1999, McPherson, 2009, USDOL, 2010).

2.1.1Mucociliary escalator

The dust-laden macrophages move to the finer bronchioles, from which further clearance takes place by mucociliary action, as described above. Eventually these cells, along with the coarser particles initially deposited within the upper respiratory tract, reach the mouth and are swallowed or expelled via spiting or coughing. Most of the dust deposited in the alveolar spaces is removed in this manner (WHO 1999, McPherson, 2009, USDOL, 2010).

2.1.2 Lymphatic system

Dust-laden macrophage cells may pass through the alveolar walls of the lungs into the lymphatic system, which starts as a mesh of fine vessels and drains the tissue spaces. These vessels come together to form larger and larger vessels that eventually discharge the lymph into the bloodstream. At the various branching points (bifurcations) of the trachea and the bronchi, the lymph passes through glands termed lymph nodes, one of whose functions is the filtration of foreign bodies. Hence, a great deal of particulate matter is deposited by the macrophages at the lymph nodes, and it is here that fibrosis of healthy tissue often starts. Other dust-laden cells may be deposited and remain on the alveolar walls where, again, fibrosis can be initiated (USDOL, 2008).

According to the US Department of Labor, a classification of dusts with respect to potential hazard to the health and safety of industrial workers may be divided into five categories (USDOL, 2008).

2.2 Toxic Dusts

These can cause chemical reactions within the respiratory system or allow toxic compounds to be absorbed into the bloodstream through the alveolar walls. They are poisonous to body tissue or to specific organs. Coal dust is not typically classified as a toxic dust (USDOL, 2008).

2.3 Carcinogenic (cancer causing) Dusts

A combination of abrasion of lung tissue and surface chemical action can result in tumour formation from freshly produced quartz particles. Studies have identified that an excessive risk for lung cancer in certain dust producing occupations exists. These included dust producing occupations such as mining, although coal-mine workers were not specifically identified. Increased lung cancer risk among coal-mine workers appears to be found only in those with exposure to high levels of crystalline silica (AIOH, 2008, WHO 1997).

2.4 Fibrogenic Dusts

The scouring action of many dusts causes microscopic scarring of lung tissue. If continued over long periods this can produce a fibrous growth of tissue resulting in loss of lung elasticity and a greatly reduced area for gas exchange and lead to pneumoconiosis and CWP (AIOH, 2008, WHO 1997).

2.5 Explosive Dusts

These are a concern of safety rather than health. Coal dust becomes explosive when small particles become and remain airborne. If an ignition source is encountered with

sufficient methane in the area, then the ensuing methane ignition can lead to a catastrophic dust explosion (AIOH, 2008, WHO, 1997).

2.6 Nuisance Dusts

Nuisance dust can be defined as dust that contains less than 1% quartz. Because of its low content of silicates, nuisance dust has been shown to have little adverse effect on the lungs. Any reaction that may occur from nuisance dust is potentially reversible. However, excessive concentrations of nuisance dust in the workplace may reduce visibility potentially causing accidents or injury, may cause unpleasant deposits in eyes, ears, and nasal passages, and may cause injury to the skin or mucous membranes by chemical or mechanical action (USDOL, 2008, McPherson, 2009).

3 TYPES OF LUNG DISEASE

3.1 Pneumoconiosis (Black Lung)

In general, the human respiratory system's physiological reaction to any inhaled particulate depends on many factors, with particle aerodynamic diameter being the main consideration relative to coal dust. Pneumoconiosis is the primary concern with coal dust (USDOL, 2008).

The term pneumoconiosis is a generic term for damage to cardio-respiratory organs caused by the inhalation of dust and effectively means dust in the lungs. It is defined by the International Labor Organization (ILO) as the accumulation of dust in the lungs and the tissue's reaction to its presence. The inhalation of coal dust, over a long period and at sufficient concentrations, can result in the formation of scar tissue and loss of elasticity, referred to as fibrosis. This reaction is termed pneumoconiosis when linked to coal dust exposure (USDOL, 2008).

Pneumoconiosis occurs in two forms: simple Coal Workers Pneumoconiosis (CWP) and complicated CWP which leads to the condition of Progressive Massive Fibrosis (PMF). Over sufficiently long periods of exposure a build-up of retained dust occurs in the lung tissue in the form of soft plaques within the lung tissue. These can be observed as a small spot on chest x-rays (NCBI, 2012). Figure 1 shows a chest x-ray of simple pneumoconiosis in a coal workers lung. There are diffuse, small (2 to 4 mm each), light areas throughout both lungs. In the right upper lung (seen on the left side of the picture), there is a light area (measuring approximately 2 cm by 4 cm) with poorly defined borders, representing coalescence (merging together) of previously distinct light areas (NCBI, 2012).

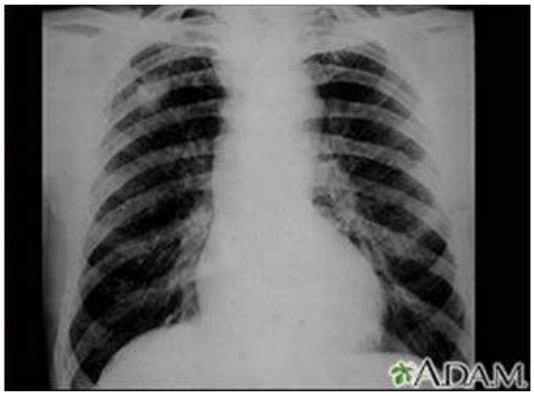

Figure 1. X-ray Showing Simple Pneumoconiosis

Figure 2 shows an X-ray of complicated pneumoconiosis. There are diffuse, massive light areas that run together in the upper and middle parts of both lungs.

These are superimposed on a background of small and poorly distinguishable light areas that are diffuse and located in both lungs (NCBI, 2012).

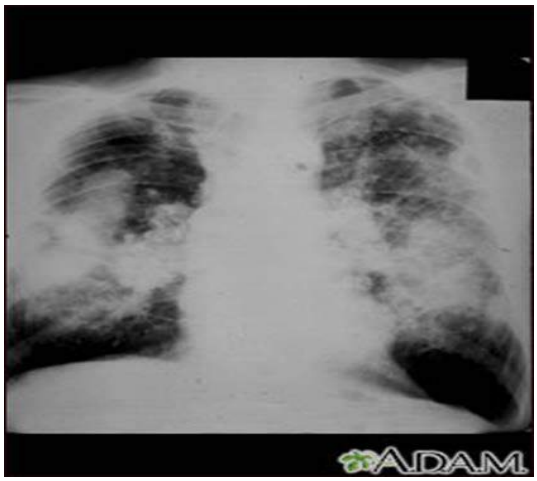

Figure 2. X-ray Showing Complicated Pneumoconiosis

Indications of CWP may not be revealed for some 10 to 15 years after initial exposure from employment in coal mines. Furthermore, the subjects may not be aware of any incapacity, or restrictions on lung function during that time. In more advanced cases, the opacities grow in size and number until they coalesce as seen in Figure 2. This is likely to be accompanied by fibrosis as shown in Figure 3 (McPherson, 2009).

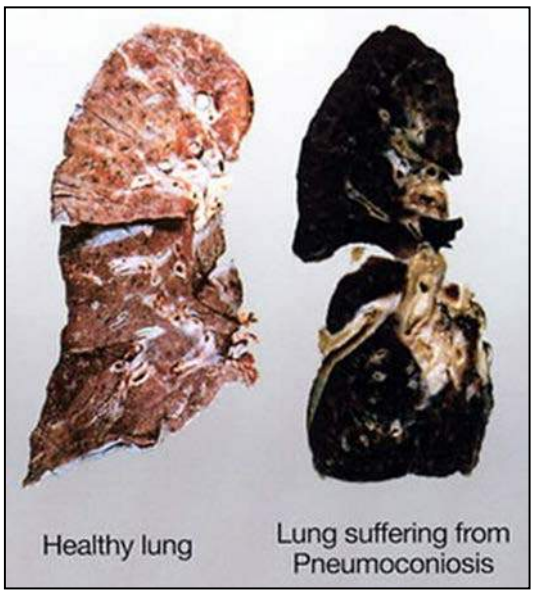

Figure 3. Healthy Lung and Lung with CWP

3.2 Silicosis

Silicosis is a fibrosing disease of the lungs caused by the inhalation and retention of respirable crystalline silica (RCS) produced during the cutting cycle of mining operations (Organiscak, et.al, 2003). The early stages of the disease produce lung accumulations that may be observed on x-ray films similar to that seen in identified cases of pneumoconiosis detailed in 2.5.1 (McPherson, 2009). Silicosis is irreversible, progressive, incurable and at later stages disabling and eventually fatal (WHO, 1999).

Four clinical types or presentations of silicosis that can be produced from the inhalation and deposition of dusts containing respirable crystalline silica have been defined as:

- simple silicosis;
- complicated silicosis
- accelerated silicosis; and
- acute silicosis.

Once these conditions have developed, no known cure or medical treatment is available, no reversal of the condition will occur over time, and it has been identified that the effects worsen even though no further exposure to silica is experienced (USDOL, 2008, McPherson, 2009, WHO, 1999).

3.2.1 Simple silicosis

Simple silicosis is the most common clinical presentation of the disease and results in fibrotic changes in the air exchange region of the lung that may occur after 10 to 30 years of inhalation of RCS. The fibrotic changes (like scars) are called silicotic lesions which are of a nodular appearance and these lesions increasingly affect the ability of the lung to exchange gases. Those changes in turn place extra stress on the cardiovascular system and reduce the body's ability to combat respiratory infections (USDOL, 2008, McPherson, 2009, WHO 1999).

Determining the exposure limit at which workers are at risk of developing simple silicosis is an extremely difficult task for a variety of reasons. These reasons include but are not limited to:

- lack of reliable past dust exposure information;
- insufficient medical surveillance information;
- individual susceptibility; and
- the role of other exposures such as smoking.

It is generally believed, however, that daily workplace exposures that exceed established exposure standards as detailed in this document can result in simple silicosis (USDOL, 2008).

The first symptom of silicosis is dyspnoea (difficult or laboured breathing and/or shortness of breath). This is first observed within the normal work activity or exercise and later as the lung function deteriorates, may be observed whilst resting or during periods of no activity. Workers with simple silicosis are usually without any symptoms. If symptoms occur, they are typically limited

to a chronic cough with phlegm (mucus) production and often get misdiagnosed as other ailments. It is also possible that there may be no shortness of breath or other symptoms and the disease may first be detected through an abnormal chest x-ray. The x-ray may show quite advanced silicosis with only minimal symptoms (USDOL, 2008).

The fibrosis in simple silicosis occurs predominantly in the upper lung zones and appears on the chest x-ray as small discrete nodules (lesions) arranged in a birdshot pattern (USDOL, 2008). Figures 4 and 5 below show a basically normal lung and a lung with simple silicosis.

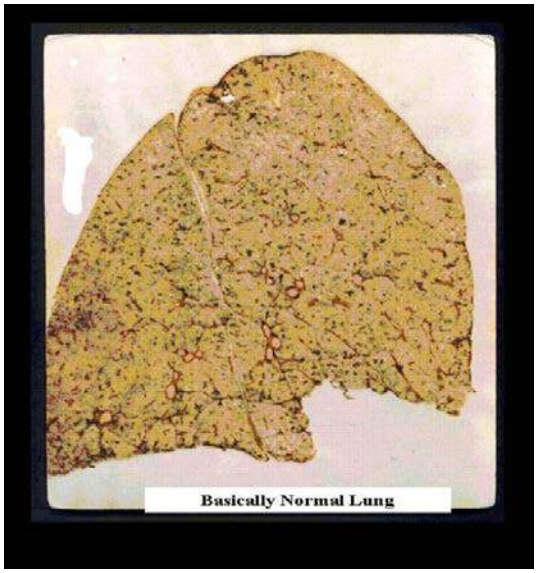

Figure 4. Normal Lung

Figure 5. Simple Silicosis

3.2.2 Complicated silicosis

Complicated silicosis usually occurs after 10 or more years of exposure at relatively low concentrations of silica dust. The silicosis nodules increase in size and coalesce into large lesions usually greater than 1 cm in diameter. The conglomerate lesions may obliterate bronchi and vessels and cause marked distortion of lung structure and function. The disease results in progressive massive fibrosis (PMF).

When progressive massive fibrosis occurs, the patient develops progressive respiratory symptoms from reduction in lung volume, distortion of bronchi, and bullous emphysema. The main symptom is shortness of breath which is related to a loss in lung volume as can be clearly seen in figure 7 below. Figure 6 shows a healthy lung.

Complicated silicosis is progressive and ultimately disabling, potentially leading to cardio respiratory failure and possible death (AIOH, 2009, USDOL, 2008).

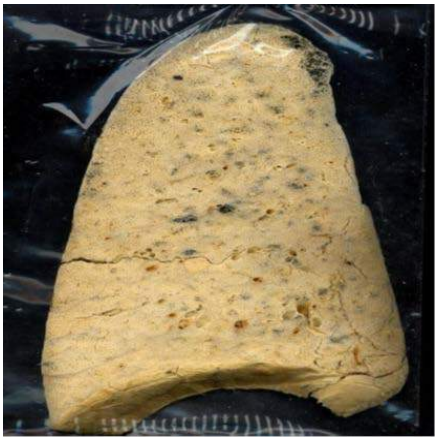

Figure 6. Healthy Lung

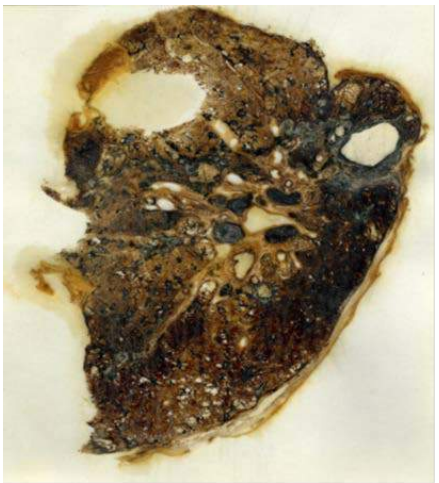

Figure 7. Complicated Silicosis

3.2.3 Accelerated silicosis

Accelerated silicosis results from the inhalation of very high concentrations of respirable crystalline silica over a relatively short period, in the order of 5 to 10 years, whereas complicated silicosis may take 10 to 30 years to develop. Although accelerated silicosis develops in a pattern similar to that of complicated silicosis, the time from initial exposure to the onset of the disease is significantly shorter and the progression to complicated silicosis is more rapid. This form of the disease is life-threatening, and death may occur as a result of insufficient levels of oxygen in the blood in as little as 10 years after exposure has occurred (USDOL, 2008, AIOH, 2009).

It has been reported that the onset of silicosis has occurred amongst drill operators within a year of being exposed to air concentrations of silica 2000 times the accepted statutory exposure level (WHO, 1999).

3.2.4 Acute silicosis

Acute Silicosis develops from the inhalation of high concentrations of RCS and is the most aggressive of the silicotic diseases. Acute silicosis develops over a very short period ranging from as little as a month to 4 or 5 years.

Acute silicosis differs from complicated and accelerated silicosis in that the characteristic nodular pattern in the upper lung is absent with the x-ray's appearance instead being similar to that of diffuse ground glass.

Symptoms of acute silicosis include cough, weight loss, and fatigue. This may progress rapidly to respiratory failure over a period of several months. Death occurs after a few months (USDOL, 2008, AIOH, 2009).

3.3 Silica and Lung Cancer

In 1997, after re-evaluating the scientific literature on respirable crystalline silica, the International Agency for Research on Cancer (IARC) published a monograph that concluded that there is now sufficient evidence in humans that inhaled crystalline silica in the form of quartz from occupational sources can cause cancer (IARC, 1997).

An IARC working group on the question of silica exposure and cancer risk in humans found that several studies among the many reviewed, were negative or equivocal. The studies also identified that the carcinogenicity of silica was not detected in all industrial operations.

However, nine studies did identify an excessive risk for lung cancer in certain dust producing occupations. These dust producing occupations included mine workers, although coal-mine workers were not specifically identified. Increased lung cancer risk among these groups appears to be found only in those with exposure to high levels of crystalline silica (IARC, 1997, AIOH, 2008, WHO 1994).

4 CONCLUSION

Particulate matter smaller than 10 micron can remain deposited in the lungs of workers exposed to these particles. Coal miners are particularly at risk of lung disease by simply performing their everyday duties.

The UBB disaster has identified that the deaths of these 29 miners may have been averted if more stringent attention had been paid to the management of dust produced during the mining cycle.

It has also been identified through detailed analysis that 71% (17 of the 24 autopsies performed) of the men that died in this disaster had advance lung disease. The fact that 71% of them showed evidence of CWP is an alarming finding given the ages and work history of these men.

With the alarming findings of lung disease from the UBB disaster, and the finding that the disaster may have been averted with greater dust control practices, all persons involved in the coal mining industry, in fact, in any dust producing industry, should place dust mitigation and control at the top of their HSE policies and planning, to prevent future disasters occurring and more importantly, to

protect all workers in any industry from this insidious and fatal disease.

Preparation of Anti-Explosive Materials by Hydrophobization Technique

E. Vogt
AGH - University of Science and Technology, Faculty of Energy and Fuels
Cracow, Poland

ABSTRACT In the work are presented new methods of manufacturing of anti-explosive materials for coal mining industry on the example of hydrophobization of limestone powder. The techniques of limestone powder hydrophobization were carried out in apparatuses of own design. The evaluation of the usability of commercial modifiers (stearic acid, silicone preparation) for hydrophobization of limestone powders was made. The degree of hydrophobization of modified materials was determined. Additionally the densimetric properties of raw and hydrophobized materials were measured in order to evaluate the effect of commercial modifier on flow properties of these materials. The suitable values of floodability and flowability indexes were assigned for tested materials. The thermal decomposition of materials was also made. It was stated that hydrophobization process improves not only water-proof properties of modified materials but also reduces their cohesion properties and improves flow qualities.

Keywords: Coal mining, anti-explosive material, hydrophobization, limestone powder

1 INTRODUCTION

Limestone powder characterized by hydrophobic properties is used as an anti-explosive agent in coal mining industry. Especially fine dispersional limestone, which grain diameter equals less than 80 μm (limestone meal) is useful for this purpose. In many works one can read that this powder (water-proof hydrophobized limestone meal) barriers very effective interrupt the flame propagation. Cybulski (2004), Lebecki (1993), Man & Teacoach (2009), Polish Standard (1994). As a precaution against coal dust explosions, limestone powder is spread within mine barriers (Figure 1).

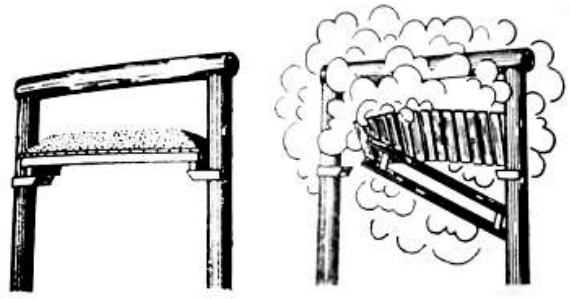

Figure1. Dust barrier activation process Cybulski (1973).

During an explosion the limestone powder disperses, mixes with the coal dust and prevents flame propagation, acting as an inhibitor. Limestone powder reduces the flame temperature to a point where devolatilization of the coal dust can no longer occur; starved of fuel, the explosion is inhibited.

The water-proof hydrophobized limestone powder nowadays is produced by milling raw limestone with stearic acid. In the consequence of modernization of quarries the quantity of possible producers of such powder could be reduce. For this reason new methods of manufacture of water-proof limestone meal should be searched. This new product protects human life so its properties are very important and should be well-known.

Hydrophobization is a beneficial process from the economic point of view since, as it is commonly known, hydrophobic materials are sensitive to the harmful effect of humidity to a much lower degree than solids with similar applications but not possessing this characteristic. In general terms, methods

of hydrophobisation can be divided into protection of material surface by substances characterised by hydrophobic properties or modification of properties inside material volume Vogt (2008). In the case of fine dispersional materials such as limestone meal the layer hydrophobisation (protection of material surface) is the most often used. This process guarantee good contacting of each fine dyspersional materials grains with a hydrophobizing preparation.

2 EXPRIMENTAL

2.1 Limestone Material

In this work limestone powder (meal) from the Czatkowice Lime Quarry Buczek & Vogt (2007) with the particle diameter less than 80 µm was used as a raw material during researches. This powder is, among others, used in the coal mining industry as one of the elements of the anti-explosive safety system (raw anti-explosive limestone powder) Polish Standard (1994), Lebecki (1993), Skalski (2005), Man & Teacoach (2009), Lebecki & Małachowski (2012). The average chemical composition of limestone meal in accordance with the manufacturer's data is presented in Table 1.

Table 1. Chemical composition of limestone meal – manufacturer's data.

Component	(% w/w)
$CaCO_3$	96.00
SiO_2+NR	1.50
$MgCO_3$	1.50
Fe_2O_3	0.11
Al_2O_3	0.08
Na_2O	0.023
K_2O	0.037
Heavy metals	In trace amounts

The real density of the limestone meal, marked with the method of helium picnometry with the use of the AccuPyc 1330 apparatus, amounts to 2.7642 g/cm^3.

2.2 Modifiers

Due to extensive pulverization of limestone meal and its cohesive properties, industrial modifiers were chosen for research as they, according to the author, guarantee good contacting of powder grains with a hydrophobizing preparation. Stearic acid is used in mining production plants for the production of anti-explosive powder with the traditional method. Another preparation used in the researches include existing on the market representatives of groups of compounds often quoted in literature and applied for the hydrophobization processes of mineral bulk materials; these are: a silicone preparation with the marketing name SARSIL® H-15 produced by the Chemical Plant "Polish Silicones" Ltd in Nowa Sarzyna. The second mentioned preparation is a solution of methyl salicylate resin in isoparaffin solvent - has got the density of 0.78 kg/m^3 and is applied for protecting building materials such as brick, concrete, gypsum, plasters.

2.3 Applied Hydrophobization Techniques

2.3.1 Selection of a modification technique

The densimetric characteristic of limestone meal was the basis for the proposed methodology of conducting the hydrophobization process. Processes enabling the dispersion of powdr to a degree which allows for the contact of single grains with the modifier were taken into account. It was assumed that the modifier should be introduced into the process in such a form which would build a monomolecular layer on the surface of single limestone powder grains. Although limestone powder is characterized by a low porosity level, it was assumed that due to its vulnerability to moisture the modifier should also block the entrances of the pores inside powder particles or coat the pores' surface with a protective layer against moisture. Both modifications were conducted on the air-dry limestone meal.

2.3.2 Hydrophobization with the use of stearic acid

In the work two techniques of applying the modifier (stearic acid) on a powder surface were proposed, which are different from the classical milling limestone with stearic acid technique.

The first proposed method of powder modification was the hydrophobization by ether solutions of stearic acid (diethyl ether, petroleum ether). It was assumed that stearic acid particles dispersed in the solution should have an easy access to the powder grains surface and easily settle on it. The concentration of the solutions used during modification was determined on the basis of the Polish Standard (1994) in such a way that the content of stearic acid in the modified powder was within the range 0.15-0.30%. Hydrophobization from solution was carried out with two methods: mixing solutions with the powder in a beaker at room temperature, and contacting the powder with the modifier in a laboratory evaporator, at an increased temperature.

The other proposed method of limestone meal hydrophobization (with the use of stearic acid) was carried out in an installation of own design, and it consisted in free sedimentation of the powder layer dispersed by stearic acid vapour in powder countercurrent flow (Figure 2). The method guarantees the fulfillment of earlier expressed expectations regarding the modification technique. Falling in a straight line and not meeting any obstacles, the powder was dispersed, and the stearic acid converted into the vapour state may freely settle on its outer surface and penetrate inside pores. The contacting time of both media was extended in relation to the time of hydrophobization from solutions, and volatile organic solvents were eliminated from the process. The author, after characterisation of material hydrophobized with the use of stearic acid, stated that second methods of hydrophobization (Figure 2) is more profitable. So sample S_18, obtained in this way, was find as a main hydrophobized by stearic acid material and its properties were studied in the work.

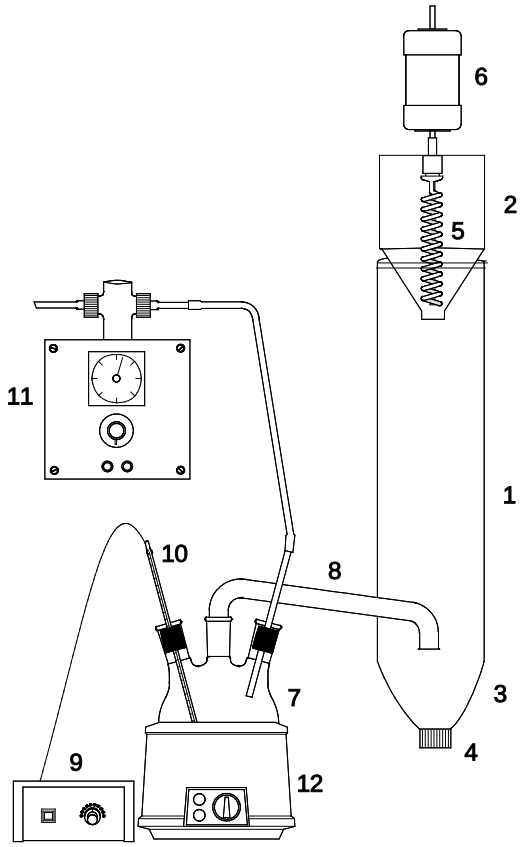

Figure 2. The hydrophobisation installation: 1 – hydrophobisation column, 2, 3 - hoppers, 4 - lock of hopper, 5 - batcher, 6 - electric drive, 7 – boiler, 8 - ting up pipe, 9 – thermoregulator, 10 – thermocouple, 11 – compressor, 12 – heater.

2.3.3 Hydrophobization with the use of silicone preparation

According to the manufacturer's instructions, the SARSIL® H-15 silicone preparation may be applied onto a dry surface of the building material by spraying or painting.

The moisture content in limestone meal (on the modification day) was established with the drier method Polish Standard (1980) and amounted to 0.04%, which is such a low value that the powder was considered as dry.

The initial research determined the preparation volume that should be added to the limestone powder in order to obtain optimal conditions for the contact of the preparation with the powder. The first experiments with a large excess of the modifier guaranteed easy and thorough mixing of reagents, but the achieved time of meal drying was too long. As a result, the limestone meal underwent the process of irreversible lumping. Further experiments

allowed to determine the optimal modifier quantity. The material obtained after modification (S_SH15 sample) was lumped only to a slight degree, and its total disintegration was achieved by sieving the meal with the use of a brush Buczek & Vogt (2013).

2.4 Hydrophobic properties obtained materials

The conducted literature analyses indicate that, although there are a large number of works on hydrophobization processes, no uniform techniques of determining the hydrophobization degree have been developed for materials modified with the use of various modifiers Vogt & Hołownia (2010). This problem is particularly visible in the case of powder materials. Both the modification process itself and the examination of hydrophobic properties of fine-dispersional materials are not as simple as analyzing the same properties for solids with large surfaces. There indeed are methods which may be applied for this purpose, but some of them are so specific that they may be applied only in an exceptional case, as it is the case, e. g. while determining the content of stearic acid in anti-explosive limestone powder Polish Standard (1994), Dang-Vu & Hupka (2005), Fuerstenau & Williams (1987). It is difficult to find a single research method which could be applied to determine the hydrophobization degree of powder materials modified with the use of various modifiers. In the presented research, it turned out that conducting it with the limestone powder helped to search for the method of examining the hydrophobization degree. This fact makes it possible to compare the hydrophobic properties of lime meal modified in the work with the properties of industrial hydrophobic anti-explosive powder available on the market, produced by limestone and margiel quarry of cement plant in Małogoszcz (PH).

2.4.1 Methods measurement of hydrophobic limestone meal properties

A relative evaluation of the hydrophobization degree of the analyzed materials was based on a very simple experiment, the so-called „floating on water" test. The experiment consisted in placing a small amount of powder on the surface of water in a beaker. The following were accepted as reference materials: raw limestone meal and hydrophobic limestone meal (limestone and margiel quarry of cement plant in Małogoszcz – PH sample). Immediately on contact with the water surface, the raw limestone powder became moist and fell onto the beaker bottom. This effect was assumed as the zero hydrophobization degree. By contrast, the complete portion of the industrial hydrophobic material PH remained on the water surface until it evaporated (within approximately three weeks). The hydrophobization degree of materials modified in the work was evaluated on the basis of the limestone meal amount floating on the water surface for a specified period of time.

On the basis of the observations, it can be concluded that the all of materials after modification acquired hydrophobic properties at the level of the hydrophobic properties of the standard material (PH). Both the powder modified with stearic acid from ether solutions, at an increased temperature, and from the vapour phase as well as the powder modified by the method of mixing with the SARSIL® H-15 preparation remained on the water surface for the period of three weeks, just as it was in the case with the commercial material (PH).

It is easy to determine the hydrophobization degree (not only as a relative evaluation but also as a number manner) of material when stearic acid is used as a modifier, because there is a standard, which defines this measurement. The manufactured sample (S_18) contains 0.18 % of stearic acid, being an acceptable level according to the Polish Standard (1994). Unfortunately the contain of stearic acid

can't be measured for meal modified with the use silicone preparation.

In the case of the SARSIL® H-15 silicone modifier the author had to work out the method for determination of hydrophobization C coefficient. The film flotation method could be used if the standard material PH was used as a comparative sample Fuerstenau & Williams (1987), Diao & Feuerstenau (1991). The C coefficient defining to what extent the hydrophobic properties of the S_SH15 sample are different from the hydrophobic properties of the PH sample on contact with a suitable methanol solution was calculated from the equation:

$$C\ [\%] = \frac{f_{pi} \cdot 100}{f_p}$$

Where f_{pi} and f_p are mass percentage of S_SH15 sample and PH sample floating on a selected (10, 20, and 60 % (w/w)) methanol solution surface respectively.

The average value of the C = 84 % coefficient shows that the S_SH15 sample obtained sufficient hydrophobic properties.

It was also measured the water wetting angle. The average values of obtained results are presented in Table 2.

Table 2. Water wetting angle.

Modifier	Wetting angle [degree]
Limestone meal from Czatkowice Quarry	
Lack	33,7 ± 6,04
Stearic acid	125,5 ± 5,77
SARSIL® H-15	101,6 ± 9,96
Standard (limestone meal) material from Małogoszcz	
Stearic acid	76,5 ± 3,99

The obtained values of wetting angle show that both modified materials have achieved the better hydrophobic properties than the commercial anti-explosive powder (PH)

2.5 Thermal Decomposition

The thermal decomposition of the hydrophobized limestone powders was studied. One of the role of limestone powder in the system of protection against explosions brings to the increasing of content of non-combustible parts in coal dust and physical prevention of the flame propagation. Under the influence of the flames temperature comes to the thermal decomposition of limestone powder and both calcium oxide and carbon oxide (IV) are emitted. This endothermic process consumes some of the flame energy. The gases mixture is enriching in non-flammable CO_2. It causes the reduction of the system's explosion.

The thermo balance TA Instruments 2960 SDT was used during researches. DTA curves and the composition of obtained gasses (EGA) were measured. The results are showed at the Figures 3-4. The continuous line (Figures 3-4) represents the course of TG, DTG and DTA curves for the raw material. The dashed lines were obtained for limestone powder modified by stearic acid (Figure 3) and silicone preparation (Figure 4).

The CO_2 contents in emitted gasses showed in the Figure 5 (EGA). The curves obtained for modified meal overlaps with this one obtained for the raw material.

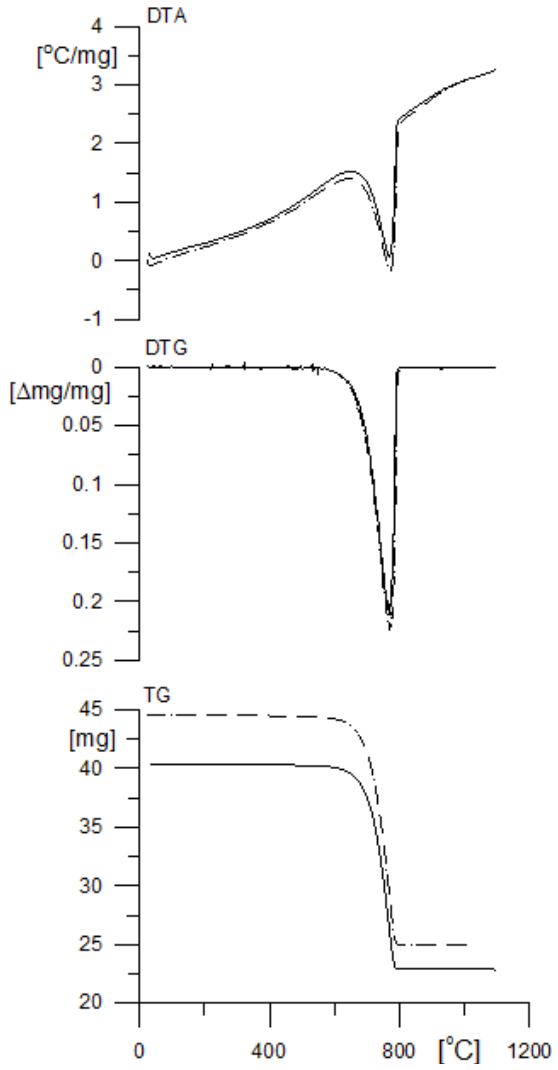

Figure 3. TG, DTG and DTA curves for limestone powder: raw – continuous line, modified by stearic acid – dashed line Buczek &Vogt (2014).

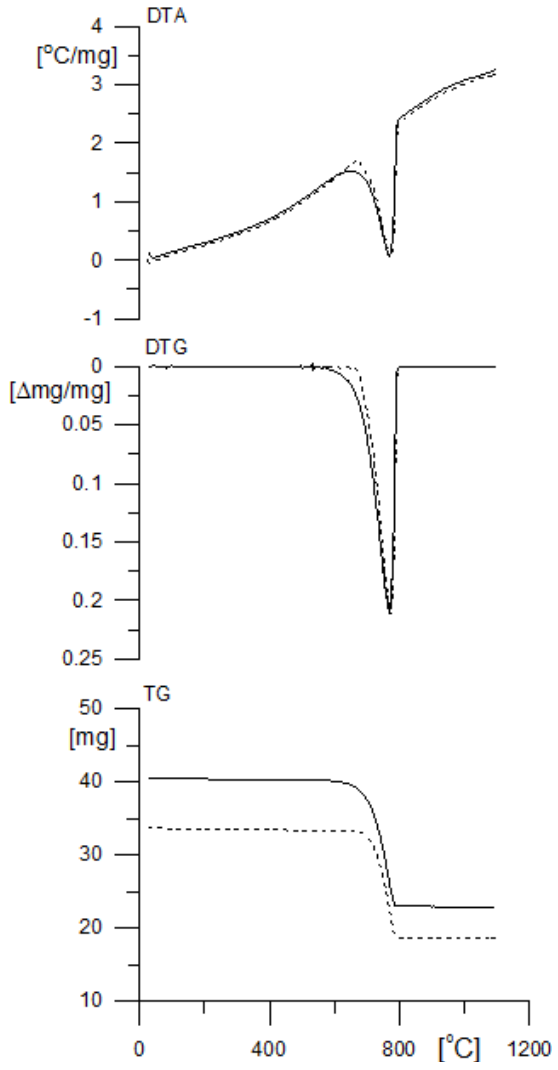

Figure 4. TG, DTG and DTA curves for limestone powder: raw – continuous line, modified by silicone preparation – dashed line Buczek &Vogt (2014).

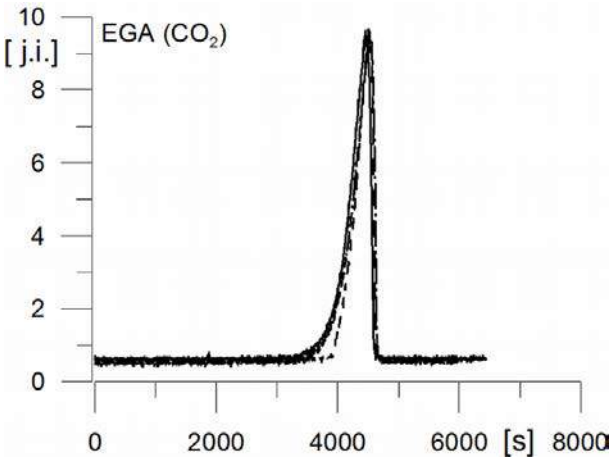

Figure 5. EGA curves for limestone powder: raw –continuous line modified by stearic acid or modified by silicone preparation – dashed line Buczek & Vogt (2014).

The little differences between of courses of TG, DTG or DTA curves for all investigated materials were stated. The obtained results show that the character of the thermal decomposition of modified samples is the same as this one for raw limestone meal, what is profitable for application of hydrophobized meal as an anti-explosive agent.

2.6 Flowability (F_1) and floodability (F_2) indexes

The densimetric parameters (obtained with the use of the Powder Characteristic Tester (PChT), type PT-E, Ser. No. 90133 enable us to estimate the flowability and volatility of powders. These parameters characterised the cohesion properties of limestone meal that are very important during storage and manufacturing of fine dispersional materials. The obtained results may be used also to assess the direction of changes of flow properties of limestone meal, which were caused by the hydrophobization process. There are special tables available which make it possible for the measured parameters to be assigned appropriate ranges of the flowability (F_1) and floodability (F_2) index values Carr (1965), Index Tables (1965), Thomas (2005). Table 3 presents the compressibility (C) and dispersibility (D) values calculated for raw and modified powders and their corresponding ranges of flowability and floodability index values.

Table 3. Values of compressibility and dispersibility calculated for raw and modified limestone meal (Czatkowice Quarry) and their corresponding ranges of flowability and floodability index values Vogt (2008).

Parameters	Material		
	Raw	S_18	S_SH15
C (%)	50.9	39.8	44.1
F_1	0-19	0-19	0-19
D	20	42	16
F_2	60-79	80-100	40-59

It can be observed that the modification process resulted in reduced compressibility of all materials. In spite of this fact the modified materials may be assigned the same range of the flowability index and they constitute the same group of materials as raw limestone meal Carr (1965), Index Tables (1965), Thomas (2005). Such a qualification suggests that during the flow, the materials have a tendency to settle in pipe elbows and clog their outlets. However, it may be assumed that in the case of modified powders flow disturbances upon storage and conveying will be present on a smaller scale than in the case of a raw material.

The meal modified with stearic acid (S_18) is characterized by dispersibility allowing assigning the highest range of floodability index values to these materials (Table 3). In the case of this material, the necessity may arise to implement special precise seals of apparatuses suitable for use with powders. The determined dispersibility of the S_SH15 material is generally comparable for raw powder.

3 CONCLUSION

The presented work is a short summary of the author's research works regarding the hydrophobization of limestone meal. The selection of the presented content was made from the point of view of the evaluation of the usability of industrial modifiers for limestone meal hydrophobization. It was taken into account that the obtained water-proof product should be useful as an anti-explosive limestone powder. The evaluation of the hydrophobization degree of modified materials were made on the basis of the results obtained with the simple method – the test of „floating on water", and special methods suitable for used modifiers. The first measurement enable us to illustrate the relative difference in hydrophobic properties of materials modified with various modifiers. The measurement of stearic acid contents for S_18 sample is suitable when this modifier is used but isn't possible to obtained the same parameter for S_SH_15 sample. The "film flotation" method is an interesting method of

testing the hydrophobization degree for limestone powders modified in different ways. On the basis of the obtained results it may be concluded that all the applied modifiers change the characteristics of limestone meal towards the hydrophobic character. Materials may be useful as an anti-explosive powders in mining.

For all investigated materials was stated that the character of the thermal decomposition of modified samples is the same as this one for raw limestone powder (TG, DTG or DTA and EGA curves). In the case of application of hydrophobized powders as an anti-explosive agent this fact is very profitable.

The densimetric measurements were used to assess the direction of changes of flow properties of limestone powders, which were caused by the hydrophobization process. Familiarity with such characteristics is useful for the designing of devices and apparatuses suitable for use with powder materials or for the proper conducting of such processes.

It was also established that the hydrophobization processes with the use of stearic acid and the silicone preparation as modifiers had the most beneficial effect as far as flow properties of limestone meal are concerned. The modification process maintained the meal powders flow abilities. The application of the water-proof limestone meal is more profitable than use of the raw limestone material.

ACKNOWLEDGEMENTS

The authors are grateful to the AGH University of Science &Technology (Project No. 11.11.210.244) for financial support of this work.

Systematical and Radical Precautions in the Prevention of Mine Accidents and Professional Diseases

T. Güyagüler
Mining Engineering Department, METU, Ankara

ABSTRACT The increasing demand for energy raw materials and various industrial minerals increased the importance of mining. It is obvious that this demand will be rising in the near future. Mining, due to the risks it involves, requires specific knowledge, experience and continuous technical inspection.

It has been observed that recently the number of mine accidents and professional diseases are increasing in Turkey. This trend can only be reversed by the application of systematical arrangements and radical reconstructions.

In this paper, the importance of technical inspection, application of accident preventing methods, approval of mining projects and the responsibilities in the occurrence of accidents and the related recommendation for the improvement will be discussed. In addition, the importance of developing a consistent health and safety policy, responsibilities of employers and employee, recommendations regarding inspection institutions and description of procedures to ensure that the inspections are fully carried out, will also be discussed.

Keywords: Health and safety, accident prevention, environment, ergonomics

1 INTRODUCTION

Accidents and professional diseases results high number of fatalities, injuries and illnesses together with huge money losses. Recently, it has been observed that the number of fatal accidents and professional diseases are increasing in mining industry.

Labor protection is defined as a system of legal acts and relevant socio-economic, technological and organizational measures ensuring safety and health, accident prevention and industrial hygiene and fitness to work

It is the duty of **government, management and workers (unions)** to provide healthy and safe working place and minimize the frequency of accidents and occupational diseases.

2 ASPECTS OF LABOR PROTECTION

2.1 Legal Provisions

The basic statutes on labor protection are **laws, regulations, directives, instructions and standards.** Revising existing statutes and bring them to EU standards is important. It is a known fact that even perfect legal provisions are useless unless effective inspection and control exist. Safety legislation oblige management to ensure safe and healthy working conditions in industry, promote safety layouts and devices that prevent accidents, provide sanitary and hygienic conditions that reduce the incidents of occupational diseases and observe safety and hygienic requirements during the operation.

Governmental inspection is necessary to prevent the violation of health and safety rules and regulation. Controlling should start at the project acceptance stage. Determining suitable mining method, ventilation, transportation and supporting system has vital importance to operate the mine. It can be said that majority of accidents occur due to the mistakes involved in above mentioned factors. The group of engineers who are employed by an institute (MİGEM) as a part of the Ministry of Energy and Natural

Resources, controls the project whether it is prepared according to the mining principles and technology or not. This control should go on throughout the mine life. Therefore the engineers employed by MİGEM should have enough knowledge and experience to do the job properly.

It has been realized that safety legislation would be ineffective or useless unless understood, obeyed and complied with. The inspectors who are employed by The Ministry of Labor and Social Security inspect the companies whether they obey to safety regulation or not. Recently, severe accidents happened in coal mines in Turkey. For this reason inspectors should be capable to find the causes leading to fatal accidents in gassy mines for gas explosion (as seen in Zonguldak) and mine fires, especially spontaneous combustion (as seen in Soma). Here, it may be suggested that an expert group of inspector can reduce the severe accidents.

If safety rules and regulations are ignored, there is an apparent need to enforce and supervise their compliance and observance.

2.2 Environment and Human Factors

In modern mining, psychological overload during working hours has greatly intensified. Therefore, new concepts such as **ergonomics, human behavior, social environment and fatigue management** should be considered in the accident prevention programs.

Ergonomics is defined as the scientific study of the relationship between man, machine and environment.

Man at work is liable to make mistake, particularly if working under stress. These mistakes may cause accidents. The incidence of such mistakes can be reduced by the application of the ergonomics.

In accident prevention programs the main emphasis is generally given on machine guards and accident preventing equipment instead of human mistakes. Most of the machines are designed neglecting to consider the natural behavior of the human being.

Human factors that may cause to accidents are short term memory, expectation, information handling capacity, underestimating the risk, failure to judgment, perceptual limitation and physical limitation (Güyagüler et. al., 2005). These factors should also be considered in accident preventing programs.

Besides the physical environment (gas and dust content, illumination, noise, temperature and humidity etc.), social environment plays an important role in the occurrence of accidents. The important factors involved in social environment are communication, management, family, friends, economics, government, unions and associates. It is very important to consider these factors to minimize the accidents (Murrel, 1979).

2.3 Other Factors

Another important factor, fatigue which is a general term used to describe the feeling of being tired, drained or exhausted should be considered in fighting against accidents. Sign of fatigue are loss of attention, increased impatience and irritability, increased risk taking, short unplanned naps, poor decision making, increased reaction time, lowered ability to think logically, feeling lethargic and inability to anticipate danger

2 APPLYING THE ACCIDENT PREVENTING TECHNIQUES

Data in accident report form can be used to evaluate hazards, prepare job safety guides, formulate new policies, redesign equipment, modify operating procedures, develop training programs etc. The detailed analysis of an accident requires the knowledge of many factors such as location, time, type of accident, profession victim, nature of the injury, personal and environmental factors etc. Detailed information is necessary to analyze the accidents end minimize the accidents, proper Accident Report Form is needed. Analyses of accidents can be done in

a minutes by computer programs using these forms.

The priority and the urgency for correcting a hazard should be determined on the basis of severity, frequency and exposure. In this context, risk levels can be determined using qualitative or semi-quantitative methods. First rating calls for immediate shutdown of the system and eliminating the causes of the hazard leading accident.

General methods of accident prevention and labor protection should be realized by applying officially accepted modern accident prevention methods such as Job Safety Analysis (JSA) and Fault Tree Analysis (FTA) (???).

Accidents can be prevented by simply eliminating one or more of the accident causes. By identifying and correcting the sources of failure, a system can be made safer and more efficient.

3 CONCLUSIONS

As a conclusion the followings can be recommended to minimize accidents and occupational disease

- Proper accident report form and coding system is necessary to analyze and to prevent the accidents. In this context the validity and accuracy of the accident report has vital importance.
- To determine the level of health and safety, legally accepted indicators should be used. It will be helpful for the further accident analysis of and accident prevention.
- Proper risk analysis should be conducted to the mines and its applicability should be controlled.
- After statistical analysis, order the type of the accidents according to their criticality (risk levels).
- Officially one of the accident preventing techniques such as job safety analysis and/or fault tree analysis should be accepted.
- Mining method, ventilation, transportation and supporting system should be suitable to the operation. The control of these should be done during the license acceptance stage and control should continue throughout the mine life.
- Inspectors sent to control the mine should be expert and certified on mine workings.
- Insufficient expenditure creates health and safety problems. Therefore, sufficient money should be spared for the health and safety. It is a known fact that the money spent after accident is always higher than the money spent to prevent the accident. In this context, legally non-fatal and fatal cost models should be prepared.
- Fatal accidents should be analyzed and related precautions should be taken immediately. There are common characteristics causing to firedamp explosions occurred in the coal mines. If the main causes are eliminated, most explosions can be prevented. The similar precautions should be taken to prevent fires resulting spontaneous combustion.
- Principles of ergonomics, fatigue management and social environment concepts should be included into the accident preventing programs.
- Management should provide education and training to the employee and give them information about the risks involved in the working area.
- Punishments given to the employer due to the wrong application of health and safety principles should be high enough to correct mistakes immediately.

As a final conclusion, all types of accidents can be prevented if required precautions are taken.

Wireless Health Monitoring System for Miners

A. Anas
Assistant Manager (E&M), Coal India Ltd., Ranchi, India

ABSTRACT The aim of this Project is to create an easy and effective Health Monitoring System for Miners working in Underground or Open cast Mines. Being exposed to dust, metals and large no. of harmful substances, Miners usually come across many health problems which are not cured on time because of lack of diagnosis and ultimately leads to disastrous results for them and their families. The Wireless Health Monitoring System for Miners speaks about an effective and user friendly system. It comprises of a server terminal and a portable terminal. The server terminal is connected to a central server and portable terminal can be installed in the mines which can periodically be used by miners to provide their body parameters to Health and Safety Officer of the respective mine. The body parameter such as Blood pressure, Pulse rate/Heartbeat, Body temperature etc. may be recorded with the help of portable terminal. A finger print based identity system may be used to save the body parameters of different individuals. These data of different individuals working in mine will be taken and transferred time to time daily, automatically to the server terminal with the help of a Zigbee (XBee) module. The data received at the server terminal will automatically be saved in the specified files in specific formats on server. These files are part of database of a Website which is accessible to appointed doctors. The data collected time to time from miners may be checked on regular basis by doctors and if any disturbance from normal in the body parameters of an individual is detected or noted, doctors may immediately call him/her.

Keywords: Health monitoring system, wireless, record of body parameters

1 INTRODUCTION

1.1 Rationale

Human health is an increasingly popular public concern. People spend lot of money on it because if one gets severely sick or dead, everything else becomes meaningless for them. Unfortunately, millions of people get their disease diagnosed when it becomes too late to receive medical treatment and care. In many of the cases it is observed that if an early action was taken, disease could have been cured. This early action needs proper examination and reports of body parameters of the concerned patient which is not feasible with the current system, as frequent access to medical examining equipment is inconvenient and expensive.

Among the most important indexes of human health, Heart beat/Pulse Rate, Blood Pressure and Body temperature are the most vital ones and they have the advantage of easy access. Unlike X-ray and MRI, the measurement of Heart beat/Pulse Rate, Blood Pressure and Body temperature is an easy conduct and does not cause much harm to human body tissues.

In current market, however there are some measurement devices available which can be used by the patients, but due to non-medical background of majority of patients, and restricted information provided by the instruments, meaningful medical diagnosis on their part is not possible. As far as Miners in particular concerned, majority are either illiterate or very less educated. All the miners are subjected to very high exposure to harmful substances such as dust and other mine gases. Unfortunately till now there is no effective working health monitoring system arranged for them.

In view of the above facts, it is need of hour to design an efficient, convenient inexpensive and user friendly system to read, record, interpret, transfer, save and display the important human body parameters which

can be made available to a doctors through Internet.

1.2 Objectives

- The device and system should be very user friendly so that patients with zero medical and technical background can also use it.
- The device should be power efficient, less costly and reliable.
- The system should be such that it can be easily integrated with present network technologies.

1.3 Functional Structure

The system consists of two parts:

1. Portable Terminal
2. Server Terminal

1.3.1 Portable terminal

It consist of the main measurement circuit, processing unit, small memory and a wireless transmitter. Measurement circuit consist of a temperature detecting sensor and a pulse detection circuit. The data from circuit is given to Analog to Digital Converter (ADC) of Micro-controller Unit (MCU). This Micro-controller Unit is employed for the conversion and processing of data. Then the processed data is taken out from UART (Universal Asynchronous Receiver Transmitter) serial channel of MCU to the Transmitter.

1.3.2 Server terminal

It consists of a wireless receiver, a server and a COM port to interface with. The data generated at the Portable Terminal is received at the server side with the help of a wireless receiver, processed and saved in the form of different files on the server and can be accessed from Internet or intra-net by the doctor through a web based portal hosted on the server.

2 HARDWARE REQUIREMENTS

2.1 Temperature Transducer / Sensor

A temperature Transducer/Sensor is required in designing this device as body temperature is a very important parameters as far as diagnosis is concerned. A simple temperature transducer that can be used here is LM35, which is an integrated circuit based temperature sensor. It converts the temperature into a proportional electric signal which can be easily converted into equivalent temperature through calibration.

LM35 temperature transducer is a precise integrated circuit based sensor, whose output voltage is linearly proportional to input temperature. It provide typical accuracies of $\pm 0.25\ ^{\circ}$C at room temperature and ±0.75 °C at over a full -55 to +150 °C temperature range. LM35 is a low output impedance, linear output and precise inherent calibration interface device. It can be used with a single power supply. As it draws only 60 μA from its supply, it has very low self-heating, i.e. less than 0.1 ^{O}C in still air.

The fabrication of a temperature sensor depends upon exploiting a property of some material which is a changing function of temperature. A silicon NPN transistor can be used for such a requirement. The base-emitter voltage (V_{BE}) of such a transistor has a temperature dependence over smaller range of temperatures. The approach developed is one where the difference in the base-emitter voltage of two transistors operated at different current densities is used as a measure of temperature.

2.2 Infra – Red Led

An Infra-Red Light Emitting Diode is required to generate an electrical signal proportional to the pulse rate of a person. A simple Infra-Red LED which can be used here is LTE4208. Some of its important parameters are:

PARAMETER	MAXIMUM RATING
Power Dissipation	100 mW
Peak Forward Current	3A
Continuous Forward Current	50 mA
Reverse Voltage	5V
Operating Temperature Range	-40 ^{O}C to + 85 ^{O}C
Storage Temperature Range	-55 ^{O}C to +100 ^{O}C
Lead Soldering Temperature	260 ^{O}C for 5 sec

2.3 Infra-Red Phototransistor / Sensor

The Infra-Red (IR) Photo-transistor can be used in the design of portable terminal for providing the complementary role of detecting the signal produced by IR – LED and reflected after striking on the finger of patient or concerned person. It consist of a NPN silicon transistor mounted in a lensed, clear plastic end looking package. Some of its important parameters are:

PARAMETERS	MAXIMUM RATING (25 ^{O}C)
Power dissipation	100 mW
Collector – Emitter Voltage	30V
Operating Temperature Range	-40 ^{O}C to + 85 ^{O}C
Storage Temperature Range	-55 ^{O}C to +100 ^{O}C
Lead Soldering Temperature	260 ^{O}C for 5 sec

2.4 Operational Amplifier (OpAmp)

An Operational Amplifier (OpAmp) can be used in the design of measurement circuit to provide voltage gain and work in the filter for obtaining desired range of frequency of the signal obtained from the Infra-Red Photo-transistor. A simple OpAmp that can be used here is LM358. It consist of two independent, high gain, internally frequency compensated OpAmps designed to operate from a single power supply over a wide range of voltages.

2.5 Micro-Controller

A Micro-controller can be used in the design of Portable Terminal for converting the filtered out analog signal to digital form with the help of its Analog to Digital Converter (ADC) and then processing it to transfer the desired result by sending it to the RF wireless transmitter. A Micro-controller is a computer-on-a-chip. It is a type of microprocessor emphasizing self-sufficiency and cost-effectiveness, in contrast to a general-purpose microprocessor. The only difference between a micro-controller and a microprocessor is that a microprocessor has three parts – ALU, Control Unit and Registers, while a micro-controller has additional elements like ROM, RAM etc.

A simple Micro-controller that can be used here is ATmega32L. ATmega32L is a low power CMOS 8-bit Micro-controller based on the AVR enhanced RISC Architecture. By executing powerful instructions in a single clock cycle, the ATmega32L achieves throughputs approaching 1 MIPS per MHz allowing the system designer to optimize power consumption with processing speed.

2.6 Wireless Transceiver (ZIGBEE)

In order to transfer the data received and processed by the Micro-controller to the server terminal wirelessly, a Radio Frequency Wireless Transmitter can be used here. Such most convenient device that can be used here is a ZIGBEE Module. Zigbee is a kind of wireless communication device which owns the lowest power consumption and cost in its field. As far as radio frequency bands are concerned Zigbee can operate in the industrial, scientific and medical radio frequency bands. Zigbee is considered to be the most appropriate device for this role in the current scenario because of the following reasons:

- Low Cost
- Secure
- Reliable and Self-Healing
- Flexible and Extend-able
- Low power consumption
- Can be globally used in the non-license requiring radio bands.
- Integrated intelligence for network setup and message routing.

Zigbee is the only standards-based technology that addresses the unique needs of most remote monitoring and control sensory network applications.

2.7 Miscellaneous

There are a many more small components which are to be used in the design of Portable terminal of the device. Some of these are:

- Resistors
- Capacitors
- Trimpot
- Battery or any other power source.
- GP Board
- 2 pin Jumper wires
- IC 7805 Voltage Regulator

Resistors and Capacitors of different value as per the requirement of circuit may be used to design both measuring as well as filter circuits. A trimpot (or rheostat) is a device used to get a variable voltage gain by changing its variable resistance. IC7805 voltage regulator is an integrated circuit based voltage regulator for a regulated D.C. Power supply of +5V. Since Micro-controller ATmega32 as well as OpAmp LM358 cannot withstand voltages more than +5V this regulated D.C. Power Supply is necessary for this design.

3 SOFTWARE REQUIREMENTS

3.1 Real-Time Operating System

3.1.1 System overview

On the system level, two sensing tasks, heart rate sensing and temperature sensing, needs to be done. Another task is needed for communication between the MCU and web-server. The temperature sensing task just needs ADC conversion so this can be done in interrupt handlers. The other two tasks need separate functions to perform. The behavior of the system should be predictable and the time when the measurements are performed needs to be recorded. In this scenario, a real time system is used to schedule the tasks.

3.1.2 Real-time OS configuration

A customized real-time OS UART library trtUart.c can be used in the program with a creation of two semaphores, SEM_RX_ISR_SIGNAL and SEM_STRING_DONE. The variable of heart rate is a shared variable between the task of communication (task 1) and the task of heart rate measurement (task 2). The semaphore HEART_OUTPUT is created to protect this variable. Also, the task of measuring heart rate is only allowed to run after a new data point is ready. Therefore, another semaphore, DATA_READY is created to control the execution of task2. Semaphore HEART_OUTPUT is initialized as unblocked and all the others are initialized as unblocked.

3.1.3 Tasks description

Task 1 communicates with the web-server and it is desirable to guarantee that the information is received or transmitted. Therefore, task 1 is assigned higher priority over task 2. The priority is assigned by giving task 1 an earlier deadline than task 2 when the two tasks are created and their deadlines are kept fixed.

In the communication between the MCU and the web-server, all the communications are initiated by the web-server. Therefore, task 1 keeps receiving instruction from the server and it is blocked until a "\r\n" is received. Once task 1 receives a "\r\n", it will perform different things according to the instructions received.

Task 2 is the heart rate detection algorithm and it is executed after a data point of the heart pressure wave is ready and it must be done before the next data point of the heart

pressure wave is ready. So at the end of the task 2, the process waits for the next data point to be ready. And when the next data point is ready in the ISR (Interrupt Service Routine), the ISR will signal task 2 to go. Task 2 is also in charge of saving data for the most recent 5 stable pulses. Two buffers are used to do this task. Once one buffer successfully records the data for 5 successive stable pulses, this buffer becomes the ready buffer and the other buffer will be in charge of recording data for the next 5 stable pulses. This guarantees that 5 successive stable pulses are recorded and the recorded data are up to date.

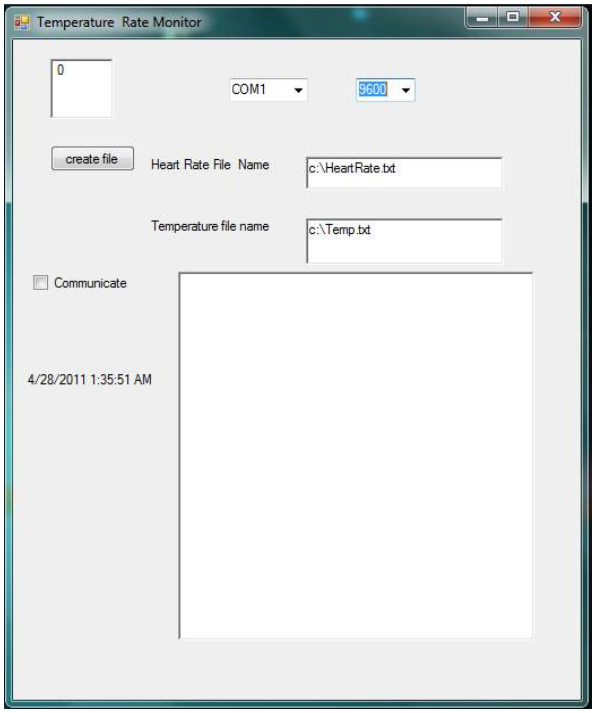
The data sampling of the heart wave needs to be accurate. Data points must be sampled at 5ms intervals to ensure correct calculation. Since interrupts have highest priority in a real time system, the sampling of data is controlled by the ISR. Timer 0 is used for the interrupt and the ISR is called every 1ms. In the 5ms interval, 2 milliseconds are assigned to the ADC conversion of the heart wave and the rest 3 milliseconds are assigned to the ADC conversion of the temperature. So at the end of the first two milliseconds, the ADC result is taken as a data point for the heart wave and the ISR signals task 2 to run. Then the ADC channel is switched and the conversion of temperature starts. At the end of the last 3 milliseconds, the ADC result is taken as a data point for the temperature. Then ADC channel is switched back and another conversion of the heart wave starts. In this way, both heart rate sensing and temperature sensing go well and the data points for the heart wave are sampled at 5ms intervals accurately.

3.2 Data Logger Software

As required a data logger program can be created to attempt to log the data periodically. The design theory behind its creation can be stated as:

3.2.1 Program Overview

The data-logger has several fields. Both the temperature and the heart rate have to be saved in different files. In the text box where it says heart Rate File Name, one has to enter the appropriate location of the heart rate file. The same is true of the temperature file name. The Com port field allows one to choose from 9 COM ports. And the baud rate field allows one to choose from the following baud rates: 9600, 2400, 4800, 9600, 19200, 38400. Once one has selected the baud rates, the com port and the file locations and names, one has to click communicate in order to activate the communication.



3.2.2 Code description

A quick description about how windows operating system works is necessary in order to explain how the code was written. Windows operating system is very much based on the idea of an interrupt event driven operating system. It has these things called event handlers. For example when you click, the communicate check box, windows will call the following event handler in your visual basic code

Private Sub cbCommunicate_CheckedChanged (ByVal sender As System.Object, ByVal e As System.EventArgs) Handles cbCommunicate. CheckedChanged

So when the status of the check box changes (which happens whenever the user clicks on the checkbox), the event handler will get called. Once this event handler gets called, the code will check to see if the box is checked or not. If the box is checked, it will disable the com port box, the baud rate box and the file name boxes. The code also enables the timer if the box is checked. However, if the box is unchecked, all of this is undone.
Once the timer is enabled, the event

Private Sub Timer1_Tick1(ByVal sender As Object, ByVal e As System.EventArgs) Handles Timer1.Tick
Dim heartRate As String

is called once every 15 milliseconds. Basically what happens in this events is that the Serial Port is opened. Next by using the write (String message) function in the serial port object that comes as one of the VB.NET libraries, we send the MCU a request for the heart rate using the string "H\r\n" or a request for the temperature using the string "T\r\n". When such a request is sent out, the program then waits until a byte is received in the serial port buffer. Whenever this happens, another event called

Private Sub serialPort_DataReceived(ByVal sender As Object, ByVal e As System.IO.Ports.SerialDataReceivedEventArgs) Handles serialPort.DataReceived

is called. Whenever this gets called, we use the ReadExisting() function in the serial Port library, to store both the current heart rate and the current temperature in two global variables. Since we are expecting the heart rate and the temperature to be received from the data-logger, this event Handler also ends up closing the serial port after the temperature is received in order to allow the Web-Server to access the com port whenever it needs to. In order to differentiate between the temperature and the heart rate, the event handler has a static variable that keeps track of the number of times the event is called. Every even number of times the event is called, the software assumes that the heart rate is received from the MCU. Every odd number of times this event gets called, the data that is received will be the temperature. The reason why we can make this assumption is because the data logger is always sending out both requests for the heart rate and the temperature one right after the other, and when the MCU sends the data, this event gets called once for the temperature and once for the heart rate. Next, this event handler will store the temperature and the heart rate in their corresponding files. But before it can do this, it will of course have to open it. Please note that since two programs cannot access the same file at once, the program will wait until the files are accessible in order to access them. Once the data has been written to the appropriate files, the data logger will then close the files so as to give access to the web-server.

3.3. MCU Programming Software

In order to program the micro-controller as per our requirements to set its ports, a micro-controller programming software is required. A simple software that can be used for such a programming is Code Vision AVR (CVAVR).

CVAVR is a C-program language compiler which is used to program the micro-controller. CVAVR is a highly versatile software which offers “High Performance ANSI C Compiler, Integrated Development Environment, Automatic Program Generator and In-System Programmer for the Atmel AVR family of micro-controllers.

4 IMPLEMENTATION

4.1 Measurement Circuit

4.1.1Temperature measurement

Temperature measurement in this design is done by LM35 temperature transducer. This semiconductor based temperature transducer has got three terminals. One terminal is the ground. Other is the +Vs which should be from 4V to 20V. The third terminal gives us output voltage proportional to temperature with 10mV/ ºC. The output pin of this device

is connected to channel of ADC of the micro-controller.

4.1.2Heart Rate / Pulse Rate Detection

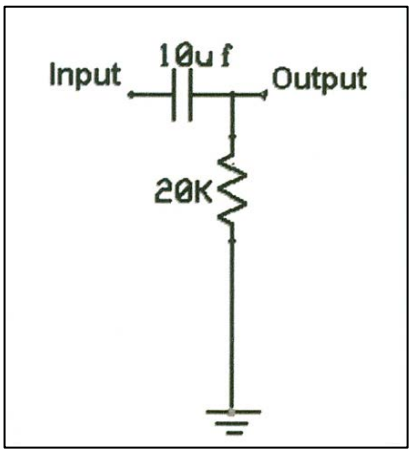
Heart rate or pulse rate detection can be done by a technique known as **Plethysmography**. Plethysmography is a non-invasive technique of measuring blood flow in the human body. In this method, a part of human body is which is under consideration, is illuminated by an Infra-Red light generating source such as Infra-Red LED. As the blood volume inside the organ pulsates due to variation in blood pressure, the IR rays reflected from and transmitted through the organ pulsates. This pulsation can be converted into electrical signals using an IR phototransistor.

As the blood volume changes in the arteries of organs due to varying blood pressure whose frequency of variation is same as that of heart beat, by detecting the variation of reflected and transmitted IR rays using photo-transistor, the Heart rate/Pulse rate can be deduced. In the design of this project, finger Plethysmography can be used. Hence finger of the concerned person, which may be a miner in our case can be used to detect the heart rate / pulse rate using this method.

4.1.3Filtering and Amplifying

The signal extracted from the finger using IR sensor needs to be filtered and amplified first to make it suitable for interpretation use. For this two stage band pass filters are used. Each band pass filter consists of a passive high pass filter (HPF), and an active low pass filter (LPF). This active low pass filter provides us with suitable amplification in our signal.

High Pass Filter (HPF) – The high pass filter we can use, is having a single pole RC circuit as shown below. This is a passive HPF.



As this contains a capacitor in between input and output so it blocks dc signal. Further the capacitance offer high impedance to the low frequency signal and vice – versa thus implementing high pass characteristics. The cut-off frequency is given as:

$f = 1/2\pi RC$

Where R = Resistance of Circuit
C = Capacitance of Circuit

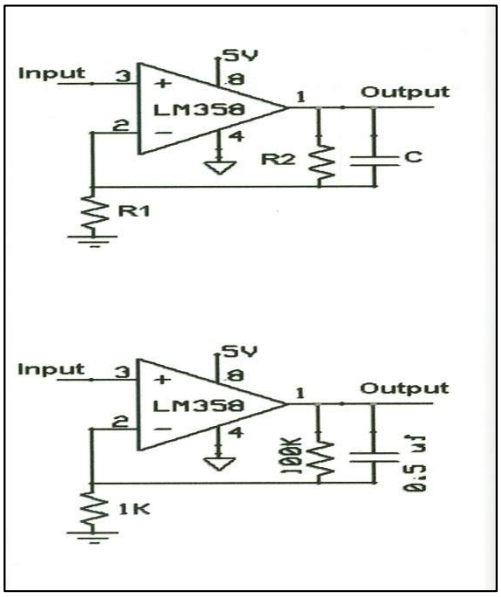
Here R = 20K, C = 10μF

Hence f = 0.8 Hz

Low Pass Filter (LPF)

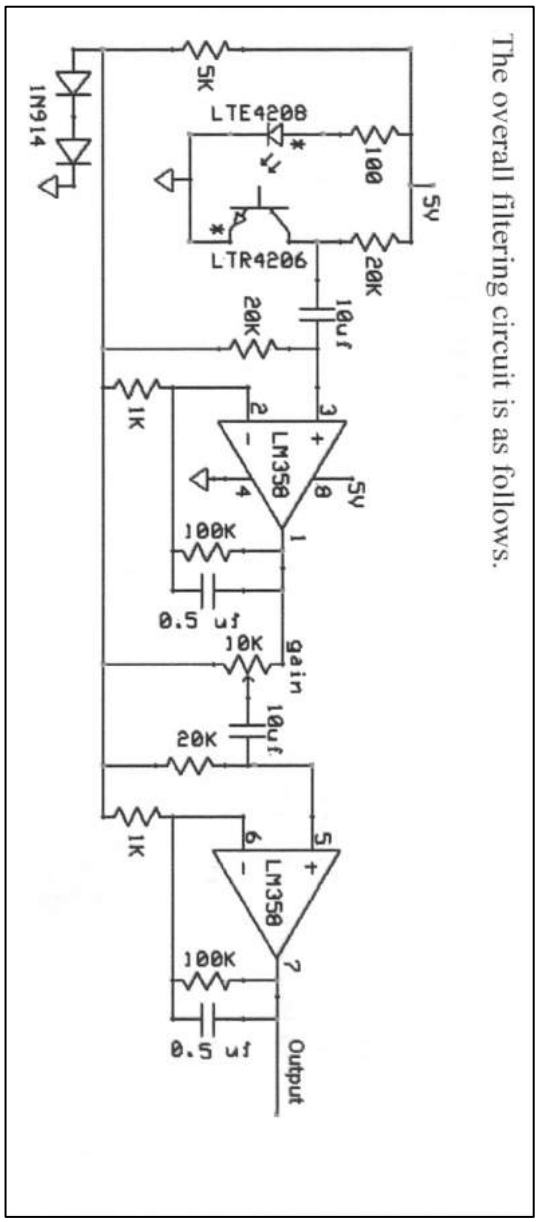
The low pass filter which can be used in this project is non-inverting OpAmp based active low pass filter.

It consists of two resistors of 1K & 100K values, which gives a non-inverting dc gain of 1+R2/R1. The capacitor C is used to make it low pass filter with cut-off frequency $f = 1/2\pi CR2$.



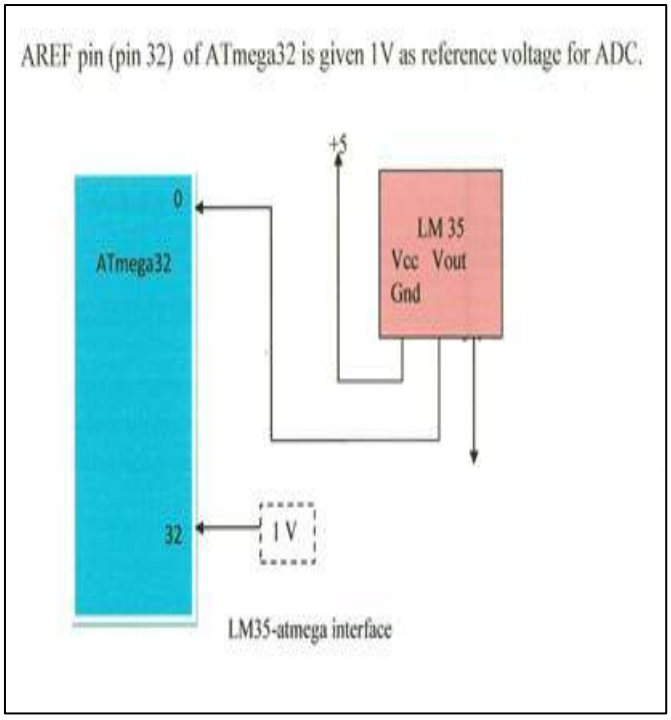
Shown above is the actual circuit with the values of capacitance and resistances. It's non-inverting dc gain is 101 and it's cut-off frequency is 3.18 Hz.

The overall filtering circuit is as follows:



4.2 XBEE – ATmega Interface

This interface will be on the portable terminal side, where slave XBEE should be connected to ATmega32 micro-controller. This interface is designed using UART of the ATmega32. Pin 14 can be the RXD (Receiving) pin of micro-controller which is to be connected to pin 2, the D_{OUT} pin of the Zigbee. Pin 15 i.e. TXD (Transmission) pin is connected to pin 3 of the Zigbee i.e. D_{IN} pin. As both the ICs have CMOS level logic, they can be directly connected.

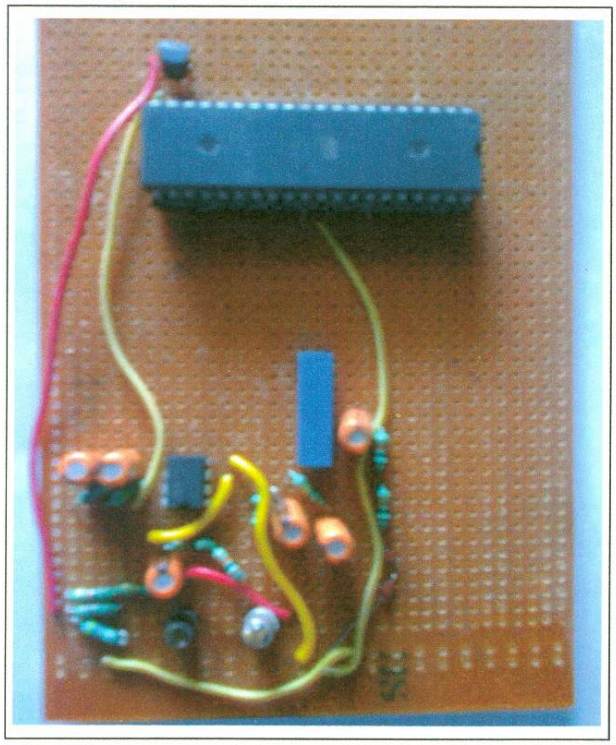


4.3 LM35 – ATmega Interface

As LM35 is a 3 pin device which gives voltage as output corresponding to the temperature in its surrounding, the output pin of LM35 is connected to ADC pin(pin A.0) on the micro-controller. Pin 32 of ATmega32 is given 1V as reference voltage for ADC.

4.4 The Portable Terminal Realization

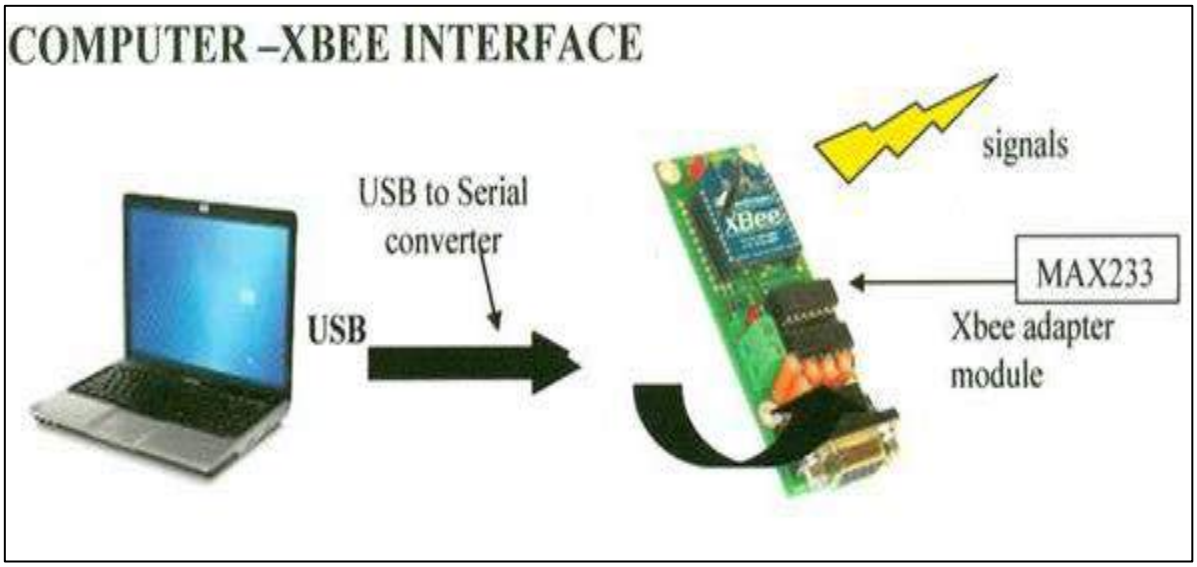
This terminal consists of the two measurement circuits, i.e. the pulse rate detection circuit and the temperature measurement, the micro-controller board and the RF Transmitter Zigbee module. The pulse rate measurement circuit is realized on a General Purpose board and the output is connected to ADC of the Micro-controller unit. Similarly the output of temperature measurement circuit is also given to ADC of the micro-controller unit. The Micro-controller converts the signal into digital form and the values as according to the micro-controller program are transferred to the Zigbee transmitter module. Zigbee transmits these values wirelessly to the server terminal. The manually realized portable terminal can be seen as below:



In this part a Biometrics based Identification and storage system can be attached which according to the identity of a concerned person saves the desired body parameters in his/her name in the memory, from where it gets transferred to the server terminal and gets saved with specific file name and format.

4.5 The Server Terminal Realization

The server terminal consist of Zigbee RF receiver module with a MAX233 level shifter. Zigbee module receives the data sent by zigbee transmitter. This zigbee module is connected to server through a COM port directly or through a COM to USB converter via MAX233. The data received is converted to the required specific format and gets saved as files in a specific folder in the system from where the data can be accessed as and when required.



5 CONCLUSION

To conclude, we can say that by this method of designing a Wireless Health Monitoring System for Miners we can implement a cheap, portable and easy to use system. The use can be as simple as installing the portable terminal part at the entrance gate of Mining areas. Each and every personnel involved in the mining activities in that particular area may get themselves registered in the Medical Incharge's office and by providing personal details, medical history and biometrics. The same may be updated in the server and the memory of portable terminal. As soon as the person gives his biometrics by giving thumb impression (or any other method suitable) on the biometrics system attached to the portable terminal, all the body parameters taken by the portable terminal will be transferred to the server and get saved in a designated for him. Thus it will be very easy for doctors to check periodically required body parameters of concerned person periodically. This has special importance for people who are prone to cardiac problems.

For Primary objective, measurement of only two important body parameters is explained here. Further enhancement can be

done as and when required to fulfill the need of Medical Officers and the patients accordingly.

Risk Assessment and Management in Mining

A Comparison: Empirical Methods or Artificial Neural Network for Peak Particle Velocity prediction in DOZ Underground Mine

S. Prahastudhi, E. Riyanto, D. Napitupulu
Microseismic Section – UG Geotech & Hydrology, Geoservices DivisionPT Freeport Indonesia, Papua – Indonesia

ABSTRACT Artificial neural network is an algorithm for data pattern recognition analysis which is basically similar with the human neural system. The application of neural network has been widely used in all of kind of studies, such as economics, earth science, medic and etc. In a case of underground mine, blasting operation is one of the most important part in the mine production and operation, then, a study regarding blasting operation and its impact in the underground mine environment, such as pillar/tunnel stability is a must. One of the blasting impacts that can be quantified is the peak particle velocity (PPV, unit mm/s). There are many ways to forecast the peak particle velocity, most of them are using empirical equation which is derived from data samples and laboratory scale analysis and it also produce a linear relation between the blasting component (such as charging and distance) and the peak particle velocity. Using artificial neural network, the data pattern of blasting operation and the resulting peak particle velocity can be analysed, then, it can be used as peak particle velocity prediction. Supervised neural network, with one hidden layer and two inputs is the neural architecture which is used in this research. The blasting monitoring data was collected during August until December 2013 in the Deep Ore Zone (DOZ) mine. Compared with another empirical method, USBM (United States Bureau of Mine, Langeford-Kihlstrom and Ambreseys Hendron, artificial neural network has the best correlation coefficient.

Keywords: Neural network, particle velocity, blasting

1 INTRODUCTION

In the underground mine, blasting operation is one of the most important part in the production process. The safety factor and the impact of the blasting is another concern beside the production target. One of the quantified parameter which can describe the blasting impact in the underground mine is peak particle velocity (PPV, unit mm/s). Peak Particle Velocity is defined as the highest speed at which individual earth particle moves or vibrates as the waves pass a particular sites (Kujur, 2010). To come out with proper amounts of maximum charging per delay (explosive) which produces limited ground vibration, several equation are available, such as Ambreseys-Hendron, USBM and Langeford-Kihlstrom (Alipour et all, 2012). According to the existing empirical predictors equations, the PPV is function of distance and maximum charging per delay (Rai et all, 2005). Use these empirical equations. Rai et all (2005) showed that using the empirical predictors, the very accurate value of charge per delay will not be obtained.

Neural network have emerge in the last decade as a promising computing technique which enable computer system to exhibit some of the desirable brain properties. Various types of networks have been applied successfully in a variety of scientific and technological fields. Examples are application in industrial process modelling and control, ecological and biological modelling, sociological and economical sciences, as well as medicine (Kavli, 1992). Within the exploration and production world, neural network technology is now being applied to geological analysis (Doveton, 1994) and seismic attribute analysis (Schultz, 1994).

Neural network research started in forties. McCulloh and Pitts (1943) describe the logical function of a biological neuron. They describe that the transmission of the neuron signal is an all-or-nothing situation. A neuron fires only if the cell has been stimulated above a certain threshold. The output signal will, in general, have constant length. McCulloh and Pitts describe that network consisting of many neurons might be used to develop the universal Turing Machine (a kind of computer described by Turing (1937) that could solve all mathematical problems.

In recent years, the neural network application has emerged as a powerful tool for analyzing of rock engineering problems. Several studies have recently been proposed to predict the environmental effects of blasting in terms of peak particle velocity on the basis of artificial intelligence (Alipour et al, 2012). As an artificial intelligence method, the sigmoid function of neural network had an ability to calculate the non-linear relationship between input and the output data. In this research, we compared the ability of empirical equations and neural network to predict the peak particle velocity produced by blasting operation in the underground gold mine in DOZ (Deep Ore Zone) mine, Papua, Indonesia.

2 SITE DESCRIPTIONS

Generally, the geological condition in the DOZ mine is in the infiltration zone. Those area located in the edge of the subduction zone between Australian and Indo-Pacific plates. The result of the infiltration make the sediment rock above the plates (carbonate) upraised then the magma intrusion was filling the edges of the plates. Those intrusions resulted a complex system of igneous rock which is had intermediate (dioritic) composition. Finally this geological process creates a complex mineralization (skarn).

The DOZ ore deposit is a part of the Ertsberg East Skarn System which is include in the carbonate tersier altered with silicate calcium-magnesium. Ertsberg East Skarn System (ESSS) is a vertical deposit with reach 1200m high and the length of the strike is more than 1000m and the average wide is 2000m. Several deposit which is occur in the DOZ mine are diorite, dolomite marble, calcite marble, limestone and skarn (forsterite skarn, forsterite magnetite skarn and magnetit skarn).

3 THEORIES AND METHOD

3.1 Empirical Predictor

In the prediction of the peak particle velocity, there are several equations which usually used. They are, USBM, Langeford-Kihlstorm and Ambreseys-Hendron. USBM assume the cylindrical charges. They conclude that any linear dimension should be scaled with the square root of the explosive charge weight based on dimensional analysis (Kujur, 2010). The equation proposed by USBM is:

$$v = K\left[\frac{R}{\sqrt{Q}}\right]^{-B} \qquad [1]$$

Any other empirical predictor is Langefors and Kihlstorm predictor (1963). They proposed the following relationship for various charging levels to estimate the peak particle velocity. The equation is:

$$v = K\left[\frac{\sqrt{Q}}{R^{2/3}}\right]^{B} \qquad [2]$$

In 1968, Ambreseys-Hendron are also derived an empirical equation to predict peak particle velocity. If the USBM investigator suggested that any linear dimension should be scaled the cubic root of the explosive charge weight for spherical geometry. An inverse power law was suggested to related amplitude of seismic waves and scaled distance to obtain the following relationship:

$$v = K\left[\frac{R}{Q^{1/3}}\right]^{-B} \qquad [3]$$

Where,
V: peak particle velocity (mm/s)

R: distance between blast face and monitoring point/sensor (m)
Q: maximum explosive charge used per delay (kg), and
K, B: site constant which can be determined by multiple regression analysis.

3.2 Artificial Neural Network

The artificial neural network divided into two major types, supervised and unsupervised. The different between them is that the supervised neural network need the data result from measurement to supervise the network training.

Back propagation neural network is one of supervised neural network type. It has an input, output and in the most application, have one hidden layer (Sutrisno et al, 2013). The number of inputs and outputs of the neural networks are determined by considering the characteristic of the application. In most of the cases, one hidden layer is satisfactory (Saemi, 2007).

Each neuron of a layer is generally connected to the neurons in the proceeding layer. Repeating forward-propagation and backward propagating steps performs the required learning. When a pattern is given to the input pattern, the forward propagation step begins. The activation levels are calculated and the results are propagated forward through the following hidden layers until reach the output layer. Every processing unit sums its respective inputs and then applies a function to compute its output. Sigmoid is the most commonly used function (Bean and Jutten, 2000).

The algorithm of multilayer perceptron neural network with back propagation type consist of three layers, there are input layer, hidden layer and output layer. Input layer and hidden layer associated with “X”, as a weighting. This process started from inputting the parameter in input layer. Activation levels are calculated and the results are sent through the hidden layer until it reaches the output layer. Each processing unit summing each input is the used to calculate a sigmoid function output (Saemi, 2007).

Sigmoid function is used in neural network with interval output value between 0 and 1 is a binary sigmoid function which is defined as

$$y = f(x) = \frac{1}{1 + e^{-x}} \qquad [4]$$

Backward propagation phase starting from the output layer, re-input layer through hidden layer. Various networks are trained by minimization of an appropriate error function defined with respect to the training set. Performance of the networks is then compared by evaluating the error function using the training validation set, and the network which have the smallest error with respect to the training validation set is selected (Niculescu, 2003).

The difference error of this result is given by:

$$\text{Error} = \frac{\sum_{i=1}(O_i - T_i)^2}{n} \qquad [5]$$

Where,

O: expected output (target)

Q: output of the forward propagation

n: total calculated data

4 APPLICATIONS

DOZ mine, is a kind of underground mine with block caving type which is operated by PT Freeport Indonesia and it located in the Papua island. Due to block caving operation (production), there were so many blasting perform in this mine, more precisely in the undercut level.

During August 2013 to December 2013, the blasting data was compiled for this research. The data consists of peak particle velocity (PPV) in mm/s unit, distance in m unit and charge/delay in kg unit. Based on the empirical relation (USBM, Langefors and Kihlstorm, Ambreseys-Hendron), the data can be used to determine the ability of those empirical relation to predict the peak particle velocity using equation 1, 2, 3.

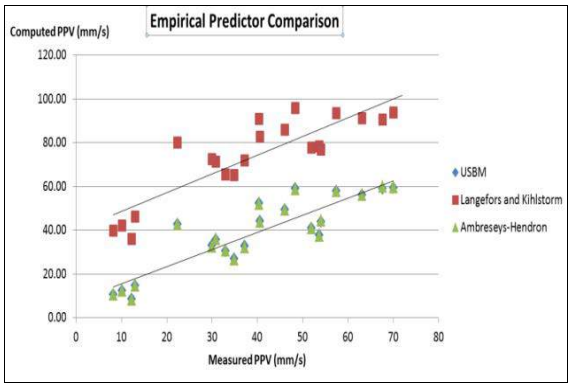

Figure1. Empirical predictor comparison for PPV prediction

The result shows that the correlation coefficient (R) for USBM is 0.7802, Langefors and Kihlstrom 0.7465 and 0.7848 for Ambreseys-Hendron. Then, the Ambreseys-Hendron has the best correlation coefficient value among those other empirical predictors.

A back propagation neural network method has been performed to analyze the blasting data to make a forecasting method. The neural architecture that used in this research is multilayer perceptron with 2 inputs and one hidden layer, the hidden layer consist of 3 nodes.

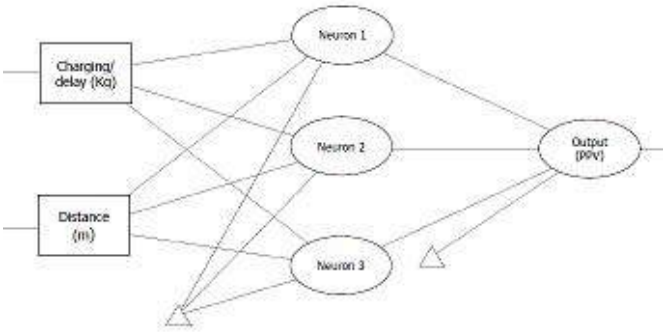

Figure2. Neural Architecture

The charging per delay (Q) and distance between blast point and sensors (r) are become the input that fill the input nodes, and the PPV fill the output layer. Sigmoid binary function has been used as the transfer function in both connected layer (input to hidden layer and hidden layer to output).

To make the iteration faster, data normalization must be perform in the input data. The charge per delay had been conditioned into tons unit. Then, the data divide into two types with proportion 60% for train data and 40% for test data.

An optimized in neural network called momentum has been used to prevent the significant change in the weights due to back propagation process. With the additional momentums the new weight at (T+1), based on the weight at (T) and (T-1).

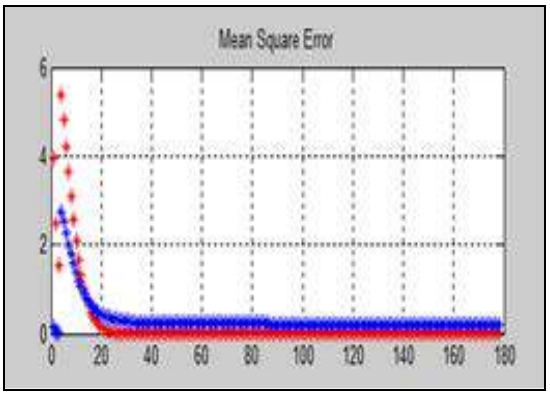

Figure3. Iteration in the back propagation process, the red line indicated the test data and the blue line indicate the train data.

From the figure above (figure 3), we can see that the system reach the convergence function after iterated 20 times.

The iteration result shows that train and test data have correlation coefficient 0.89, which is better than any other empirical relation, in this case is Ambreseys-Hendron, USBM and Langefors-Kihlstorm.

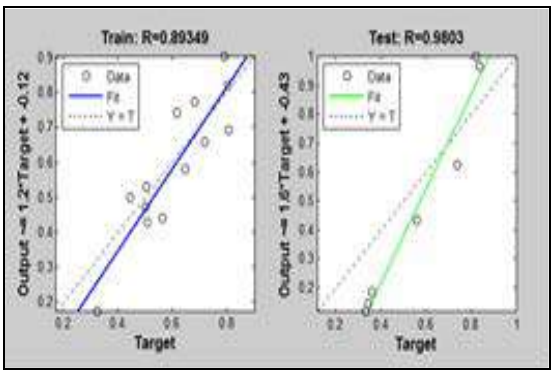

Figure4. The correlation coefficien of the neural network prediction and the real data

5 CONCLUSIONS

Compared with the empirical methods (Ambreseys-Hendron, USBM and Langefors-Kihlstrom), supervised back propagation neural network have a better correlation coefficient to predict the peak

particle velocity from blasting operation in an underground mine. The advantage of using neural network that it can recognize the pattern of the blasting data and accommodate the nonlinear relation between charging per delay, distance and the peak particle velocity which is the empirical relation cannot be done because their linear relation.

Future research by adding another parameters such the influence of ground support, tunnel geometry and any other discipline must be included so it can be compared with the damage classification in underground mine

S. Özdemir
Department of Environmental Engineering, Sakarya University, 54187, Sakarya, Turkey,

ABSTRACT Every scale of mining activities have huge impact to environment. Monitoring and assessing of the size of the effect and take measure is vital. In this present study risk assessment studies in mining areas and their effect to especially groundwater and ecosystem was investigated. Risk assessment steps were determined, explained detailed especially for huge amount of mining wastewater. Tailings are fine-grained waste material from the mining industry and main source of pollutant. Pollution risks of the groundwater, and after its reaching to human are crucial. Our study showed that management of mining wastewater is vital. Results show that Environmental impact assessment and monitoring studies must be carefully done before and closure time. Relevant policies must be ready and applicable. Factors of climate, geology and human health must be considered for long time period. International assumption, standards and health risk assessments should be done as mandatory.

Keywords: Risk assessment, mining wastewater, pollution risk

1 INTRODUCTION

Mining operations and the pollutant sources of concern can affect water (surface and groundwater) quality in terms of many parameters, create hydrologic impacts, decrease air quality, contaminate soils, and diminish ecosystem quality. The major categories of environmental problems arised from mining are water pollution and its reaching to human (EPA, 1997; Celebi and Özdemir 2014).

Mining industry is one of the emerging sectors in the world. For instance in Turkey, only overall 2011 gold production is expected to reach 25 mt/y, compared to 17 mt/y in 2010. In the long-term, analysts expect it to stabilize around 60 mt/y. But preparing the mining waste policy and applications can acceptable quite new in Turkey (GBR, 2012).

Tailings are fine-grained waste material from the mining industry, contain all other constituents of the ore but the extracted metal, among them heavy metals and other toxic substances. Moreover, the tailings also contain chemicals added during the milling process (Ganesh, 2006). The quality of the drainage is, nevertheless, controlled by a series of mineralogical and geochemical reactions in the waste area, and the outcome of these reactions is reflected in the seepage waters surfacing through tailings dams (Blowes, 2003; Lottermoser 2007; Heikkinen, 2009). The seepage quality additionally changes due to precipitation and dilution during transport to the receiving water body (Chapman, 1983; Räisänen, 2005). The leak to groundwater during mining operation and even after the closure period is typical huge environmental risk factor.

Abandoned mine sites also generate chronic environmental hazards. Contaminated runoff from abandoned mines impacts land, groundwater, streams, rivers,

and lakes. Principal environmental pollutants from abandoned mines are arsenic, lead, and other heavy metals associated with acid rock drainage. The degree of potential contamination depends on many factors which the commodity being mined (gold, copper, chromium, etc.), mining methods, ore processing methods and disposal methods. Other contaminants can include chemicals used to process ore and fuel, lubricants, and solvents used to operate and maintain equipment (The Sierra Fund, 2008).

Main objective of the present study is to attract and show best mining management issues in the mining operation and how size potential risks are in the mining areas to water and water related pollution.

2 GROUNDWATER POLLUTION RISK IN MINING AREAS

Groundwater is vital part of ecosystem and also direct or indirect effective to human. İts contamination is extremely difficult to remedy if we compare with surface water, once it occurs makes it a serious concern. Mining operations may affect groundwater quality in many ways. The most obvious occurs in mining below the water table, either in underground workings or open pits. This provides a direct conduit to aquifers. Groundwater quality is also affected when waters (natural or process waters or wastewaters) infiltrate through surface materials (including overlying wastes or other material) into groundwater. Contamination may also occur when there is a hydraulic connection between surface and groundwater. Any of these could cause elevated pollutant levels and contamination in groundwater. Further, disturbance in the groundwater flow regime can affect the quantities of water available for other local uses. Eventually, the groundwater may recharge surface water down gradient of the mine, through contributions to base flow in a stream channel or springs.

Figure 1. The seepage water points at showing the upper area at the toe of the upper section of a dam (Heikkinen, 2009).

The ability of pollutants to dissolve and migrate from materials to groundwater varies significantly depending on the constituent of concern, the nature of the material/waste, the design of the management, soil characteristics and local hydrogeology (including depth, flows, and geochemistry of the underlying aquifers). An example of mining area is showing on Figure 2. Risks to human health and the environment from contaminated groundwater usage vary with the types and distance to local people. Besides, impacts on groundwater may also indirectly affect surface water quality (through recharge and/or seepage) (EPA, 1997). Sustainable groundwater management is vital. The Dutch Intervention Value for groundwater is based on the serious risk level for humans and the ecosystem, including direct consumption of groundwater as drinking water. The value is a trigger for further investigation and a decision about the urgency for remediation of historical groundwater contamination (Lijzen et al., 2014).

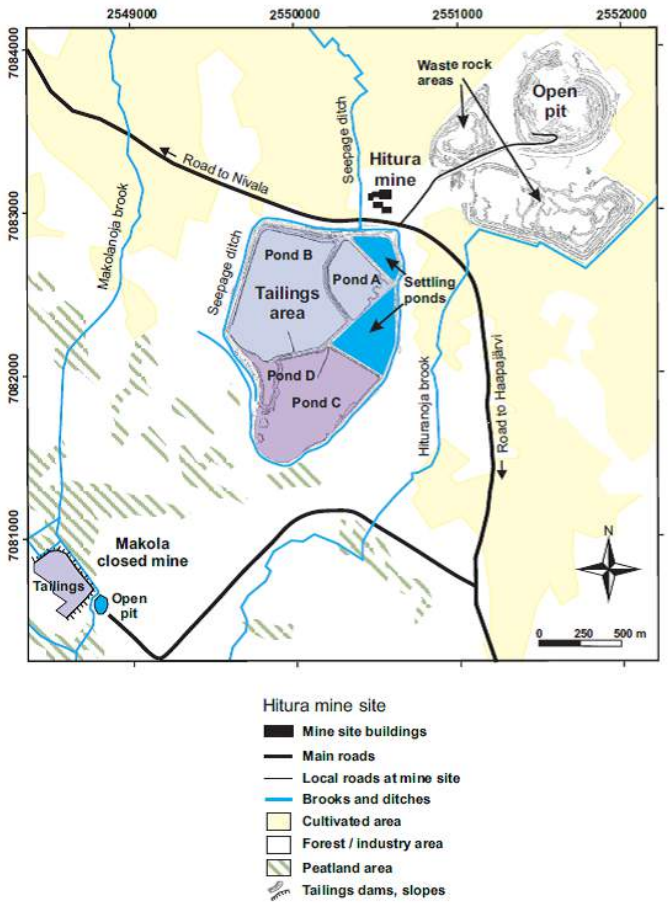

Fig. 2. Overall setting of the Hitura mine and the tailings area in Finland (Heikkinen 2009).

Recent studies revealed about mining area groundwater contamination. It is used to characterize pollutant sources and to quantify the resulting current and future effects on both groundwater and river water quality in a study in many location and Germany as well. The reactive transport simulations illustrate the long-term fate of sulfate from the mining dumps into groundwater and from groundwater into surface water. The simulations indicated that groundwater borne diffuse input of sulfate into the rivers is 2200 t/years and could increase till 11000t/years in the next 40 years. The results for the River compare well with the observed increase of sulfate concentrations before and after passing the mining area (Graupner et al. 2014). Arsenic is a common constituent in groundwater that affects human health adversely at levels as low as 10 lg/L (WHO, 1993; Bhattacharya, 2002). In a mine area of western Turkey, arsenic showed high spatial variation ranged from 33 to 911 lg/L in the groundwater samples. Arsenic concentration values increased close to the mines, reaching 305 lg/L and decreased to the south of the study area (Gemici et al., 2008). A wide variety of adverse health effects, including skin and internal cancers and cardiovascular and neurological effects, has been attributed to chronic as exposure, primarily from drinking water (NRC, 1999).

3 ASSESSMENTS OF ENVIRONMENTAL EFFECTS AND ECOLOGICAL RISK FOR MINING ACTIVITIES

Mining causes land disturbances naturally. These disturbances affect aquatic resources, wildlife, and vegetation and can lead to habitat destruction. Surface mining activities directly destroy habitat as a result of removal of overburden to expose ore bodies, deposition of waste and other materials on the ground, surface the construction of roads, buildings and other facilities.

Two major types of impacts on aquatic resources occur in mining operation and aquatic life. The first type of impact results from the contribution of eroded soil and material to water bodies and from the release of pollutants from ore, waste rock or other sources. The second results from the direct disruption of ephemeral, intermittent perennial streams, wetlands or other water bodies. Disruptions occur from road construction and similar activities. Permanent impacts are caused by actual mining of the area or by placement of refuse, tailings or waste rock directly in the drainage way. In addition, lowering of area surface water and groundwater caused by mine dewatering could affect sensitive environments and associated aquatic life. The impacts of mining operations on aquatic resources can be also beneficial. Potential impacts also vary significantly with the affected biota. For example, increases in

stream flow may preclude habitation of certain species of fauna and/or flora but may also provide new habitat for other species of aquatic life. Mining negative effects are also visible. A good example of visible effect to environment are shown Figure 3.

Figure 3. An open pit of copper mining area in Romania (VQR, 2012)

The impacts of mines on aquatic resources have been well documented. Mineral Creek fisheries and habitat survey conducted by the Arizona Game & Fish and the U.S. Fish & Wildlife Service showed that significant damage was caused by an active mining activity on the shores of Mineral Creek. The upstream control station showed an overhead cover (undercut bank, vegetation, etc.) of 50% to 75%. The dominant substrate was small gravel and in stream cover consisted of aquatic vegetation. Five species of fish were observed for a total of 309 individual fish. In another side, the downstream station showed an overhead cover of less than 25%. The dominant substrate was small boulders and in stream cover consisted of only interstitial spaces and very little aquatic vegetation. No species of fish and very few aquatic insects were observed or captured. This Mineral Creek survey proves a significant degradation of habitat below the mine. In another study and area, which received a massive discharge of tailings and pregnant leach solution from an active copper mine, was also surveyed (EPA, 1994 and 1997). The tailings had a smothering, scouring effect on the stream (Kauppila et al. 2011).

Mining operations can have substantial impacts on terrestrial wildlife, ranging from temporary noise disturbances to destruction of food resources and breeding habitat. Unless closure and reclamation return the land essentially to its pre-mining state, certain impacts to some individuals or species will be permanent. Biological diversity is often viewed as a way to measure the health of an ecosystem. Noise during the construction phase or during operations, for example, can displace local wildlife populations from otherwise undisturbed areas surrounding the site. Some individuals or species may rapidly acclimate to such disturbances and return while others may return during less disruptive operational activities. Still other individuals may be displaced for the life of the project. Other wildlife impacts include habitat loss, degradation or alteration. Wildlife may be displaced into poorer quality habitat and therefore may experience a decrease in productivity or other adverse impact. Habitat loss may be temporary (e.g., construction-related impacts), long-term (e.g., over the life of a mine), or essentially permanent. Vegetation strongly related to the diversity of wildlife. All vegetation is removed before and during mine development and operation in the area. Vegetation immediately adjacent could be affected by the roads, water diversions or other development. Vegetation further removed from activities may be affected by sediment carried by overland flow and by fugitive dust (EPA, 1997).

West African rainforest birds were observed most strongly affected by adjacent mining whether the mining was immediately adjacent or >500m away, irrespective of distance to forest edge in Ghana. Even no

additional forest loss, increased surface mining is likely to result in declines of forest birds (Deikumah et al., 2014).

In general, risk management tools are not designed specifically for the mining industry. They are usually borrowed from other areas such as the nuclear, petrochemical or construction industries or from military structures. Risk management practices, standards, tools and approaches used both in the mining industry and in other industrial sectors. Catalogued risk evaluation standards and guides (e.g. ANSI/AAMI/ISO 14971: 2000; ISO-17776: 2000 and DOE-DP-STD-3023-98: 1998) and risk analysis techniques (e.g. NASA: 2002 and DOE Guidelines: 1992) Komljenovic & Kecojevic, 2007; Badri et al. 2013).

Risk assessment is important part of environmental protection issue and should apply latest standards for all mining operations. Basically we can use table x for pre assessment. Firstly we should Determine the consequences; the most probable consequence in terms of harm should an event occurs with existing risk controls. For example Catastrophic: Long term environmental damage (5 years or longer), Insignificant; Negligible environmental impact, managed within operating budgets. Secondly we should Determine the likelihood; the most probable likelihood of the determined consequence occurring. Almost certain Is expected to occur in most circumstances and has a history of occurrence, Once a year or more frequent; Rare: May occur only in exceptional circumstances, Once in 100 years or more. Then we can use the table for each identified hazard.

Table 1. Risk Matrix

Likelihood	**Consequences**				
	Catastrophic 1	Major 2	Moderate 3	Minor 4	Insignificant 5
Almost certain A	Extreme	Extreme	High	High	Medium
Likely B	Extreme	Extreme	High	Medium	Low
Possible C	Extreme	High	Medium	Medium	Low
Unlikely D	High	Medium	Medium	Low	Low
Rare E	High	Medium	Low	Low	Low

Environmental risk assessment studies are one of the risk assessment study and they are in same base. In Figure 4 showing a good example of Environmental risk management standard and the process with steps.

With respect to the overall framework in risk management (Figure 4), steps 1 to 3 above represent that first step (before risk assessment) is the 'establish the context' phase, step 2nd represents the Risk assessment (identify risks, analyses risks, evaluate risks) and step 3rd (after risk assessment) represents the 'treat the risks' phases.

ESTABLISH THE CONTEXT; All external, internal, risk management context along with clear evaluation criteria and descriptions must be prepared before the Risk Assessment step.

RISK ASSESSMENT*; Identify risks* involves the use of risk assessment "tools" appropriate for identifying potential loss scenarios associated with the Project. The tools consist of:

- Introduction – Before the potential issues are brainstormed, it is important that the whole team had a good understanding of the Project. This is confirmed by the facilitator.
- Brainstorming –Used to draw out the main issues using the understanding, relevant experience and knowledge of the team.

This session also use prompt words to build on the experience base of the team and identify any potential environmental issues and potential loss scenarios.

- Modified Hazard and Operability Analysis – This involve the review of key words drawn from the Project and aerial photographs and environmental issues at each location during each phase of operation (Stratford Coal 2012).

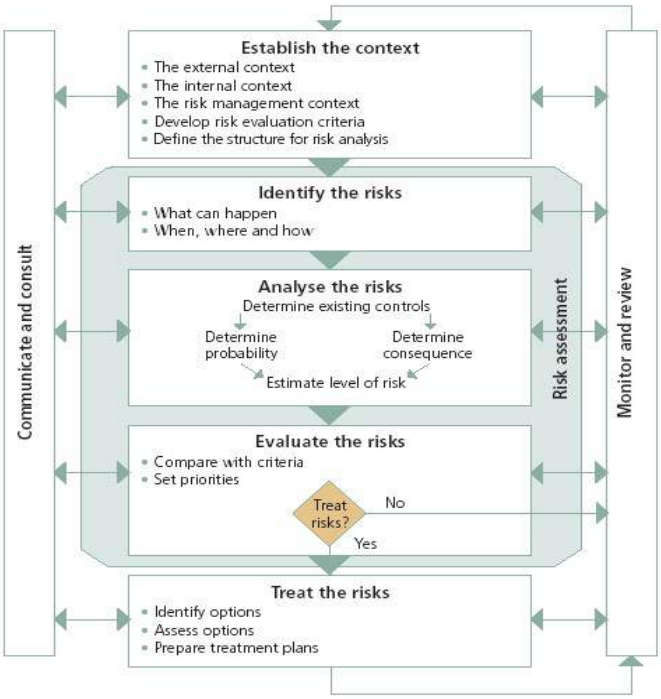

Figure 4. Risk Management Process (AS/NZS ISO 31000:2009)

Risk identification must be conducted at the level of the mining enterprise building. Besides, all the enterprise stakeholders should participate in this activity: employees, ecologists, and representatives of local, regional and national authorities (Buysse and Verbeke, 2003; Delmas and Toffel, 2004). Only such sustainable cooperation enables construction of complete risks. The selection of instruments of environmental and social risk assessment in all stages should include new conceptions according to a management paradigm (Kowalska, 2014).

4 CONCLUSION

Big environmental effects, especially disasters from mining areas are certainly preventable, barring unpredictable scenarios. Today's technologies are available to ensure safe containment of hazardous material. Environmental Risk Assessment studies should be done detailed for all size mining activity. This assessment should be done qualitative and quantitative as taking into account all necessary parameters and long time. Especially groundwater pollution should be monitored well and should not use as drinking water by local inhabitant people. Effect to ecosystem and natural life could be very negative, irreversible. Relatively small investments today can prevent future liabilities and environmental losses. Further researches about groundwater contamination and Environmental Risk Assessments are crucial for sustainable management of mining sites. Besides each large mining area may have specific conditions and they must be considered individually.

ABSTRACT In a 20 days continuous engagement (07/16 – 08/03 2014) a covered mine fire in the Kalın Damar seam, whose development 5.5 months lagged, could be extinguished by using a One Seven MINING 6000 machine and the Class A foam-concentrate AM. This system is capable to produce compressed air foam, also known as CAF. A total amount of about 91,000 m³ wet and dry foam was brought into the dammed fire area. The water consumption was 4,200 m³; the foam-concentrate consumption was 6,320 liters.

Finally, it was found that by use of the OS MINING 6000 and the foam-concentrate One Seven AM a fire area could be regained which had to be abandoned using the conventional method (nitrogen inerting).The equipment was recovered and the excavation of the Kalın Damar seam could be continued.

Keywords: Firefighting, One Seven MINING 6000, the Class A foam-concentrate AM, Amasya

1 HISTORY OF THE FIRE

The fire suffered in a geological fault area of the Kalın Damar seam on 02/05/2014 either as spontaneous combustion of coal or an over the shield column placed phenolic foam, in the goaf of the langwall face.

The fire escalated in the course of 02/08. There was a lot of smoke and an upcoming CO-production, at least the mining area was evacuated and dammed off. The gas values measured in the evening of 02/08 were: CO 115 ppm, CH4 0.70 %, O2 20.4 % and CO2 0.002 % at a ventilation rate of 500 m³/min. The gas values measured at the head gate dam were on 02/10: CO 665 ppm, CH4 1.38 %, O2 19.5 % and CO2 0.44 %. The fire obviously had been escalated further!

At 03/09 nitrogen inerting of the abandoned area was started. Within five days of inerting an extinguishing could not be achieved, the inerting was terminated on 03/16. The overall nitrogen consumption was 49,300 m³.

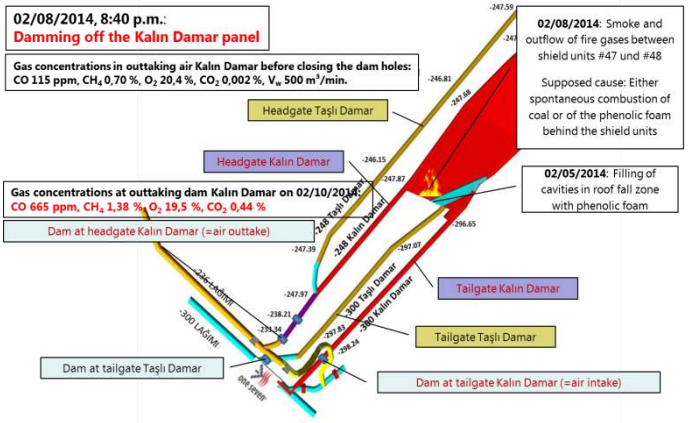

Figure 1. Amasra mine, southeastern working section

.

2 THE ONE SEVEN SYSTEM

2.1 Where Does the Name Come From?

By adding a special foam-concentrate and compressed gas (air or nitrogen) to the water, the volume of one drop of water expands into seven foam bubbles.

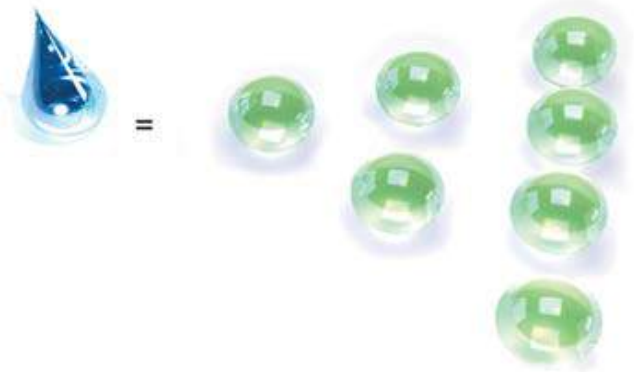

Figure 2. The seven times expansion of a water drop

At the end you get a CAF: Compressed Air Foam.

2.2 The MINING 6000 Machine and Its Properties

The MINING system was developed for use in mines with a ruggedized design for tough job. It´s an explosion proof system (ATEX I).The water and gas (air or nitrogen) has to be supplied by installations in the mine. The operational pressure for both is from 2 bar (29 psi) up to 10 bar (145 psi). The machine flows up to 6.000 l (1.585 gal US) of foam per minute.

Figure 3. The One Seven MINING 6000

The technical data are as follows:

- Dimensions (LxWxH): 2.550 x 990 x 1.420 mm
- Weight (dry): 1.550 kg
- Weight (operational): 1.750 kg
- Water consumption: max. 300 l/min @ min. 2 bar (29 psi) and max. 10 bar (145 psi)
- Gas consumption: max. 6.000 l/min @ min 2 bar (29 psi) (Nitrogen/Air) and max. 10 bar (145 psi)
- Foam-concentrate: One Seven® Foam Class AM (0.3%)
- Foam-concentrate tank: 150 l (build-in)
- Foam quality: free adjustable for firefighting (wet) to preventive (dry)
- Life-time of dry foam: about 5 h

The One Seven MINING system is usable for prevention as well as for firefighting!

3 STARTING THE MISSION

Because the matter is that the longwall face working is in the steep formation, the fire-fighting operations have been carried out in three phases:

Phase A: From 07/16 until 07/20 the tail gate gallery was backfilled with foam, which was also the intake airway at the

same time, to completely cut off the fire area of the air supply.

Phase B: After the machine´s removal to the head gate dam the fire area was completely inundated with foam over the head gate gallery from 07/20 until 08/02, so that…
Phase C: …from 08/03 the mine rescue brigade was able to penetrate under auxiliary ventilation and continuous carrying of foam into the fire area.

With our arrival at the mine site on 07/14 we got the first up-to-date information, the gas concentrations at the outtake dam at head gate Kalın Damar were:
CO 4-6 ppm, CO2 2,4 %, CH4 14-16 % und O2 11 %
This gas mixture becomes explosive at 17 % O2 and up!
Due to the fact that there was no pressurized nitrogen with 2 bar (minimum required pressure for the machine) available on mine site the machine was operated with compressed air.

On 07/15 the machine was placed in an old gate road of the Tavan Damar seam. There the coal mine has a parallel road to the head gate of the affected mining panel. From there two holes were drilled into the Kalın Damar goaf (= suspected hot spot), see figure 6. About these holes the foam should be placed from above onto the suspected source of fire. This test had to be terminated uncompleted due to the insufficient swallow capacity of the boreholes. Supposedly foaming of the head gate as the next step - thus with gravity - would certainly be most effective and would probably lead to fast success, but this wasn't debatable, because we were "up" on the return air side of the fire, and so that we were in toxic and explosive gases.

4 FIREFIGHTING WORKS

4.1 Phase A

The machine was situated about 60 m west of the tail gate dam (see figure 1, below left). It was connected via a hose line to the 75mm diam. pipe in the dam. With the beginning of the foaming works on 16th air samples were taken at the head gate dam Kalın Damar (outtaking air) every three hours and were evaluated in the laboratory. The graphic figures of trends in the concentrations of CO, CO2, CH4 and O2 during the operation are shown in figure 4. The foaming work was commenced with wet foam, later conversion to dry foam. Continuation of the foaming work until 07/20, at 0:00 a.m.: Opening the dams headgate Kalın Damar and tailgate Taşlı Damar while maintaining the foaming in the tail gate Kalın Damar. After about 20 minutes the CO-concentration at borehole #1 increased rapidly up to 80 ppm. A reignition had to be assumed, the fire hadn't been extinguished! In the morning hours of 07/21 the team leader decided to close the two dams again. During this works a pressure hose DN 75 was put through the dam at the head gate Kalın Damar to keep the opportunity open for foaming in this way.

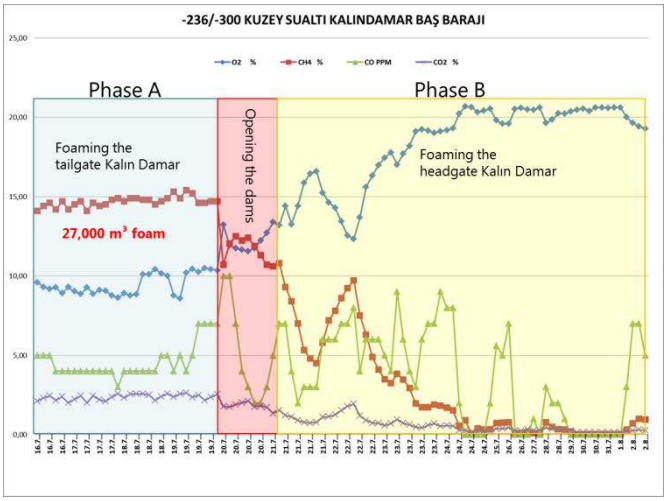

Figure 4. Gas development during phases A and B at outtaking dam Kalın Damar

Termination of phase A and begin of phase B. During phase A 27,000 m³ foam have been discharged into the tailgate.

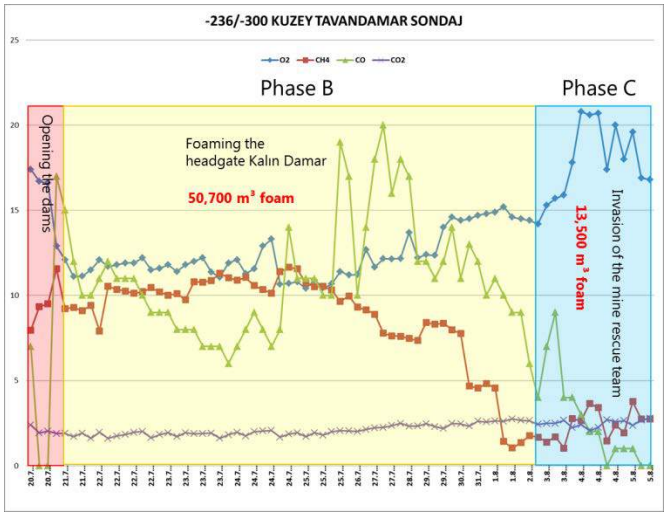

Figure 5. Gas development during phases B and C at borehole #2 in Tavan Damar

4.2 Phase B

With the beginning of Phase B on 07/20 – foaming the headgate – measurements of the gases CO, CO2, CH4 and O2 were carried out through the borehole #2 in Tavan Damar, the courses can be read in the graphic, figure 5. From 07/24 a measuring station was set at the tailgate dam in Kalın Damar (air intake!), for values see subsequent table 1. Parallel to the foaming through the headgate dam the borehole #1 in Tavan Damar was ready for foaming. Also here the foaming work was commenced with wet foam, later conversion to dry foam. On 08/02 end of phase B, newly opening the dams. During phase B 50,700 m³ foam have been discharged into the headgate and borehole #1. Begin of phase C.

4.3 Phase C

On 08/03 0:00 a.m. reopening of the head gate dam Kalin Damar while maintaining the foaming (dry foam), approach of the mine rescue brigade under auxiliary ventilation, see subsequent photo, fig. 7. Begin of phase C: Proceeding of the mine rescue brigade into the affected mining area encountering a heavy fall east of the junction headgates Kalın Damar and Taşlı Damar, see figure 6. This had to be worked over for further action. Beginning the removal of the heavy fall under auxiliary ventilation and under protection of the foam dam. After the workover of the heavy fall the crews went section by section in the direction of the longwall face, in which they placed repeatedly dry foam as a new protection barrier and tracking the auxiliary

ventilation. With this approach longwall access had been reached at the end of the 32nd week. This action was carried out in the longwall face according to the same pattern in the 33rd week.

End of Phase C and completing the mission.

The equipment could be recovered and prepared for continuing the excavation of Kalın Damar seam.

Figure 8. Result of phase B: The head gates Kalin Damar and Taşlı Damar are totally inundated with foam (in front: ventilation engineer and assistant)

5 SUMMARY & INTERPRETATION

The One Seven MINING 6000 machine can be operated with both nitrogen and air as the gas pressure medium. Due to the fact that there was no pressurized nitrogen with 2 bar (minimum required pressure for the machine) on site available the machine was operated with compressed air. At the first sight it is a disadvantage that air oxygen was brought into the fire area with the foam. It had to be assumed that a successful extinguishing only could be achieved by direct contact of the foam with the source of the fire.

Accordingly, the gas values in phase A did not indicate the successful extinguishing of the fire. These changed with the start of the 2nd phase to good and to the final fire extinguishing. We interpreted the CO-course in the borehole #2, and then we might expect a slight decay of the fire until 07/24. However, from 07/25 the CO production increased up to 07/31 recognizable again and then fell relatively quickly to zero (finally on 08/04). The interim CO-increases during phase B could be explained with methane fires while switching the O2/CH4-mixture between inside and outside the flammability-triangle. The sudden decline of CO and CH4 could be affected by the displacement of the fire gases through the foam. To this interpretation fits the development of the gas values at the tail gate dam Kalın Damar. Especially the CO and CH4 values led us to suppose, that the foam replaced the gases literally in front of them and simultaneously increased O2 content constantly.

Finally, it was found that by use of the OS MINING 6000 and the foam concentrate One Seven AM a fire area could be regained for extraction, with the conventional method (nitrogen inerting) this fire area would have to be abandoned.

The key finding is that the opening of the fire area and the safely entrance of the mine rescue brigade in the fire area was possible just under the protection of the

previously placed foam and the carriage of the new mined out foam.

A critical evaluation must be said that a foaming of probably with nitrogen foam would have been more efficient and would have led to a faster successful extinguishing. The experiences from this application show us that the gas composition in the fire area can be in the explosive range with compressed air foam over a longer period, possibly this state can be first produced by the air entrance even. This firefighting can be seen as uncritical, if it is dammed up with an explosion-proof dam. The conclusion is that with unavailable pressurized nitrogen it isn't necessary to waive the using of the One Seven MINING technology, when the fire area is dammed explosion-proof!

The practiced scheme can be briefly described as follows:

a) In the dammed state the cut off of the fire area from any ventilation and the displacement of all gases are to bring about by complete foaming of the fire area.

b) After opening of the fire area: section-by-section approach under the auxiliary ventilation by constantly reciting a foam dam, which worked almost like a drift face and protect the work area against the ingress of toxic and explosive gases.

All potentially flammable materials such as coal, wood, etc. were wetted by the first foaming and at the moment nonflammable (antipyrogenic effect of the One Seven AM foam).

c) Restoration of continuous ventilation.

6 CONCLUSION

In a 20 days continuous engagement (07/16 – 08/03) a covered mine fire, whose development 5.5 months lagged, could be extinguished by using a One Seven MINING 6000 machine and the Class A foam- concentrate One Seven AM.

A total amount of about 91,000 m³ wet and dry foam was brought into the dammed fire area. The water consumption was 4,200 m³; the consumption of foam concentrate was 6,320 liters.

A comparable safety by opening and inspecting a fire area has never been seen in the coal mining industry before. The longwall equipment was found largely undamaged, which is suggestive of a limiting of the fire in the goaf. The equipment was recovered and prepared for continuing the excavation of Kalın Damar seam

Early Detection of Spontaneous Combustion Using Laboratory Gas Evolution Tests

ABSTRACT A laboratory gas evolution test has been developed to assist with identifying the most relevant gases and gas ratios for trending and setting trigger levels as part of the Principal Hazard Management Plan for Spontaneous Combustion. The purpose of this paper is to present case study results of gas trends for a high volatile A bituminous coal where the results show differences in gas evolution trends with increasing coal temperature. Carbon monoxide evolution progressively increases from ambient to the advanced stages of heating, whereas ethylene only appears in significant concentration during the advanced stages.

Keywords: Spontaneous combustion, early detection, principal hazard management plan

1 INTRODUCTION

Underground coal mines use gas monitoring systems to detect the presence of seam gas emissions and signs of coal self-heating. Additional gas analysis is performed using gas chromatography to detect the presence of higher hydrocarbons (ethane and ethylene) and hydrogen.

The site-specific nature of coal has a major effect on the gas evolution trends that occur during self-heating. For example, the presence of seam gas such as CO_2 can distort the CO/ CO_2 to the extent that it is unreliable as an indicator of heating development. Conversely, the presence of ethane as a seam gas may provide an early indication of coal temperature increase due to increased ethane desorption, but only if other gas indicators are showing a similar trend. Instances of localised high ethane seam gas content can create misleading interpretations in terms of spontaneous combustion indication (Claassen and Beamish, 2010).

The Principal Hazard Management Plan (PHMP) for spontaneous combustion at the mine can use the gas analysis information to provide trigger levels for actions to be taken in response to stages of a heating development. This is formally known as a Trigger Action Response Plan (TARP) and various trigger levels are set in the TARP, which range from “normal” up to “evacuate the mine” based on the gas levels present.

It is therefore important that appropriate gas indicators are identified for each mine to assist with gas trending analysis and interpretation.

This paper presents results from laboratory testing of a high volatile A

bituminous coal sample that demonstrates the process used to identify site-specific gas indicators, which can be used to support the setting of trigger levels in the TARP.

The testing also highlights the complications that can occur from the presence of seam gas.

2 COAL SAMPLE AND GAS EVOLUTION TESTING

A summary of the coal quality analysis for the coal used in these tests is shown in Table 1. The ASTM rank of the sample is high volatile A bituminous and the coal type is inertinite-rich, as shown on the Suggate rank plot (Suggate, 2000) in Figure 1.

The seam has a very low gas content (<0.5 m^3/t) which was determined from standard gas content measurements. The R_{70} value for this coal is 2.44°C/h, which rates the coal as having a medium intrinsic spontaneous combustion propensity.

Table 1. Summary of coal quality analysis.

Moisture (%)	(air-dried basis)	2.2
Ash (%)	(air-dried basis)	13.5
VM (%, dmmf)		25.3
CV (Btu/lb, mmf)		14 466
ASTM rank		hvAb

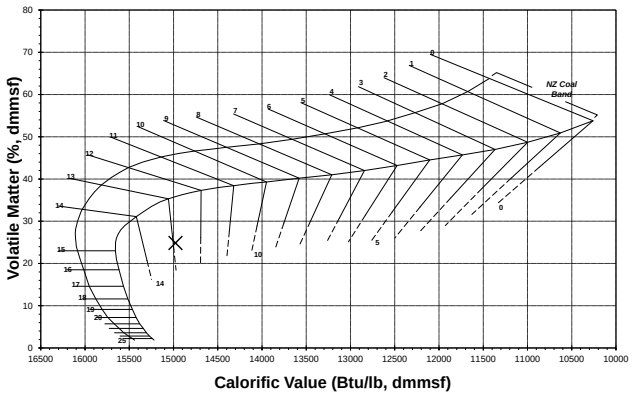

Figure 1. Suggate rank plot of coal sample used for gas evolution testing.

3 EXPERIMENTAL

Fresh coal samples are crushed, placed in a sealed flask in an oven and left to equilibrate at the pre-set start temperature. A flow of dry air is passed through the sample and the oven set to heat the sample to approximately 200ºC.

A Micro Gas Chromatograph determines the concentrations of oxygen, nitrogen, methane, carbon dioxide, carbon monoxide, hydrogen, ethane and ethylene at regular temperature increments. This information is used to evaluate the gas evolution trend of the coal in response to increasing temperature. In addition, established gas indicator ratios such as Young's, Graham's, Jones-Trickett and CO/CO_2 are calculated to establish the most reliable gas ratios for trending the development of a heating event.

4 RESULTS

1.1 Evolution of Individual Gases With Increasing Coal Temperature

The gas evolution results for individual gases are shown in Figures 2 -7 and the following trends are apparent:

The carbon monoxide (CO) evolution, shown in Figure 2, progressively increases with coal temperature, which makes it a reliable indicator of the stages of coal self-heating.

The trend for carbon dioxide (CO_2) evolution shown in Figure 3 is similar to that for CO. When these readings are obtained at the mine the presence of seam gas must be considered.

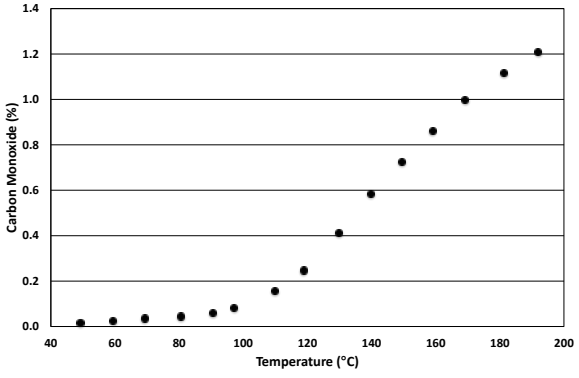

Figure 2. Carbon Monoxide evolution in response to increasing coal temperature.

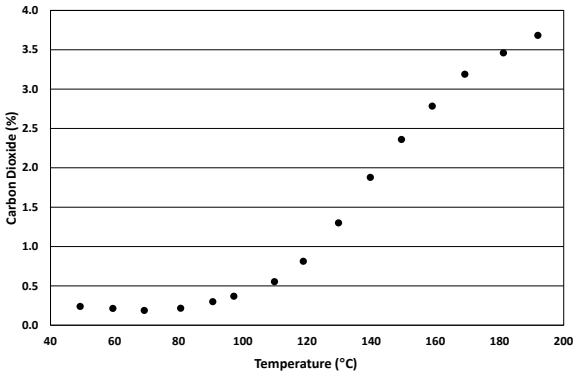

Figure 3. Carbon Dioxide evolution in response to increasing coal temperature.

Hydrogen (H_2) evolution, Figure 4, is measureable even at low temperatures and progressively increases with coal temperature and it is clear from Figure 4 that significant H_2 is evolved at the elevated temperatures of an advanced heating.

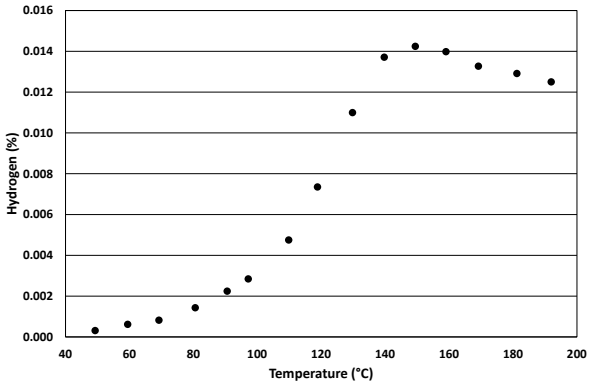

Figure 4. Hydrogen evolution in response to increasing coal temperature.

Methane (CH_4) evolution, Figure 5, for this coal does not reach significant levels until the coal exceeds 120ºC. There are only traces of methane as seam gas in this case.

The ethane (C_2H_6) evolution presented in Figure 6 shows a strong decreasing trend at low temperatures and then increases again once the coal exceeds 130ºC. The initial ethane evolution is associated with residual ethane present as seam gas and the subsequent increase in ethane evolution is due to coal oxidation. The desorption of the ethane as the coal warms may be an early detection indicator of self-heating and this feature has been used previously at the Spring Creek Mine in New Zealand (Beamish and Hughes, 2009).

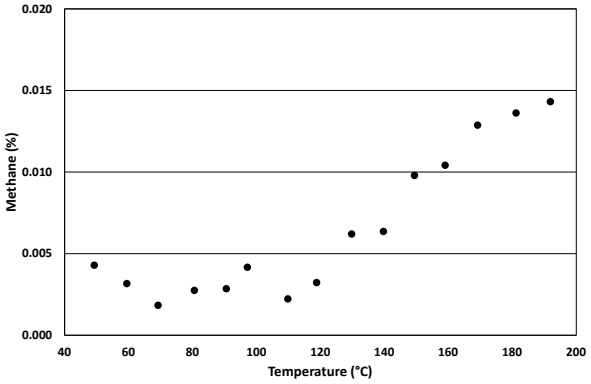

Figure 5. Methane evolution in response to increasing coal temperature.

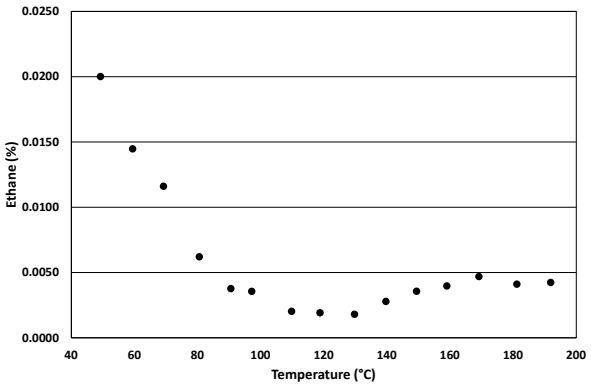

Figure 6. Ethane evolution in response to increasing coal temperature.

Ethylene (C_2H_4) evolution, Figure 7, does not occur for this coal until the temperature exceeds 140ºC. It is a clear marker of advanced coal self-heating for this particular coal and could be used for setting the upper trigger levels of the TARP.

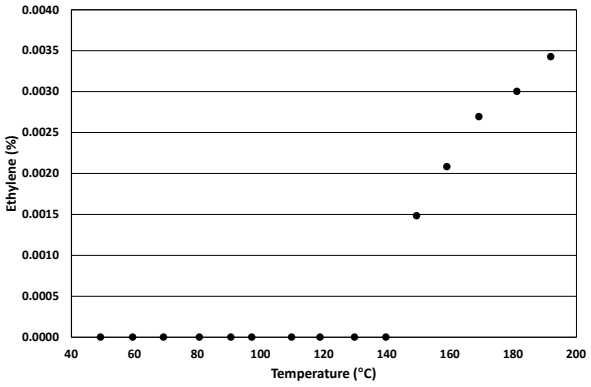

Figure 7. Ethylene evolution in response to increasing coal temperature.

1.2 Gas Ratio Response with Increasing Coal Temperature

One of the most common gas ratios used by the coal industry as an indicator of spontaneous combustion is Graham's Ratio (GR). This is calculated as the ratio of carbon monoxide produced to oxygen consumed (oxygen deficiency) using the following equation:

GR = (CO × 100)/(oxygen deficiency)

Where, for fresh air:

Oxygen deficiency = $(20.93/78.11 \times N_2 - O_2)$

A factor of 100 is applied to the ratio to produce meaningful numbers for comparison as CO is generally in concentrations of parts per million, whereas the other major gases are in units of per cent. It should be noted that the GR value is very sensitive to low levels of oxygen deficiency and may produce anomalous results due to this sensitivity (Brady, 2008).

An example of how the GR value can be related to the stages of a heating is reported by Moreby and Chalmers (2009) Table 2, but it should be noted that these values can vary for individual coals:

Table 2. GR value related to heating stages.

GR ≤ 0.4	Indicates normal value
0.4 ≤ GR ≤1.0	Indicates possible early stages of heating
1.0 ≤ GR < 2.0	Indicates event almost certain
2.0 ≤ GR < 3.0	Indicates serious event
GR ≥ 3.0	Indicates active fire

For the coal tested in this study, the GR values show a strong positive correlation with increasing coal temperature, Figure 8, and there is a noticeable change in slope once the coal exceeds 100ºC, which may be due to moisture removal from the coal freeing up easier access to reactive sites. Based on the trend of the GR values in Figure 8, the normal background is expected to be 0.20 assuming an ambient temperature of 30ºC. This would need to be confirmed with current on-site measurements to set a baseline value for normal conditions in the TARP. Subsequent trigger levels could be defined using a doubling of the GR value for example.

Young's Ratio (YR) uses CO_2 instead of CO as the indicator of oxidation according to the equation:

YR = CO_2 / (Oxygen deficiency)

Where for fresh air:

Oxygen deficiency = $(20.93/78.11 x N_2 - O_2)$

$CO_2 = CO_2 - 0.035/78.11 x N_2$

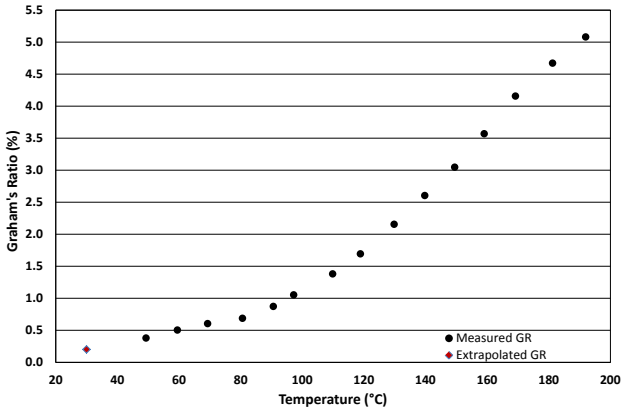

Figure 8. Graham's Ratio in response to increasing coal temperature.

The initial trend in the YR values shows a decrease followed by an increasing trend above 70ºC (Figure 9) and shows a similar trend to the GR values. The initial decreasing trend is in response to seam gas desorption. As such, for this coal the YR values would not provide a reliable early indication of coal self-heating at low temperatures, but could be used to confirm heating development at higher temperatures.

The Morris ratio (MR) is a measure of the amount of oxygen absorbed in relation to the amount of the major oxidation products (CO and CO_2) generated by the coal:

MR = (Nitrogen excess) / (CO + CO_2)

Where, for fresh air:

Nitrogen excess = $(N_2 - 78.11/20.93 \times O_2)$

$CO_2 = CO_2 - 0.035/78.11 x N_2$

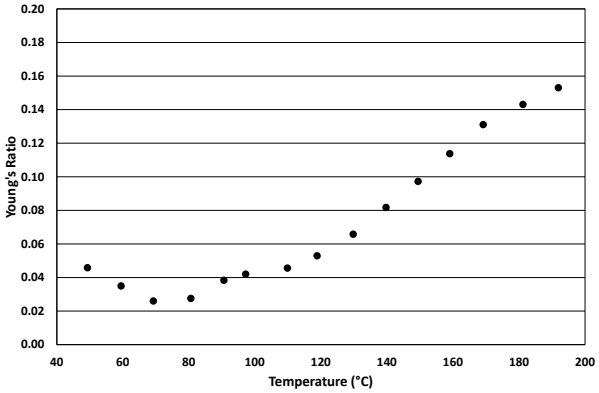

Figure 9. Young's Ratio in response to increasing coal temperature.

Again, for this coal the low temperature region shown in Figure 10 indicates an influence of CO_2 seam gas desorption as the MR values increase initially and then consistently decrease in excess of 70ºC.

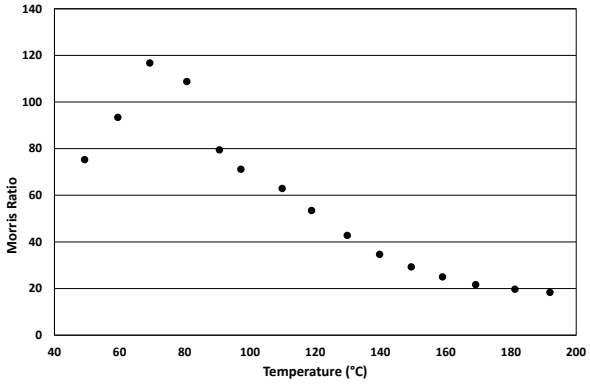

Figure 10. Morris Ratio in response to increasing coal temperature.

The CO/CO_2 and H_2/CO ratios are independent of oxygen deficiency and are therefore valuable in supporting confirmation of heating progression shown by other gas indicator ratios that rely on accurate oxygen deficiency results. The trends obtained for the coal (Figures 11 and 12) show differences in the nature of the gas evolution of these oxidation products as the CO/CO_2 ratio provides a consistent increasing trend up to approximately 130ºC compared to the H_2/CO ratio, which shows a maximum value at 90ºC before consistently decreasing. The absolute value of the CO/CO_2 ratio obtained from laboratory testing should not be considered to apply at the mine site as due to the presence of seam gas desorption from pillars, caved coal and other strata the actual ratio can be up to two orders of magnitude lower. However, the trending would be the same as the coal temperature increases.

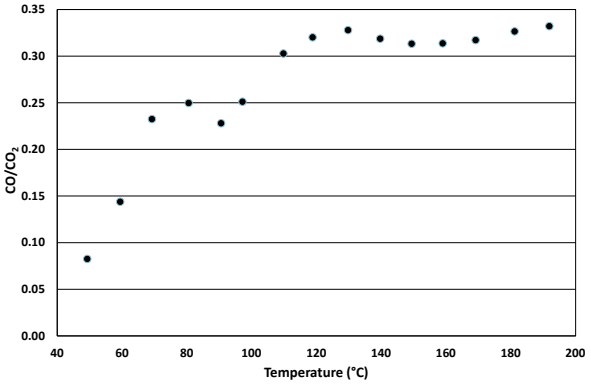

Figure 11. CO/CO2 Ratio in response to increasing coal temperature.

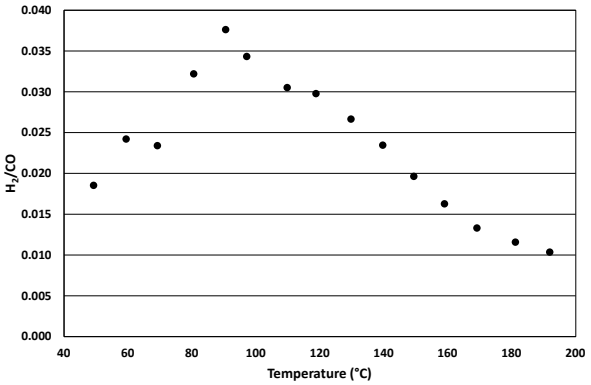

Figure 12. H2/CO Ratio in response to increasing coal temperature.

5 CONCLUSIONS

For the high volatile A bituminous coal tested in this study there are clear trends shown by most of the normal gas indicators used for spontaneous combustion detection. CO evolution provides a continuous record of heating development, which is supported by the Graham's ratio.

The coal has a unique ethane desorption signature at low temperature that may provide an early indication of the coal self-heating.

Advanced stages of self-heating are indicated by the evolution of ethylene and confirmation is provided by gas ratios such as Young's ratio and Morris ratio.

Providing a Risk Model for Iran's Mines Based on Extreme Value Theory

R.Noori, M. Ahmad Sherbafi
Iran's Mining Investment Insurance Corporation, Tehran ,Iran

ABSTRACT Lack of proper knowledge about the risk already exists in the credit insurance of the miners has led to a poor market to issue mine's credit policy. In Iran, as a country with a huge potential in its minting sector, this has also been one of the main reasons why investors are generally reluctant to run projects in the sector.

Credit risk of miners has been tried to be analyzed with the usage of Extreme Value Theory as one of the risk management's tool in this current paper. This theory works based on the Generalized Extreme Value and the Generalized Pareto distribution methods to estimate distribution function of the losses in credit risk.

The analytic data has been collected from Iran's mines. As a result, we model extreme historical losses of Iran's mines credit risk and find an optimum threshold for them.

Keywords: Extreme Value Theory, risk model

1 INTRODUCTION

After oil, mining is the second important sector that the Iranian economy relies on, playing a very important role in the economic development of the country. However the mining sector hasn't achieved the real position in the economy yet due to lack of necessary investments are caused by management which is not eligible at the micro and macro level especially risk management. Investment in the mining sector, which is regarded very risky, needs proper insurance covering such as the credit risk which is normally covered through insurance services. However, insurance companies seem to have no proper knowledge about the level and intensity of risks associated with mining operations, which is mainly due to the fluctuations in the economic, cultural, technical, environmental, legal and management conditions in the country. The current paper analyzes the losses associated with the credit risk in Iran's mining activities using the Extreme Value Theory which can offer a proper model in risk analysis in the sector.

The Extreme Value Theory is one of the major tools for analysis and modeling of risks which is mainly conducted in two manners, namely the Generalized Pareto Distribution (GPD) and Generalized Extreme Value (GEV). The method has been used in a wide range of applications in various sciences including credit risk measurement, Gillli and Kellezi (2006); Paul and Barnes (2010); Manchini and Trojani (2010), risk management in insurance industry, Embrechts and I.Resnick (1999), climate and natural hazard, Das, et al (2012) and risks in stock and share market, Karmakar and Shukla (2014); L.c.dasilva and V.de melomendes (2003).

However, the EVT has been rarely used in measurement of risks in the mining industry with exceptions like the recent study in South Africa in which the method was applied to the mining sector, CHinhuang et al (2014). The study was conducted on mining companies' indicators in Johannesburg mining stock market. The EVT model was also used in oil industry in Thailand in 2014 that the price of crude oil was predicted based on GPD and GEV models, Taveeapiradeecharoen et al (2014). In the Iranian literature of research however, there has been no case of the method being used in the mining sector.

The current study is based on the data provided by the exclusive insurer of the mining activities in Iran and the sole excusive lender in the sector. The results identify the main obstacles for the insurers, banks and credit institutions in engaging in mining activities and provide projections on the potential losses that may arise in the sector. It also provides the banks and insurance companies with this knowledge to decide on the issue better.

2 MINING AND THE NEED FOR A CREDIT RISK, A CASE STUDY ON IRAN

Mining is a very risky, adventurous operation with many threats for the investors who are active in the sector. Depending on the value of the mining project and the risk could be a function of many economical and physical uncertainties like the price of the mineral and its quality, expenditures, planning and other environmental conditions that most of them still are unidentified, Martinez (2009).

The investment in mines is either in direct form by the investor or through the loans and credits provided by the banks. In the former case, any potential loss in the benefits of the project and the return of investment is totally inflicted on the investor and his partners. However, if banks invest in mining projects, it will be their assets and possessions that would suffer most from the credit risks in the mining activities. This is one of the main reasons why banks are reluctant to invest in mining projects. The current amount of unpaid loans or loans that may not be returned show how much the operation could be risky for the banks. The weak management of the portfolio risk, little attention to economic changes or other conditions that may risk the credit position of the banks also contributes to the situation. This could be more evident in the work of those mining companies that are closely dependent on the technical and economic conditions and especially the government's policies. In other words, banks should not only take into account the investment needed for compensating the risks, they should also have the required knowledge and expertise about the identification, measurement, protection and control of credit risk in the mining sector.

Better management of the risks associated with the losses in the mining operation or mining companies' delay in reimbursement of loans needs a proper system of insurance cover. Iran’s Mining Investment Insurance Corporation (MICO), which is run by the government, is the sole and exclusive insurer of the sector in the country which was established based on article 31 of Iran's Mining Law, IRI Parliament Research Center (2014). All mining companies are referred to this fund for receiving credits and loans.

The fund takes the mines' license as the principal collateral and uses it to compensate the potential losses brought about by the negligence of the mining companies. During the process of issuing the insuring policy which is used by miners for receiving loans from the banks, the experts are working for the fund study the mining project and if it justified economically, the current investment and the potential investments would be estimated.

The management of the risks associated with the negligence of the miners is through taking strong collaterals and guarantees from the insured. The banks and credit institution then accept the policies issued by the fund as the collateral to grant loans to the miners.

If the loans are not reimbursed during the operation of the mines, the banks will inform the fund through a notice so the fund compensates the losses for the bank. The portfolio management of the fund is done through selling the collaterals unless the insured pays the amounts he owes.

Now that we have studied the prevalent mechanism for credit insurance of the mines in Iran, we can present and analyze the loss model.

3 THE EXTREME VALUE THEORY

The management of risks has become a must for many businesses. The measurement and management of risks triggered by

uncertainties have created a necessity for owners of businesses to look for a proper system for measurement of the risks associated with their assets and possessions and this naturally applies to all fields of business including the financial, engineering and insurance markets. The significance of such necessity has been doubled over the past two decades in which markets have experienced a meaningful instability, proving the huge and infinite dimensions of the losses. This has forced the financial institutions to look for more thorough and robust methodologies for modeling large-scale, extreme losses, Paul and Barnes (2010).

The Extreme Value Theory is one the most distinguished tools for risk managers in the loss modeling. The theory has proved to be very effective in the most advanced areas of science, engineering and insurance. Used as a statistical tool, the theory has a wide range of applications in various field including insurance, McNeil (1997), financial risk estimate, Gilli and Kellezi (2006); Mancini (2010); Paul and Barnes (2010), hydrology and meteorology, L.Smith (1986); A.Tawn (1988);, stock market, K.Singh, et al (2012); L.C.dasilva (2003); Karmakar and Shukla (2014); Taveeapiradeecharoen, et al (2014), communication, geology and seismic studies, biology and public health. Penalva, et al (2013) have classified these applications in two major groups:

- Environmental area such as the study of sea levels, wind speed, water flow in rivers, etc.
- Reliability and structural safety area like measurement of credit risk in risk management.

The quantification of the most extreme losses in financial markets is a necessity in the current situation of the global economy and the extreme value theory is the best method to perform such a mission.

Banks normally look for the best statistical method for protecting their giant reserves against any potential losses. For example, the Swiss Bank Corporation has introduced a statistical model for calculation of risks (ACRA) in which the measurement is defined based on the Expected loss, the Unexpected loss and the Stress loss, Embrechts, et al (1999).

The current paper uses the EVT in modeling the credit risk loss of the mining projects in Iran for the first time. The study is conducted based on the data provided by the sole specialized insurer of the mining sector in the country. The results are then used to analyze the mining credit risk cover provided in the sector which can further be applied by other insurers, banks and credit institutors. The credits and loans granted to the mining sector in Iran are only provided by this insurer. The data used in the study is only those provided by this fund that is related to all mines in Iran.

The Extreme Value Theory's use in insurance leads to a modeling for positive random variable which shows the amount of money that the insurer should pay the insured due to the loss occurred. The variable is in fact the maximum loss or the extreme loss. The finite behavior of these maximums is studied in the Extreme Value Theory and heavy-tail distributions are used for their modeling.

The choice of loss random variable is based on GEV(Generalized Extreme Value Distribution) and GPD(Generalized Pareto Distribution)methods. The GEV uses similar blocks of observation like fixed periods or monthly or yearly periods. These observations are called Block Maxima and they can be modeled through finding their distribution function which is then extended to the Extreme Value Distribution function. The GPD has nothing to do with observations in fixed periods but it considers the maximums that are beyond a limited threshold. These observations are then called Peaks-Over Threshold (POT). These maximums are modeled and estimated through General Pareto Distribution, Gilli and Kellezi (2006), Gencay and Selcuk (2001).

4 THE MATHEMATICAL MODEL FOR EXTREME VALUE THEORY

4.1 The Generalized Extreme Value Distribution

4.1.1 Block maxima

In this method, the random variables are selected from observations in a fixed period of time which are called the block maxima. - Assume a sample $X_1,X_2,\ldots,X_N$ of independent and identically distributed data drawn from an unknown distribution F.

We divide the sample into m non-overlapping subsamples of n observations each (n-blocks), for given integer m ,n (0<m ,n<N) and denote $M_{n,j}$ are the maximum of the j^{th} subsample. Assume that F belongs to the maximum domain of attraction of $G_{\xi,\mu,\delta}$ for some $\xi,\mu,\delta \in \Re$ with$\delta > 0$.

The GEV method fits distribution function $G_{\xi,\mu,\delta}$ to the sequence of block maxima $M_{n,1}$,…, $M_{n,m}$ with estimated parameters $\hat{\xi},\hat{\mu},\hat{\delta}$.

4.1.2*Theorem1, Fisher and Tippett (1928); Gnedenko (1943)*

Let X_n be a sequence of independent and identically random variables. If there exist constants $c_n>0$, $d_n\in \mathbb{R}$ and some non-degenerate distribution function H such that $\frac{M_n - d_n}{c_n} \xrightarrow{d} H$.Then H belongs to one of the three standard extreme value distributions 1, 2 or 3:

Fréchet: $\phi_\alpha(x)=\begin{cases}0, & x\le 0\\ e^{-x^{-\alpha}}, & x>0\end{cases}$ $\alpha > 0$ (1)

Weibull: $\psi_\alpha(x)=\begin{cases}e^{-(-x)^{\alpha}}, & x\le 0\\ 1, & x>0\end{cases}$ $\alpha>0$ (2)

Gumbel: $\Delta(x)=e^{-e^{-x}}$,$x\in R$ (3)

Jenkinson (1955) and vonMises (1954) have proposed that the above mentioned functions be showed as a one-variable function in which $1+\xi x > 0$,

$$H_\xi(x)=\begin{cases}e^{-(1+\xi x)^{-\frac{1}{\xi}}} & \text{if } \xi\neq 0\\ e^{-e^{-x}} & \text{if } \xi=0\end{cases} \quad (4)$$

This generalization is known as the Generalized Extreme Value distribution (GEV).

4.2The Generalized Pareto Distribution

4.2.1Peak-Over –Threshold (POT)

This approach is to consider the distribution of exceedances over a certain threshold like u. We are interested in estimating the distribution function F_u of values of x above a certain threshold u. The distribution function F_u is called the conditional excess distribution function and is defined as

$F_u(y)=P(X-u\le y|X>u)$, $0\le y\le x_F-u$ (5)

In which X is the random variable, u is a given threshold and y=x-u are the excesses and $x_F \le \infty$ is the right endpoint of F.

4.2.2*Theorem2, Pickands (1975), Balkema and de Haan (1974)*

For a larger class of distribution functions F, the conditional excess distribution function $F_u(y)$, for u large, is well approximated by

$F_u(y)\approx G_{\xi,\sigma}(y)$, $u\to\infty$ (6)

Where

$$G_{\xi,\sigma}(y)=\begin{cases}1-\left(1+\frac{\xi}{\sigma}y\right)^{-\frac{1}{\xi}} & \text{if } \xi\neq 0\\ 1-e^{-\frac{y}{\sigma}} & \text{if } \xi=0\end{cases} \quad (7)$$

For $y\in[0,(x-u)]$if $\xi\ge 0$,$y\in\left[0,-\frac{\sigma}{\xi}\right]$ if $\xi<0$

$G_{\xi,\sigma}(y)$ is the so called Generalized Pareto Distribution (GPD).

5 DATA AND SELECTION OF VARIABLES FOR STARTING ANALYSIS

The data used in this paper covers the losses aggregated in Iran's mining insurance corporation for all mines across the country which was paid between 2006 till August 2014. The insurer has a 12-year experience in the mining sector and the data used in the paper is about the period after 2006. The analysis and modeling of the data are conducted using R 2.15.1. Figures1 and 2 show the time series and histogram for losses of credit insurance of the mining activities in Iran between 2006 till August 2014 respectively.

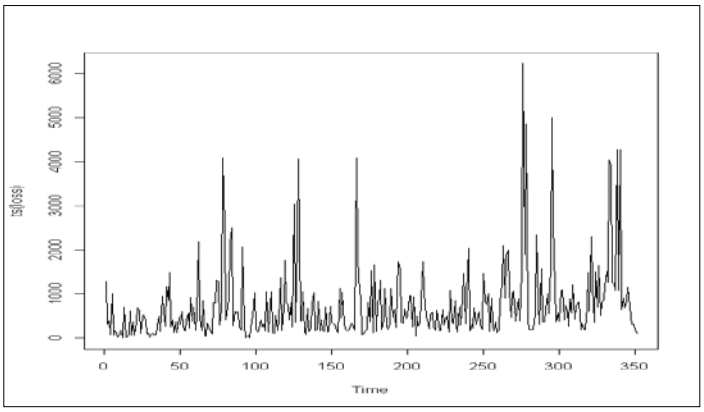

Figure 1. Time series plot of losses.

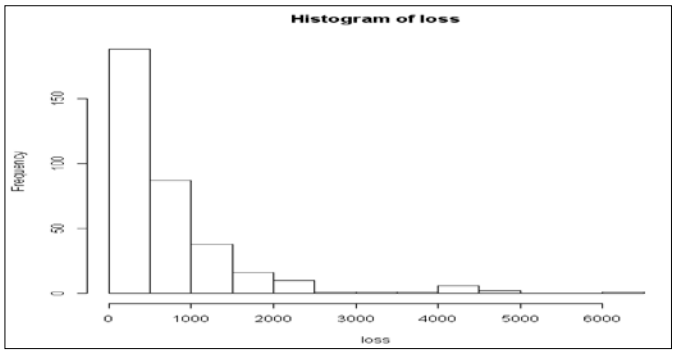

Figure 2. Histogram of losses.

Table 1 shows that the normality assumption of the data distribution is rejected at all levels of significant. The probability plot indicates the empirical distribution of the data is exponential distribution with an average 728.15 million Rial (IRR). Considering the loss data that is usually heavy-tail, so this result isn't beyond the fact (Figure 3).

Table 1- Descriptive statistics summary

n	Min	Max	Mean	Stdev	Kolmogorov -Smirnov (P-value)	Skewness	Kurtosis
351	1.82	6226	728.14709	844.86	0.2997(0.00)	2.99	11.45

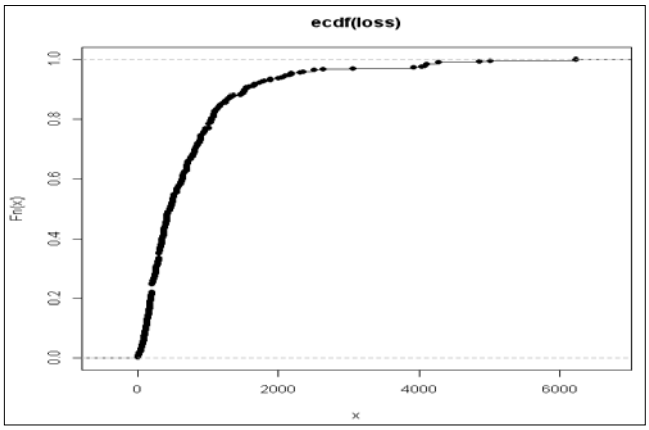

Figure 3. Emprical function of losses.

5.1 Estimating the Generalized Extreme Value distribution

In order to show the distribution function based on GEV model, we should first block the data. Seasonal blocks are used in the current paper due to the fact the Iran's mining insurance corporation is almost young. It is also because of the lack of the data in each year so we decided to use the seasonal data and then select their maximums. The estimate of the model parameters for seasonal blocks of the loss can be seen in Table 2.

Table 2 shows that the Maximum Likelihood Estimation (MLE) for shape parameter ξ of model is positive. This means that the block maxima of the credit insurance loss in Iranian mining industry follow the $Fréchet$ model with $\xi = 0.3615$. Diagnostic plots for assessing the accuracy of the EVT model for this data are shown in Figure 5. These plots show the $Fréchet$ model as being adequate for modeling this data. A 95 % confidence interval for parameter ξ shows that is always positive (Figure 4).

Thus, using the block maxima method, the loss model for credit insurance in Iran's mines based on the distribution function is estimated as following

$$H_{\xi}(x) = e^{-(1+0.3615x)^{-2.7}} \qquad \xi>0 \qquad (8)$$

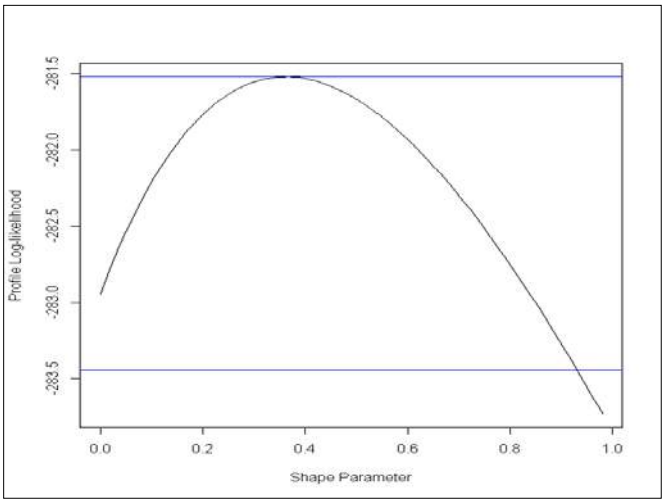

Figure 4. 95 % confidence interval for ξ.

Having the loss distribution function of x, we can now expand our study for each x in range of variable and obtain the probability of various losses. The assessment and discovery of the central tendencies and scattering measurements in the portfolio losses of the credit insurance is conducted through using the model. For example, the average maximum of occurred losses based on the seasonal blocks which is viewed as one of the main central tendencies is estimated to be $\mu = 1551.68$ million Rial (IRR).

Table 2. GEV outputs for losses

Block size	Maxima	Estimated parameters and standard errors					
		ξ	s.e(ξ)	δ	s.e(δ)	μ	s.e(μ)
4	31	0.3615	0.243	1482.5	297.3	1551.68	337.1

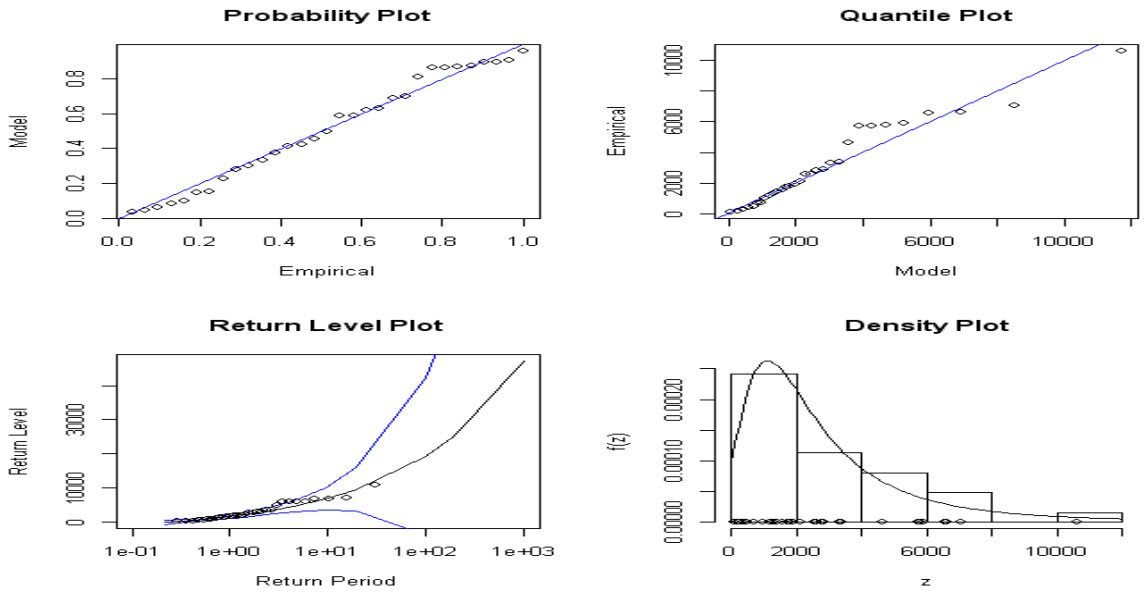

Figure 5-Diagnostic plots for GEV fit to the losses.

5.2Estimation of loss through the Generalized Pareto Distribution (GPD)

The main objective in the GPD model is to estimate a proper threshold u so that the distribution function of exceedances over u would include Generalized Pareto Distribution model. The Mean Excess and the empirical distribution of loss are used for the assessment of the threshold (Fig 6, 7). Figure 6 shows that the u threshold which is between 1246 and 1538 million Rial (IRR) is a logical and acceptable threshold, because at least 85 percent of data is smaller than the current threshold. The selected values are used for the estimation of the thresholds that

are coincidence with 85% to 90% quantiles of the data. Table 3 shows the estimation for parameters of Generalized Pareto Distribution for threshold between 1246 to 1538.

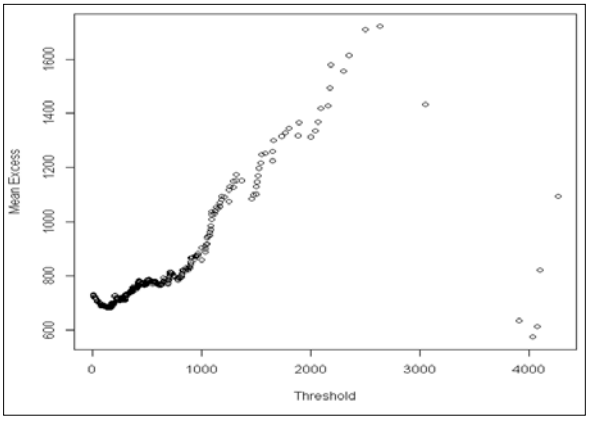

Figure 6- Mean excess function of losses

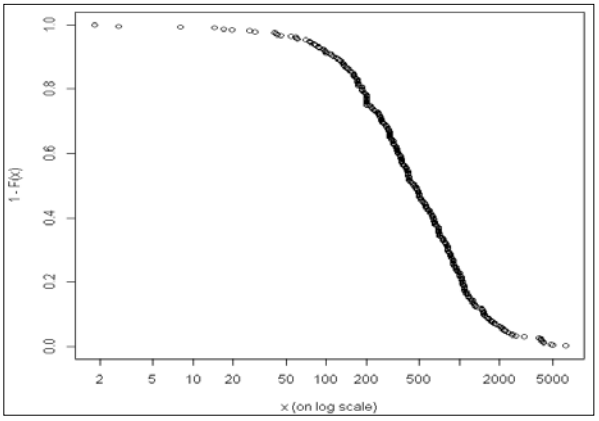

Figure 7- Empirical function of losses

Table3-GPD outputs for losses

Threshold	Extremes	Method	Estimated parameters and standard errors			
P	u	n		ξ	s.e(ξ)	σ	s.e(σ)
0.85	1246.5	50	MLE	0.200	0.218	870.3	225.1
0.87	1311.2	45	MLE	0.118	0.223	998.3	267.2
0.89	1510	37	MLE	0.150	0.291	982.5	328.0
0.90	1538.4	35	MLE	0.067	0.290	1105.8	370.7

The Maximum likelihood Estimation method (MLE) is again used for the estimation of the variables. It can be seen from Table 3 that the standard errors of the estimated parameters increase as the threshold increases. In order to select the optimum threshold, one should use the validity plots like the following chart (Fig 8) in which the value of u=1246.5 is viewed as a desired threshold for the data of the losses in the threshold.

The Generalized Pareto Distribution model would be as following:

$$G_{\xi,\sigma}(y)=1-(1+0.000231\,y)^{-4.980}\ ,\xi>0 \quad (9)$$

This model indicates that the threshold of loss in an insurer's portfolio of credit insurance is 1246.5 for one policy. This can inform the insurer about the loss threshold in a credit policy issued for mining projects which is equal to 1246.5 in the portfolio and the insurer must take reserves for losses more than threshold.

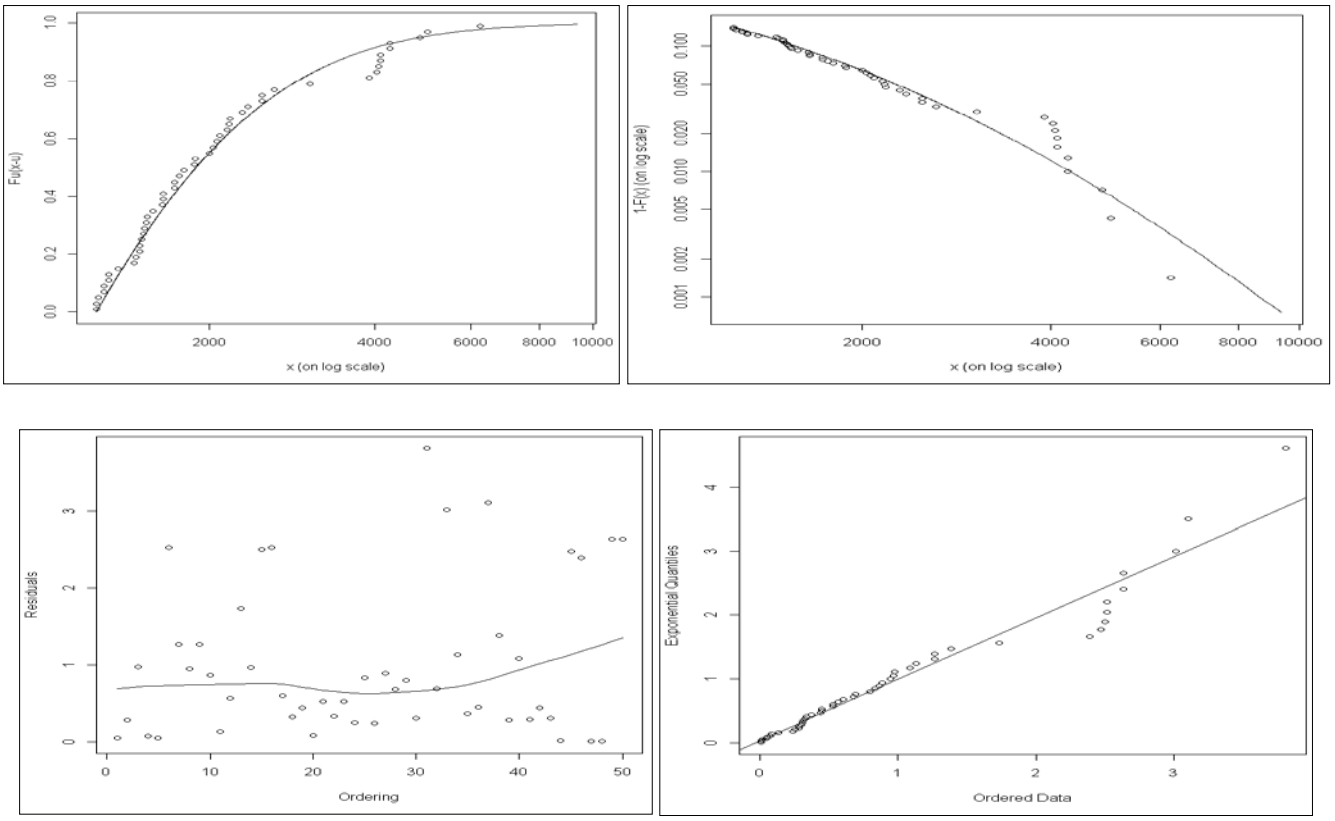

Figure 8- Excess distribution(top left),tail the underlying distribution(top right), a scatter plot of residuals(bottom left) and Q-Q plot(bottom right)for losses.

6 CONCLUSION

The aim of this paper has been to consider two alternative models, namely GEV and GPD for the loss of mining credit risk. These models provided better fit that the classical normality assumption due to the kurtosis and skewness of the loss data in mining credit risk. In addition, Extreme Value models are able to capture the probabilities of the extreme events in mining credit risk.

The financial loss data in mining credit risk was fitted with GEV the using block maxima approach and GPD using the POT method at various threshold values. Graphical analysis, such as diagnostic plots, Mean Excess plot and Q-Q plot have revealed that these models provide good depiction of our data and result quantifies the loss latent information in the portfolio of the credit section of a mining insurance company clearly.

It is hoped that the outcomes could benefit all stakeholders and principal decision makers in Iran's mining sector so that they can conduct more optimized management in their risk coverage operations.

Risk Analysis in Mining Projects by using Fuzzy Synthetic Evaluation Technique

M. H. Basiri, A. Azad
Department of Mining, Faculty of Engineering, Tarbiat Modares University, Tehran, Iran

ABSTRACT Uncertainty is one of the most important features in mining projects. The extractive industries encounter with a high level of risk associated. Risk management plays a central role in this regards. Risk ranking, particularly when the number of risk factors increases, is an important part of the risk assessment process. In this research, the Multiple Attribute Decision Making (MADM) methods accompanied with the Fuzzy technique have been implemented for ranking the risks. A Fuzzy Synthetic Evaluation (FSE) approach is proposed as a new tool for this purpose. This method, as a tool in the multi-criteria decision making, has been adopted in many fields, including evaluating of reservoir water quality, health risk assessment, etc. This paper measures the risk index for each particular risk and evaluates the overall risk indices of mining projects.

Key words: Risk analysis, mining project, MADM, fuzzy synthetic evaluation

1 INTRODUCTION

Mining industry makes a major contribution to the world's economy as well as to the well-being of society as a whole. Uncertainty is one of the most important features of the mining projects. The investment in the project is heavily influenced by risk factors. Therefore the decision making for financing the projects needs to consider the risk management techniques.

The purpose of risk management is to reduce the impacts of these kinds of risks. Mining industry are accompanied with inherent potential of major accidents that may lead to injure or kill many people, damage the environment, cause serious loss of production and profit. Therefore it needs a particular consideration to implement the risk management.

Risk assessment aims to employ the effective management of risks, by identifying the followings:

- Which risks have more priority to be reduced, and the procedures to achieve this matter?
- Which risks need careful on-going management, and the nature of that on-going attention?

Risk management is the identification of project risks, assessing and prioritization of them, and adopt appropriate.

One of the central methods to identify and classify risks is the Risk Breakdown Structure (RBS).

Various risk assessment techniques are different in the way of combining the suitable aspects into one value. In mining industry many risk assessment techniques are performed, various risk assessment techniques are different in the way of combining the different aspects into one value.

In the mining industry, many risk assessment techniques are performed, such as; Using simulation analysis for mining project risk management (Chinbat, 2011, Takakuwa, 2009).

Risk assessment in the mining industry: Apply Management (Radosavljević and Radosavljević, 2009) and etc.

The complexity of mining projects is characteristic of these projects. Therefore, for risk assessment we need high quality data.

One of the researches done to risk analysis in ultra-deep scientific drilling project (Liu, Li, Wang, 2013), to overcome the

difficulties mentioned above proposes an analytic hierarchy process / analytic network process, AHP/ANP, based fuzzy synthetic evaluation (FSE) approach to evaluate risks in deep scientific drilling project.

Therefore, in this study, because access to high-quality data in the mining industry is problem, after pointing out the risks of the mining industry, we refer to fuzzy synthetic evaluation method.

2 IDENTIFYING RISKS

Identifying risks are the process of determining which risks may affect the project and documenting their characteristics (PMI, 2008).

This is perhaps the critical step of a risk assessment. A risk which is not identified cannot be actively managed. There are many techniques available for identifying risks, but none of them can be expected to identify all the risks.

In the mining industry, identifying risks are very difficult, because these projects have different situation from mine to other mine. When undertaking the first study of a mine in which there has been no previous formal risk assessment, any attempt to identify all risks in detail would result in an extremely long list, of which only the most severe could be analyzed, assessed and treated in the foreseeable future. The degree of detail in risk identifications should be appropriate to the objectives of the investigation.

The following sections are some of the major risks of the mining industry, the impact of each on the outcome of the project is important.

2 RISKS IN MINING PROJECTS

Due to uncertainties in the mining industry, this industry is constantly exposed to the critical state. One of the reasons is the lack of sufficient knowledge of the land situation.

On the other hand, external factors affecting the project are too risky. One of those factors is condition price and the market. Thus the conditions for the project will be positive or negative, if the conditions are good or poor. Risks of the mining industry are very important. If you do not pay attention to these risks, the failure of the project and will lose both time and money for companies. Therefore, for the readers understanding of the key risks in the mining industry are listed below.

Figure 1. Risks in mining projects

2.1 Risks in Exploration

Exploration is the initial stages of mining projects. At this stage of mining, there is a proven source of minerals and if to be valuable mineral, the output of this stage quantity and grade of mineral reserve and the distribution of grades in the region.

Thus it can be seen that the stage sensitivity is high. Because if done carefully down the steps, the other steps are will problem.

With incorrect exploration information, mining companies are suffered very high financial losses. Therefore, the exploration risks are component of major risk in mining projects.

2.2 Market Prices

One of the most important economic risks of the mining industry is the market prices risk.

Profitability of the company is variable with increase or decrease the price of products.

Profitability of the company is dependent to many factors; they are which most sensitive to price.

Thus, we can reduce the impact of this risk with forecast market conditions.

2.3 Political Risks

Mining companies operate in different countries with varying regulations on mining claims.

The regulations in some countries rarely change, but others have more volatile legal system.

So, even if a mining company has a great deposit, the capital to develop it and a favorable market, a change in the political environment where the deposit is located can throw a wrench in successfully getting the minerals to market.

Mining companies that operate in stable countries are preferable from a risk perspective, but mining companies go where the minerals are, so it is often a question of how much political risk an investor is reasonable.

2.4 Environment Risks

Where material is excavated from an open pit, is one of the most common forms of mining for strategic minerals. This type of mining is particularly damaging to the environment because strategic minerals are often only available in small concentrations, which increases the amount of ore needed to be mined.

Environmental risk is very important, in many cases; this risk is to stop the project.

2.5 Societal Risks

This risk depends on the social component, such as: Social conditions in the region, Social satisfaction of project activity, Increase or decrease in demand in the industry, Population growth rate, Rate of unemployment, Social stresses, etc.

2.6 Financial Risks

Financial risk is rooted in economic factors and the impact of these risks on the project is undeniable.

Some of them factors include: Inflation rate, Interest rate, Tax Law, Economic sanctions, World prices, Market conditions, Government subsidies, Energy and fuel prices, etc.

2.7 Management Risks

Due to extensive mining projects, the management of these projects is difficult.

In case of poor management, projects face many risks, projects which are likely to fail.

2.8 Workforce

With efficient manpower productivity in industry will progress. In this respect, it is important to identify the workforce risks for project success.

This risk depends on many parameters such as: motivating work, appropriate wage, good working condition, etc.

2.9 Technical

Due to the uncertainty existing in the mining projects, the design of each project is different from other projects. Therefore, requires a unique design. The design should be carried out optimized and economically, which depends on the ability of the design team.

3 ANALYSES RISKS

Risk analysis is “A systematic use of available information to determine how often specified events may occur and the magnitude of their likely consequences” (McKensey, 1979).

The complexity of mining projects is characteristic of these projects. Therefore, for Risk assessment we need high quality data.

One of the researches done to risk analysis in ultra-deep scientific drilling project (Liu, Li, Wang, 2013), To overcome the difficulties mentioned above proposes an

AHP/ANP based FSE approach to evaluate risks in deep scientific drilling project.

A FSE approach, as a tool in the multi-criteria decision making, has been adopted in many fields, including evaluating of reservoir water quality, health risk assessment, public–private partnership PPP project risk analysis, deep scientific drilling project, etc.

Therefore, in this study, because access to high-quality data in the mining industry problems, we refer to fuzzy synthetic evaluation method.

3.1 Fuzzy Synthetic Evaluation Approach

The procedures of fuzzy synthetic evaluation approach are as follows (Liu, Li, Wang, 2013):

(1) Determine the set of basic criteria/factors π= {f1, f2, ⋯, fm},
where (m) is the number of criteria.

(2) Determine the set of grade alternatives E= {e1, e2, ⋯, en},

where n is the number of alternatives. For example, e1=very low; e2 =low;
e3 =moderate; e4=high; and e5= very high. Grades will be given for each alternative, such as 1=very low; 2=low; 3=moderate; 4=high; and 5=very high.

(3) Determine weight for each criterion or factor W= {w1, w2, ⋯, wm}.

The weight of each criterion can be obtained by various approaches, for example, AHP/ANP, etc.

(4) For each criterion, an evaluation is a fuzzy subset of grade set, whose membership function can be established by the risk assessment group.

All the evaluations form a fuzzy $R = (rij)m * n$ evaluation matrix where rij is the

degree to which alternative ej satisfies the criterion fi.

(5) Fuzzy synthetic evaluation. The results of the evaluation are obtained by calculating the fuzzy composition of the weighting vector and the fuzzy evaluation matrix, where ° is a fuzzy composition operator.

D= R ° W

$$\mathrm{dj} = \min\left(1, \sum_{i=1}^{m} wi * rij\right), \quad dj \in D$$

The final evaluation denoted by D is also a fuzzy subset of the alternative set.

(6) Normalize the fuzzy evaluation vector and calculate the risk index according to

$$\mathrm{RI} = \sum_{k=1}^{n} dk * ek$$

The evaluation of each risk has been done now, and the risks can be rated by the numerical value of their risk index.

4 CONCLUSIONS

In the mining industry, many risk assessment techniques are performed; uncertainty is one of the most important features of the mining projects. In mining industry, identifying risks are very difficult, because these projects have different situation from mine to other mine.

The complexity of mining projects is characteristic of these projects. Therefore, for Risk assessment we need high quality data. FSE approach, as a tool in the multi-criteria decision making, has been adopted in many fields, Therefore, in this study because access to high-quality data in the mining industry problems, we refer to fuzzy synthetic evaluation method.

Risk Reduction of Minerals' Revenue in the Economy of Resource Rich Countries

N. Adibee, M. Ataee-pour
Department of Mining and Metallurgical Engineering, Amirkabir University of Technology, Tehran, Iran

ABSTRACT Some countries have a variety of mineral products and commodities which is the source of government revenue and foreign exchange. These revenues are essential for development of mineral countries. Because of some local and international changes in mineral markets, the revenue gained from minerals may be very variable. In order to plan for mineral revenue by governments, the risk of mineral revenue should be decreased. In this paper, minerals are considered as risky assets to apply the Modern Portfolio Theory (MPT). This method is able to decrease the risk of minerals' revenue by optimum diversification. As a case study, minerals production of Iran mining sector is studied. The non-linear model is solved by quadratic programming. To achieve the country's expected revenue the model determines the type and quantity of minerals to be produced. The findings show that the MPT model has an adequate potential to reduce the risk of government's minerals revenue compared with the current situation.

Keywords: Modern Portfolio Theory, risk reduction

1. INTRODUCTION

Some of the world's countries are rich in mineral resources. Mineral and energy commodities play an important role in national economic development (Dorian and Humphreys, 1994). Mineral resources are a gift of nature available to be developed, sold, and used to better the lot of a nation's citizens. Mineral production generates income and foreign exchange (if exported), can stimulate local economies through the local purchase of inputs, and can be the basis for downstream processing and manufacturing industries. Mining companies employ workers, who earn income, some of which they spend on domestically produced goods and services. Governments receive tax revenues from mineral production, which are available to fund education, health care, roads, electric-power supplies, and other forms of infrastructure (Eggert, 2001 and Power, 2007). Foreign direct investment, Balance of payments, Human capital development and social investment are other benefits of mineral industry. The mining industry makes a major contribution to the economy of mineral rich countries. It is a very important force in the global economy, occupying a primary position in the supply chain resources. Despite this fact, its role varies and greatly differs at national level from an economy to another (Dorin et al., 2014).

Minerals are essential in a large number of industries such as constructions, electronics, glasses, and metals. Mining is economically critical for millions of the world's poorest people with some 50 countries being significantly dependent on mining (ICMM, 2014). The Contributions of mining to economic of countries with low or middle national income, where mining brings significant direct economic benefits, are presented in Table 1.

Table 1. Contributions of mining to low and middle income economies in resource rich countries (ICMM, 2012).

Mining benefits	Share in the contries
Foreign direct investment (FDI)	60–90% of total FDI
Government revenue	30–60% of total exports
Government revenue	3–20% of government revenues
National income (GDP*)	3–10% of total national income
Employment	1–2% of total employment

*. Gross Domestic Product

Mineral market has uncertainty because more of them are trading in global markets. These lead to some fluctuations that are harmful effects on countries whose economies are based on mineral production. The volatility of mineral earnings makes it difficult for developing countries to plan investment because of the tendency to induce sudden swings in mineral revenues from the mineral sector. The aim of this paper is providing a method for achieving sustainable revenue for these mineral countries. The proposed method is based on Markowitz's modern portfolio theory that introduced in 1952.

This paper demonstrates how governments can use portfolio-optimization methods to determine a set of mineral productions that provides the minimum risk for a given level of revenue.

2. MODERN PORTFOLIO THEORY

The mean–variance framework pioneered by Markowitz (1952) has long been recognized as the cornerstone of Modern Portfolio Theory (MPT) and has been widely adopted and applied in both academia and industry (Yao et al., 2014). In the portfolio selection problem, given a set of available securities or assets, one want to find out the optimum way of investing a particular amount of money in these assets. Each one of the different ways to diversify this money between the several assets is called a portfolio. For solving this portfolio selection problem, Markowitz (1952) presented the mean-variance model, which assumes that the total return of a portfolio can be described using the mean return of the assets and the variance of return (risk) between these assets. The portfolios that offer the minimum risk for a given level of return form what it is called the efficient frontier. For every level of desired mean return, this efficient frontier gives us the best way of investing our money (Fernández and Gómez, 2007). MPT is a mathematical problem. According to Markowitz, investors could virtually eliminate their exposure to the risks unique to individual securities by choosing stocks that do not move precisely together. An investor is supposed to be risk-averse, hence he/she wants a small variance of the return (i.e. a small risk) and a high expected return (West, 2006). MPT is typically applied to common stocks. However, it can also be applied to bonds if there are risks with respect to default, exchange rates, inflation, etc. (Muller, 1987)
When assets are combined in a portfolio, the expected return is a weighted average of the individual asset's expected return. The weights are the proportions of these assets held in the portfolio. The portfolio risk is however more complex. The portfolio risk depends not only on the weights and the individual risks but also on the correlation between assets. The correlation coefficient, ρ, (also written as R^2) measures joint movements between the two variables, how they fluctuate together. The value can vary from –1.0 to +1.0 as illustrated in Figure 1. Although for most variables, the correlation coefficient falls somewhere between these two values. The risk is at its maximum when all correlations are perfectly correlated (+1). In this case, assets are substitutes for each other, which mean that as one of the variables increase or decrease in value, so does the other in exact proportions. When the correlation is -1.0, the return are perfectly negative correlated meaning that as one of the variables increase or decrease in value, so does the other in opposite proportions. The correlation coefficient for assets without any correlation at all is zero (Sandberg, 2005). Effective diversification is finding risky assets with as low correlation as possible. Zero correlation results in that the assets interact independently of each other. One asset's movement does not affect another asset's direction, consequently efficient diversification is accomplished. A compounded portfolio with an overall low

correlation is crucial for investors' that aims to diversify in order to eliminate the risk (Sharpe, 2000).

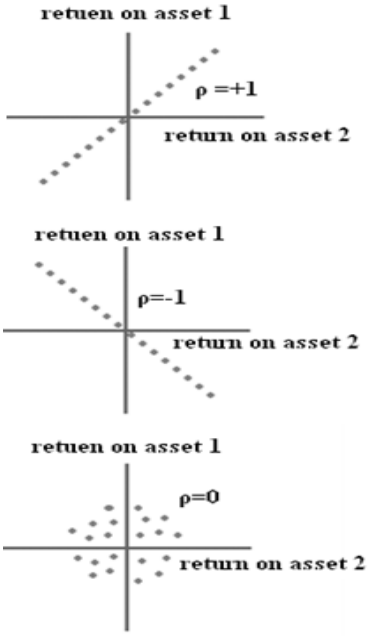

Figure 1. Correlation analysis of two assets' returns (Sandberg, 2005).

Figure 2 illustrates four concepts of portfolio. A feasible portfolio is any portfolio whose proportions sum to one. The feasible set is the set of portfolio means and standard deviations generated by the feasible portfolios; this feasible set is the area inside and to the right of the curved line. A feasible portfolio is on the envelope of the feasible set if for a given mean return it has minimum variance. Finally, a portfolio is efficient if it maximizes the return given the portfolio variance (or standard deviation). The set of all efficient portfolios is called the efficient frontier; this frontier is the heavier line in the graph (Benninga, 2008).

The mathematical form of standard Markowitz mean-variance model for the portfolio selection problem is as follows (Markowitz 1952):

$$\text{minimize} \sum_{i=1}^{N} \sum_{j=1}^{N} x_i \, \sigma_{ij} \, x_j \qquad (1)$$

Subject to:

$$\sum_{i=1}^{N} \mu_i x_i = R \qquad (2)$$

$$\sum_{i=1}^{N} x_i = 1 \qquad (3)$$

$$0 \leq x_i \leq 1 \ , i = 1, \ldots, N \qquad (4)$$

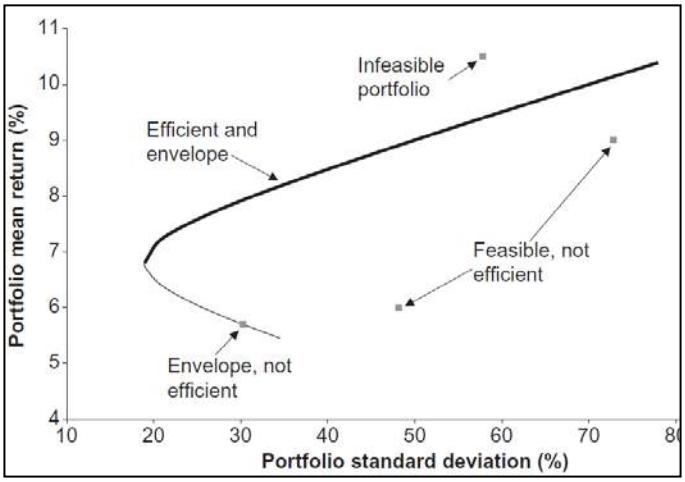

Figure 2. Efficient frontier and feasible portfolios (Benninga, 2008).

where N is the number of assets available; μ_i is the mean return of asset *i*; σ_{ij} is the covariance between returns of assets *i* and *j*; *R* is expected return of portfolio and x_i is the decision variable that represents the proportion of capital to be invested in asset *i*.

Equation 1 minimizes the total variance (risk) associated with the portfolio while Equation 2 ensures that the portfolio has an expected return of *R*. Equation 3 ensures that the proportions add to one. In Equation 4 the proportion held in each asset is between zero (minimum amount) and one (maximum amount). This formulation (Equation 1-4) is a quadratic programming problem and nowadays it can be solved optimally using available software tool. By solving the above optimization problem continuously with a different *R* each time, a set of efficient points is traced out. This efficient set called the efficient frontier and is a curve that lies between the global minimum risk portfolio and the maximum return portfolio. In other words, the portfolio selection problem is to find all the efficient portfolios along this frontier (Chang et al. 2009).

The portfolio's variance in matrix notation, can be written as

$$Var(r_p) = X.S.X^T \qquad (5)$$

$$X = [x_1, x_2, \dots, x_n], \quad X^T = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix},$$

$$S = \begin{bmatrix} \delta_{11} & \delta_{12} & \delta_{13} & \cdots & \delta_{1n} \\ \delta_{21} & \delta_{22} & \delta_{23} & \cdots & \delta_{2n} \\ \delta_{31} & \delta_{32} & \delta_{33} & \cdots & \delta_{3n} \\ \vdots & & & & \\ \delta_{n1} & \delta_{n2} & \delta_{n3} & & \delta_{nn} \end{bmatrix} \qquad (6)$$

3. METHODOLOGY

The proposed method includes a number of steps as follows:

- Identifying of mineral resources of the country
- Calculating of mineral returns and their variance-covariance matrix and mean
- Modeling of problem as a portfolio optimization problem
- Solving the model under quadratic programming
- Finding the optimize portfolio (minerals that should produce)

4. APPLYING MPT TO IRAN MINERALS MARKET

To evaluate the performance of the MPT model in minerals market, Iran mineral sector is selected as a case study. Iran produces a wide variety of minerals therefore its mineral sector has enough potential for using the proposed model.

Iran has more than 68 kind of mineral and total country reserve is 43 Billion MT, with an estimated value of 700 B US$. Iran Export of mines and mining industries was around 8 Billion US$ last year. The mines and mining industries employed more than 620000 employees in Iran. Market Share of mine and mining industries in Tehran Stock Exchange is more than 25% of the total value equal to 30 B US$ (IMIDRO, 2014)

The country was estimated to account for about 9% of the world's output of gypsum and pumice; more than 2% of the world's output of barite, feldspar, and sulfur; and more than 1% of the world's output of cement, industrial (or glass) sand, molybdenum, and nitrogen (USGS, 2012).

In accordance with the result of "WORLD-MINING-DATA" (Reichl et al., 2013), Iran is one of the most important mineral producers in the world, ranked among 15 major mineral-rich countries (Fig. 3).

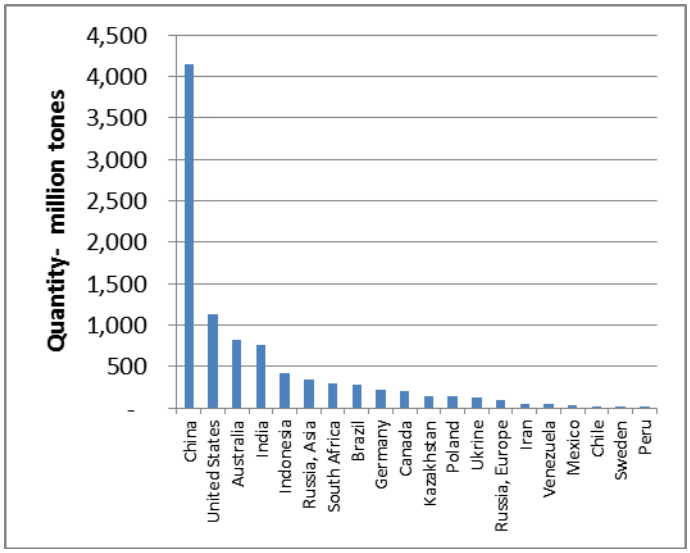

Figure 3. 20 largest producer countries 2011 (without oil, gas and construction minerals).

The mining sector's (includes exploitation and mineral processing) contribution to the Iran economy is only about 1% and employ 0.38% of the country's workforce with 84922 employees. Iran mineral production's value is presented in Figure 4.

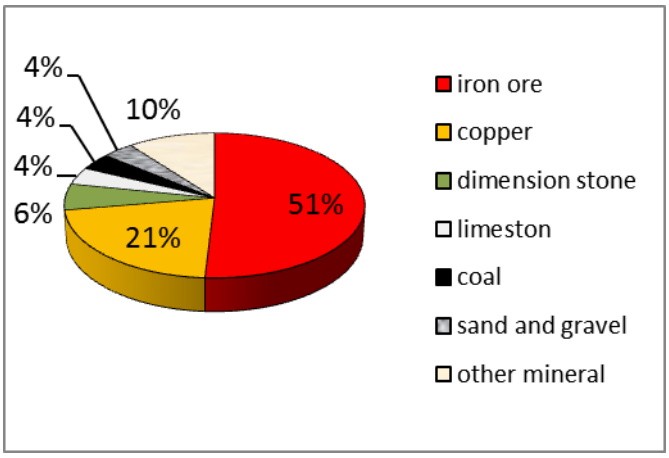

Figure 4. Iran mineral production's value in 2012.

According to the Figure 5, productions of six mineral that have highest value in Iran are include: iron ore, copper, dimension stone, limestone, coal, sand and gravel. The share of other minerals is about ten percent of the country's mineral production. A detail information of Iran minerals product

between 2012 and 2013 is presented in Table 2.

Table 2. Detail information of Iran minerals market in 2012-2013.

4.1. APPLICATION OF MPT

The MPT has been applied to the Iran mineral market for reducing of mineral revenue risk in national level. Iran mineral sector's historical data (related to Production and revenue) is collected from 2005 to 2012. This information was gathered from Iran Statistical Yearbooks. Then the minerals unit price is calculated from its annual income divide by production tonnage. Based on unit prices and using Equation 8, the minerals return is calculated (Table 3).

$$r_{i,t} = \frac{p_{i,t}}{p_{i,t-1}} - 1 \qquad (8)$$

where, $r_{i,t}$ is yearly returns of the mineral and metal i at the year t; $p_{i,t}$ is the price of mineral and metal i at the year t and $p_{i,t-1}$ is the price value of mineral and metal i at the year t-1.

The mean and standard deviation of minerals return are presented in two last row of Table 3. Covariance matrix also is presented in Table 4.

Table 3. Annual returns of Iran's mineral value per ton.

The MPT model was solved using Matlab software. The efficient frontier curve and share of mineral in optimal portfolio are shown in Figures 5 and 6 respectively. Figure 5 explains the risk value of efficient portfolio in a given return. for example, if the portfolio return is 20%, then corresponding risk is 12%. Figure 6 describes that what kind of minerals are in the portfolio and how much are their shares. for example in the return of 20% , the share of coal, iron ore, copper, sand and gravel, dimension stone, limestone and other minerals are 1, 7, 0, 47, 0, 0, 45 respectively.

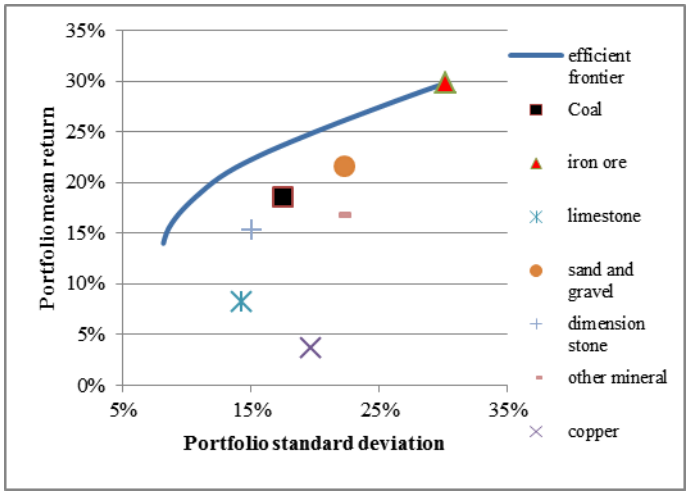

Figure 5. Efficient frontier of Iran mineral market

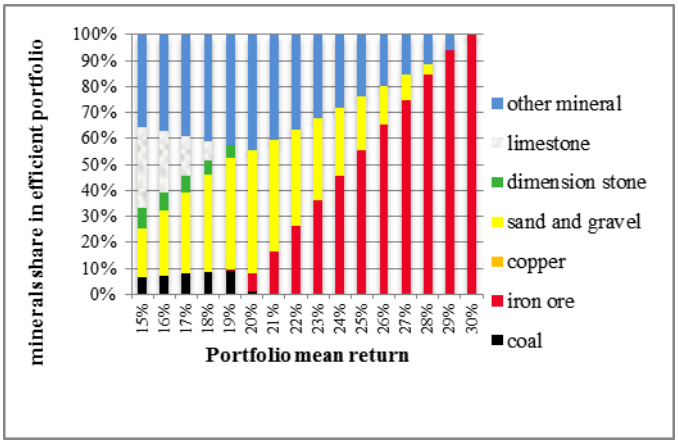

Figure 6. Share of mineral in optimal portfolios

5. DISCUSSION

Based on efficient frontier (Fig. 5), the efficient portfolios' return varies between 3.7% (as a minimum) and 29.8% (as a maximum) that is related to copper and iron ore return respectively. It means that the optimal portfolio returns (in terms of no short-selling ($x_i \geq 0$), which was applied in the model) is between the minimum and the maximum returns of minerals. On the other hand, the corresponding risk of the efficient portfolios varies between 8% and 30%. According to Table 3, the minimum risk of mineral is 14.3% that is related to limestone. Therefore, the risk of optimal portfolios can be less than the minimum risk of minerals.

To achieve the higher return in mineral market, one need to borne more risk. In low return (for example 12% in Fig. 5) risk is low (8%) but in higher return (for example 24%) risk is higher (18%). Generally, minerals with higher risk are contributed highly in the efficient portfolio. For example iron ore in Figure 6, with a risk of about 30% has the largest share in the optimal portfolios that their returns are more than 23%.

Figure 6 shows the share of minerals in efficient portfolio. According to the Figure 6, there is not any comprehensive efficient portfolio that contains all the minerals. For example in return of 24%, the share of mineral is presented in Table 5. The quantity of mineral in this return also, is presented in Table 5.

Table 5. Optimum portfolio of mineral production based on MPT – return 24 %.

Description	Ls	DS	S-G	Cr	Cp	IO	Co
Share in portfolio-%	0	46	0	26	0	0	28
Current year revenue - 1000000 IRR	101209836						
Share in portfolio-1000000 IRR	0	46327545	0	26344320	0	0	28537971
Unit price- 1000 IRR/ton	1372	1295	10719	40	416	32	165
Production - ton	0	35774000	0	658608000	0	0	172967400
Sum of productions-ton	867349400						

If the decision maker (government) decides to select the optimum portfolio in return of 24%, the mineral production in future year will be increase from 340461317 ton (Table 2) to 867349400 ton (Table 5). This is an inaccessible production because there is not enough capacity in the country for Multiplier production of some minerals. For example in this case (optimum portfolio in 20% return) the production of sand and gravel should be extended more than 10 times. It needs to capacity building that it takes time. Additional production of mineral also, may not use in the country or for export market. There another problem in the result o MPT model. Production of some mineral is stopped that it leads to the closure of mines and related factories. In this case (optimum portfolio in 20% return) production of coal, copper, dimension stone and limestone should be stopped.

For solving the issue, the minimum and maximum limits of production should be added to the model. Therefore the decision maker needs to study each mineral market and identify the upper and lower bound of each mineral's production level in the country.

To evaluate the performance of the MPT model in the Iran mineral market, we want to evaluate that how much MPT models reduce the mineral's portfolio risk. Based on information that is presented in Table 2, the expected return of Iran mineral market portfolio is:

$$E(r_p) = \sum_{i=1}^{N} \mu_i x_i = (0.185 \times 0.038 + 0.298 \times 0.509 + 0.037 \times 0.214 + 0.216 \times 0.037 +$$

$0.153 \times 0.059 + 0.082 \times 0.039 + 0.168 \times 0.104 = 20.44\%$

The variance is calculated based on given data and Equations (11-13):

$$[0.0382 \quad 0.5092 \quad 0.2142 \quad 0.0371 \quad 0.0586 \quad 0.0388 \quad 0.1038] \times$$

$$\begin{pmatrix} 0.0306 & 0.0429 & 0.0190 & 0.0224 & 0.0092 & 0.0070 & -0.0031 \\ 0.0429 & 0.0911 & 0.0276 & 0.0394 & 0.0255 & 0.0285 & 0.0013 \\ 0.0190 & 0.0276 & 0.0387 & -0.0003 & 0.0010 & -0.0013 & 0.0111 \\ 0.0224 & 0.0394 & -0.0003 & 0.0498 & 0.0231 & 0.0143 & -0.0232 \\ 0.0092 & 0.0255 & 0.0010 & 0.0231 & 0.0228 & 0.0105 & -0.0082 \\ 0.0070 & 0.0285 & -0.0013 & 0.0143 & 0.0105 & 0.0204 & -0.0144 \\ -0.0031 & 0.0013 & 0.0111 & -0.0232 & -0.0082 & -0.0144 & 0.0483 \end{pmatrix} \times \begin{pmatrix} 0.0382 \\ 0.5092 \\ 0.2142 \\ 0.0371 \\ 0.0586 \\ 0.0388 \\ 0.1038 \end{pmatrix} = 0.039$$

Its value is $var(r_p)= 0.039$ and standard deviation (risk of portfolio) is 0.197. The risk of portfolio at certain return (20.44%) is show in Table 6.

Table 6. risk reduction value in Iran's mineral market using MPT models.

	Return	Standard deviation (Risk)	Risk reduction
Current portfolio	20.44%	19.70%	
Optimum portfolio	20.44%	12.50%	36.54%

According to Table 6, the risk reduction value of minerals portfolio in MPT model is 36.54%. With accordance to the result, a significant amount of risk reduction shows the efficiency of this method.

6. CONCLUSIONS

There is a portfolio of minerals production in the mineral rich countries with variety of minerals that is sometimes necessary for governments' revenue. Because of some changes in the mineral market, achieving to the certain revenue may not feasible. The main objective of this paper is reduction of such risk with using diversification via MPT model. In this regard, the MPT model was used. This model was applied in Iran minerals market as a case study. Some important minerals with share more than 4% of total mineral income of Iran were selected. Remained minerals with less than 4% share are considered as "Other mineral" in the assets list. The result of MPT model was plotted in the efficient frontiers. In a certain return, the risk value of optimal portfolio was obtained from the model and compared with Iran's current mineral market portfolio. The result showed that using the MPT model might lead to decrease of government's return risk around 37% then to current situation. Because of limitation in the mineral production capacity in each country, the result of MPT is acceptable when the decision maker consider the mineral minimum production level. Using the MPT model, governments would be able to select an optimal portfolio of minerals to meet their requested revenue while complying with production restrictions. At the same time, governments seek to control the overall risk of the portfolio. The application of portfolio optimization problem is attractive because it is able to show the result of the mineral production strategy. The proposed method can provide an efficient and convenient tool for investors (governments or mineral international companies). With different risks, investors are able to find efficient portfolio based on a fixed amount of assets.

3D Ore Model and Resource Estimation of Garpenberg North, Garpenberg Mine, Sweden

N. Fjellström
M.Sc Mining Engineer,Boliden, Skelleftea, Sweden

ABSTRACT This paper presents Boliden's methodology upon preforming modeling and resource estimation of the North ore body of Garpenberg mine. Programs used in the evaluation are Leapfrog Geo, Snowden Supervisor and Datamine. In 1997 the first drill hole for the North ore body was made and it intersected a Zn-Pb-Ag mineralization. The finding was hosted within a dolomitic marble in an area where barren hanging wall lithologies were expected. Follow-up drilling showed the Kaspersbo ore body to be a silicified dome like sub structure slightly offset from the northern limb of Garpenberg syncline; most likely structurally controlled. The mineralization within the dome structure is hosted within dolomitized marbles, pyroxene and amphibole skarns and altered footwall volcaniclastics. In 2013, as drilling progressed along strike to the east, it became apparent that what had initially been referred to as the northern extent of the Kaspersbo deposit is essentially the depth extension of the main North ore deposit.

Keywords: 3D modelling, resource estimation

1 INTRODUCTION

Mining of the deposits at Garpenberg, Central Sweden, began way back in the 13th century and the oldest letters patent still in existence for mining operations at Garpenberg were issued in 1354 by Swedish King Magnus Eriksson. This means that Garpenberg is one of the oldest mining areas in the world that is still operational. Boliden acquired Garpenberg in 1957 and exploration work has since resulted in a substantial increase in its ore reserves.

Garpenberg mine (Figure 1) is located near Hedemora, 157 km north-west of Stockholm, Sweden.

Today, Garpenberg mine produces complex ores containing zinc, lead, silver, copper, and gold, and it is this metal mix that has contributed to the areas favorable cost position. Successful exploration, coupled with modern technological development, has enabled an expansion of the Garpenberg mine. Thus, production will increase from 1.4 to 2.5 million tonnes of ore per year in 2015 and make Garpenberg one of the world's most cost-effective and modern underground mines.

Ore Reserves and Project Evaluation Division within Boliden has been assigned to create a resource block model for the North part.

The aim of the paper is to present the resource estimation methodology that Ore Reserves Division within Boliden applies for the resource estimates of Boliden mines and resources.

Figure 1. Location of the Garpenberg Mine

2 GEOLOGY

Regional setting; the geology of the Bergslagen region is characterized by successive generations of intrusive rocks that surround multiple inliers, the latter consisting primarily of felsic metavolcanics and metasedimentary rocks formed ca. 1.89 – 1.91 Ga. These supracrustal inliers can extend to 2km in depth and are often highly deformed and metamorphosed. Importantly; the majority of the many mineral prospects in Bergslagen are associated with these volcaniclastic successions, including Garpenberg (Figure 2) (Stephens *et al*., 2009).

The Garpenberg mine exploits a series of polymetallic deposits hosted within a NE-SW trending syncline which is *ca.* 15 km long and 7 km wide (Vivallo, 1985). The deposits are, for the most part, hosted along the same stratigraphic level within the predominantly rhyolitic sequence. This succession is considered to have been originally formed within a large, shallow marine depositional environment where pyroclastic flow material was abundant during multiple periods of volcanic activity. Bedforms and facies associations indicate that the thick footwall succession accumulated mainly below the wave base prior to a change in conditions that enabled the formation of the limestone unit that is intrinsically linked to all of the Garpenberg sulphide deposits (Allen, 1999).

This limestone unit is thought to represent a volcanic hiatus during which relatively stable and shallow sub-wave base marine conditions prevailed; facilitating the development of an extensive stromatolitic reef. The overlying lower hanging-wall stratigraphic package represents a later depositional environment characterized by uplift, exposure, erosion and shallow water environments, followed by subsidence to deep water conditions (Allen *et al*., 2003).

The Garpenberg ore deposits vary somewhat in style depending on their origin and subsequent location within the sequence, from massive in-situ mineralization associated with the altered Limestone unit found along the footwall – hanging wall contact, to tectonically remobilized ‘bands’ of ore that run sub-parallel to the dominant footwall foliation.

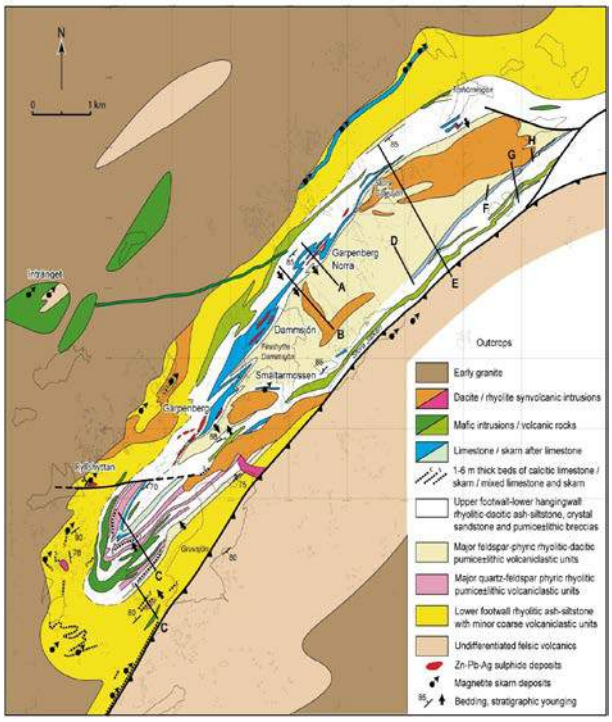

Figure 2. Geological map of Garpenberg region (Allen *et al.* 2003)

3 STRUCTURE

Regionally, the Garpenberg syncline has a complex geometry and it has been generalized (Allen, 1999) that the entire down dip extent of the Garpenberg North deposit is characterized by a series of doubly plunging to locally flat-lying parasitic folds.

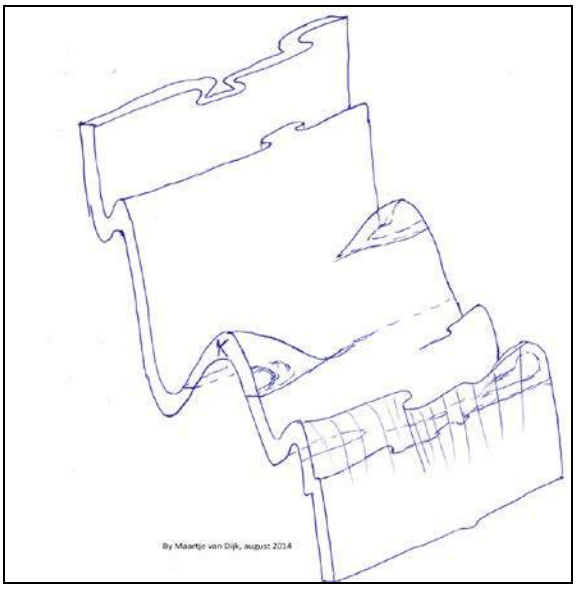

Figure 3. Sketch of the Kaspersbo structure (“K”) within northern limb of Garpenberg syncline (Maartje van Dijk, 2014)

One such structure is the Kaspersbo deposit structure is located immediately west of the Garpenberg North deposit between the 900m and 1150m level and is understood to be a dome-like antiform structure, stemming from the main northern limb of the syncline. (Figure 3) Accordingly, ore zones are broader on the upper reaches of the antiform where they are compressed and the 'double dipping' dome like structure results in significant thickening of the mineralized sequence along the lateral extent (Allen et al. 2003), making it an attractive prospect. Due to the proximity of Kaspersbo deposit to the western extent of the target 'Garpenberg North towards depth' mineralization, the two deposits are structurally interconnected between 990 – 1250m levels, which are difficult to interpret or define. In this study, the working 'boundary' between Kaspersbo deposit and north lenses was set at the eastern extent of the dome structure. This 'boundary' is evident in grade modelling whereby the altered limestone hosted 'in-situ' style mineralization that characterizes the Kaspersbo deposit has a consistently higher Ag grade than the Garpenberg north lenses (Figure 4).

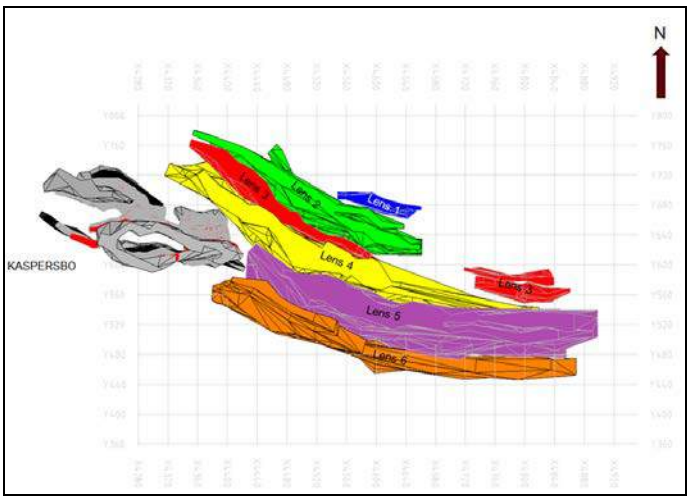

Figure 4. Garpenberg North lenses between 990-1250 z in top view

4 EXPLORATION DATA

4.1 Drilling

The majority of the drilling data utilized in this calculation was carried out by Near-Mine exploration during 2013 and 2014. The aim of this programme was to extend the 50 m by 50 m resource drilling of 'Main ore' ore deposit to the east of Kaspersbo from 4400Y to 4850 Y between 1000-1250Z from the 1080 exploration drift (Figure 4). The exploration programme consisted of 45 drill holes drilled during 2013, followed by further 16 drill holes in 2014, totalling 16600 meters of drilling over 10 profiles with a N-S orientation (local mine grid). This programme also included complimentary drilling on profiles 4400 Y, 4500 Y and 4550 Y with two oblique (local grid west) profiles from 4650 Y where further 'in-fill' data was required (Figure 4). The interpretation and digitization of geological sections and preliminary ore calculations were carried out in conjunction with core logging.

The recent programme of resource drilling was a structured follow-up of earlier drill testing that began in 1997 when the target area was tentatively explored from, 870 Z, 900 Z and 990 Z respectively. Latterly, in 2007 the western extent of the mineralization was tested from the 1080 Z exploration drift.

All cores have been drilled with T56 drill rods (hole diameter 56.3mm) except on the rare occasion where technical issues have required that smaller diameter rods be utilized over short intervals of perhaps 2-3 meters.

4.2 Sampling Data

All drillcore has been logged using WellCAD logging software. Core has been sampled so that any interval featuring visible sulphides or potential to host mineralization (based on lithological and / or mineralogical parameters) has been assayed. During the 2013 and 2014 exploration programme, ca. 83% of all core drilled was assayed. Core that remained unsampled was, for the most part, either barren footwall intersected prior to mineralization or barren hanging wall intersected when drilling had exited the system.

4.3 Surveying of Drill Holes

All drill holes that are longer than 100 m are surveyed with Reflex Maxibor. Maxibor is an optical method to measure changes in slope and direction.

4.4 Geophysical Surveys

No downhole geophysical surveys have been carried out on this drilling.

4.5 Logging and Coding

Logging was carried out digitally on WellCAD software. Prior to logging all core is measured to check for correct core length and any possible core loss. For a list of lithologies used in logging see under stratigraphy in chapter seven. Rock quality is recorded during logging by noting attributes which are known to affect operations at Garpenberg. Attributes found most to affect rock stability here include structure, mineral and rocktype. Primarily, logging of structural attributes with respect to delineating rock quality aims to record instances of crushed rock and schistocity, quantified by intensity. Any schistose rock type is per automatic included in this classification. Perhaps most importantly, certain minerals must be recorded as they are known to cause instability during drifting and mining operations; specifically talc and chlorite.

4.6 Sampling and Sample Preparation

During 2013 & 2014, *ca*. 5850 core samples were taken from diamond drill core that had intersected the study area. Sample intervals do not exceed 3.5 meters (minimum length of 0.85 m) and are determined by key geological factors such as lithological boundaries, alteration zones (where deemed relevant) and observed variations in sulphide content. If for example a barren dyke is intersected within a mineralized zone then it too is sampled so as to maintain data availability for subsequent modeling of the ore zone. Drill core is cut on site in Garpenberg and half core samples are sent for preparation, including drying, crushing, splitting and pulverizing. Pulps are sent for assay in Vancouver where they are analyzed for Au, Ag, Cu, Zn, Pb and S utilizing aqua regia digestion followed by atomic absorption spectrometry (Zn, Cu, Pb), leco furnace and Infrared Spectroscopy (S) and fire assay (Au and Ag).

4.7 QAQC System and Results

Check assays (on average one duplicate every 20^{th} sample) were analysed at laboratory for QAQC. The two assay results from a single pulp sample are monitored over time to identify for any variation in results. Blanks and Boliden in-house standards (reference) samples are also used as part of the QAQC routine. The assays from standards and blanks are regularly monitored for inconsistencies that may represent poor quality control at the laboratory, such as sample ‘mix up’ or contamination. The QAQC system has been developed to ensure that a proportional number of blank samples, standards are sent relative to the actual number of samples from each drill hole.

5 RESOURCE MODEL

5.1 Geological Interpretations and Mineralization

Geological Interpretations are based on geological knowledge over the area and geological logging data which has been gathered through underground diamond drillings.

Mineralised boundaries were drawn within the massive and semi massive sulphide.

In accordance with existing understanding of the ‘Main ore’ deposit, drilling has shown that it is dominated by tectonically controlled remobilized Zn-Pb-Ag (with weak inconsistent Cu-Au) stringer style mineralization. These stringers are often sub-parallel to dominant cleavage and lithological boundaries, and can therefore appear to be beds of sulphides (and have historically been interpreted as such). They

are understood to have been tectonically emplaced (Allen, 1999) after or late in the main F2 folding and as such; these zones are essentially mechanically remobilized from primary ore zones.

The 3-4 key mineralized zones run parallel to the dominant structural trends (WNW-ESE in the mine grid) and are sub-parallel to stratigraphy of the footwall volcaniclastics (modelled as Lens 1 – Lens 3). These lower footwall lenses are somewhat discontinuous 'along strike'. The most continuous and indeed broadest of the ore lenses are hosted within the upper footwall along the hanging wall contact (modelled as Lens 4 - Lens 6). In the west of the study area where these lenses boarder the Kaspersbo deposit, improved grades are observed. This is likely influenced by the increased occurrence of higher grade (increased Ag) in-situ style mineralization common along the boundary between the Kaspersbo anti-form structure and the adjacent footwall.

Generally, the footwall hosted remobilized mineralized zones are associated with strong silicification; however less common skarn associations have been observed (possibly a result of local reaction between the remobilizing fluids and localized carbonate occurrences). In the study area, structurally controlled zones of remobilized mineralization are observed to be broader and richer the nearer they are to footwall-hanging wall contact and associated altered carbonate hosted in-situ mineralization. Conversely, zones of remobilized mineralization located lower down in the footwall sequence are weaker and more inconsistent 'along strike'. Especially (and this may be significant) the further east they are from the Kaspersbo anti-form, it is of course unclear what influence the Kaspersbo structure has had (if any) on these remobilized stringers.

This has created a slight paradox in the study area whereby grades and thicknesses of the footwall hosted stringer zones become more prospective at depth (especially in the upper footwall lenses (Lens 5 – Lens 6). However, considering the geometry of the steeply dipping, undulating northern limb of the anticline, these remobilized zones have been assumed to have come from above (Z as opposed to stratigraphy) and would therefore become weaker at depth. That the most prospective lenses are those located within the upper footwall, nearest to or indeed on the actual footwall – hanging wall contact at depth may raise the possibility of an additional source / structure at depth (as yet untested by drilling).

East of Kaspersbo, the altered limestone horizon extends along strike from silicified dome at 4400-4500 Y (Figure 3 and Figure 4) and progressively diminishes as it is replaced by a skarn horizon which also follows the hanging wall-footwall contact. This continuous skarn horizon subsequently tapers out until 4600 Y where it essentially disappears. There are however, discontinuous relatively small skarn lenses at this stratigraphic level at 4800-4850 Y. This discontinuity along the contact could be a result of structural deformation and /or extreme alteration that has overprinted original lithologies. Generally, mineralized zones follow this diminishing trend eastwards, especially between 1000 – 1150 Z. East of 4700 Y the most prospective target is the upper footwall lenses Lens 5 and Lens 6 at depth (below 1150 Z); these are currently open along strike east of 4900 Y and at depth below 1250 Z.

Interpreting the ore distribution is not straightforward; although footwall hosted remobilized ore is a common feature of the Garpenberg mine, at the Garpenberg North main ore zone between 990 and 1250 Z it is evident that the most prospective zones are those located in the upper footwall nearest hanging wall contact. That these remain open along strike to the east of recent drilling and towards depth below 1250 Z suggests that the ore distribution is not controlled by stratigraphy alone, it is also possible the lenses are off-set along strike by lateral shearing. Observations along the stratigraphic contact show that host lithology does not appear to affect the presence/absence of the ore in any significant way.

In addition, occurrences of disseminated Willemite (Zn2SiO4) have been observed within the footwall sequence; such disseminations are however inconsistent and do not appear to be directly associated with the remobilized massive sulphide mineralization.

5.2 Estimation and Modeling Methodology

5.2.1 Zn – Ag grade shells

Ore boundaries have been interpreted based on massive and semi massive sulphides in combination with Zn and Ag analyses. Zn and Ag grade shells (Figure 5 and Figure 6) have been created in Leapfrog Geo software to understand the difference in different domains visually. Before interpretation, each domain has been checked against geological consistency, single grade population and single continuity orientation. Domains have been further studied statistically in Snowden Supervisor.

Based on geology and grade shells, 6 different mineralized domains have been interpreted.

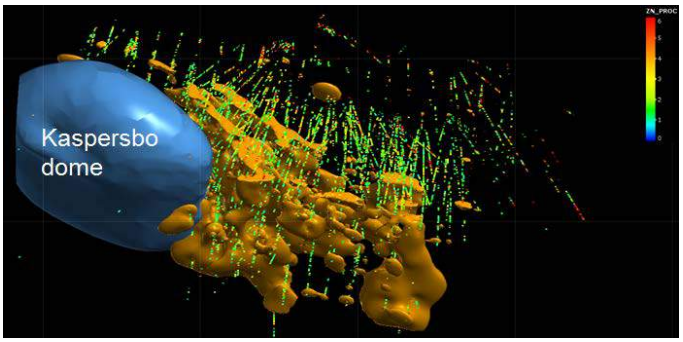

Figure 5. Zn grade shells (Zn>2%) in isometric view, Leapfrog Geo

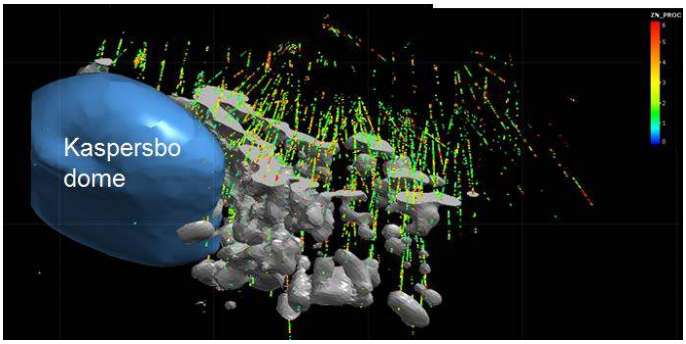

Figure 6. Ag grade shells (Ag>70ppm) in isometric view, Leapfrog Geo

5.2.2 Assay statistics

Geostatistical studies have been completed in Snowden Supervisor in order to understand the high and low grade tendencies and relation between geology and the data in Main ore region.

In addition, composite length analysis, top-capping and variogram parameters for Kriging were also analyzed in Snowden supervisor.

5.2.1.1 Composite length analysis

To be sure about the coverage of the sampling, a log histogram over different analyzed section lengths has been plotted. In the histogram, dominating length was observed around 3m which was corresponding 90% of the analyze lengths. The effect of change in composite length on zinc and silver grades has also been studied.

Assay mean and variance for each element has been calculated in Datamine and plotted in Excel. Later on, the compositing has been performed by using 10 different composite lengths and length weighted means and variances have been calculated for each analyzed section length and added on the graphs.

5.2.1.2 Declustering and compositing

For declustering, decluster by cell weighting technique has been used. By this technique, the data is covered by a grid and each sample in the data has a weight according to number of samples within each cell in the grid. This technique is used to decrease the effect of a high grade sample on mean grade.

By compositing, sample grades have been weighted in every 3m.

5.2.1.3 Box-and-whisker plot

6 different domains within the Main ore zone have been compared with Box-and-whisker plot in order to see the grade trends by compared to each other.

5.2.1.4 Top-capping

Extreme grades in a data set can cause wrong grade calculation. Since high grades of Au, Ag and Pb have been observed in North lenses, these high values have been re-set to the top capping values. Top capping values for Au, Ag and Pb have been decided according to as follows:

1. Data has been declustered.
2. All data has been plotted for each domain in a log-scale histogram
3. The points where the high grade tail starts in log scale histogram has been selected as top capping values.
4. The selected values have been compared with previous production grades of the mined out areas in the same ore body.

5.2.1.5 Variography

The North ore body consists of 6 lenses. Before the evaluation of the continuity in the domains, hangingwall and footwall lenses have been grouped. With the variography the direction of the lowest difference in grades for the longest distance is set for strike, dip and plunge.

In this study, the grade continuity of the all grades (Au, Ag, Cu, Zn, Pb, S) within ore body have been analyzed. The directions of maximum continuity for Lens 1, 2 and 3 have been chosen according to Lens 4 and zinc element as a reference. For Lens 5 and 6, different continuity parameters have been chosen due to the change in continuity.

5.2.1.6 Kriging neighbourhood analysis

KNA calculations have been carried out in Snowden Supervisor to decide the block size, minimum and maximum number of closest samples, the size of search ellipse and block discretization.

In Supervisor, many different block sizes have been tested and the one which gave the highest kriging efficiency and slope of regression has been selected. The same procedure is also applied for the other parameters.

It has been checked that the block size is neither too small nor not too big for the model. As a rule of thumb, the block size should not be smaller than half of the drill spacing.

Orientation of the search ellipse has been arranged according to variography. The continuity and the geology have been taken into consideration for both the orientation and the size of the search ellipse.

In addition to minimum and maximum number of nearest samples, maximum number of samples per drill hole has been set as a controlling parameter to avoid too many samples from a same drill hole come into the estimation of a block.

Model has been estimated by ordinary Kriging.

5.3 Model Validation

Model has been verified by visual and statistical validation methods. Model validation has been made to understand if the created model is a reflection of a drill hole data.

5.3.1 Visual controls

Visual validation for Zn, Ag and ore value of the blocks have been done in Datamine by comparing the grade of composites with block grades section by section in every 6m. Zn grades comparison is shown in Figure 7.

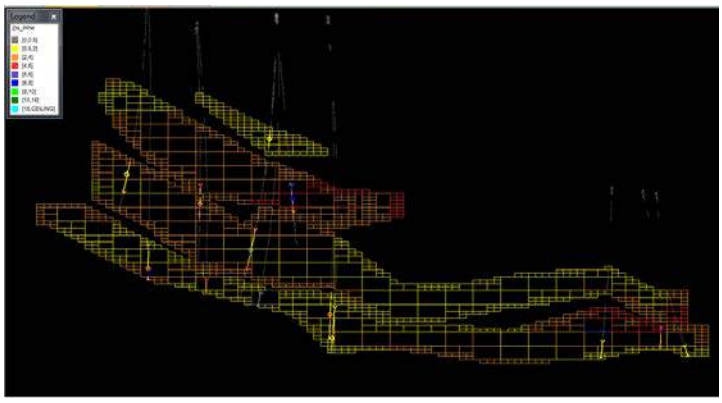

Figure 7. Comparison of Zn grades in block model and composites at level 1230z, Datamine Studio3.

5.3.2 Statistical controls

Statistical controls have been carried out in Snowden Supervisor software. First of all, trend plots have been created for each direction as Easting(x), Northing (y), and RL (z) for Ag and Zn (dominating grades within the ore body) grades in block model and composites. The block and composite grades have been compared to see whether both of them are following the same trend in easting, northing and depth.

In Figure 8, validation of Zn grades by Easting is shown.

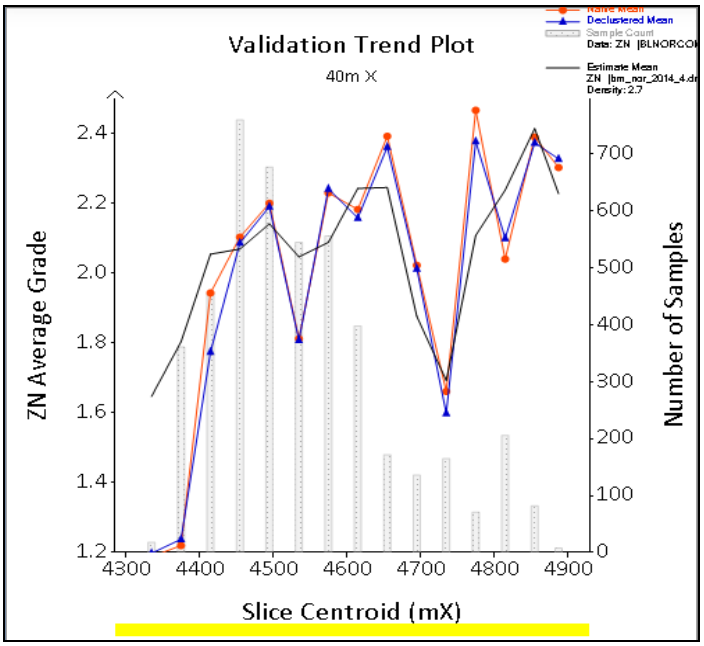

Figure 8. Validation plot for Zn by Easting (X)

Top capping has also been checked if it was too hard on the estimated grades.

The average block grade and the average grade of the drill hole data set has been compared for each domain.

In the analysis the following has been observed:

Excessive peaks in drill hole/composite grades have been smoothed out in the block model. Areas with a limited number of composites show less correlation between the composite grades and the block model grades. In some areas, the block model grades seem high due to a small number of high grade composites affecting a relatively large number of blocks. Moreover, Zn and Ag grade of estimates have been compared with composite grades in Statistical comparison table in Snowden Supervisor and it has been verified that the difference was below 5% (Figure 9)

6 CONCLUSION

In this paper, the methodology of resource estimation that Boliden follows has been described and Garpenberg mine has been selected as an example for this study. Modelling is maybe the most important step to interpret the geology in numbers. New tools and technologies contribute a lot for the accuracy of resource estimation as soon

as the geology and the input data are understood and used together properly.

Advancing Exploration Projects to Production: Critical Inputs for Success

A. Ebrahimi
Principal Consultant at SRK and Adjunct Professor at UBC, Vancouver, Canada

J.P. Siddorn
President, SRK Consulting (Canada) Inc

ABSTRACT "Easy mining" doesn't exist anymore. It takes years to build a mine. A mining project goes through a series of expensive phases before generating a positive cash flow. Exploration is the most uncertain and risky phase of developing a mine. Having a well-defined plan (road map) will increase the success rate of exploration companies. In modern exploration activities goals goes beyond defining only resources. Geotechnical, metallurgical, environmental, water, power, logistics, community and political issues are all examples of additional data collection and assessments that exploration companies need to cover. These are the pieces that must be put together to have a clear picture of potential mine.

Not all exploration activities lead to constructing a mine. Early diagnosis of major problems helps to reduce the general risk of investment as well as reducing the time of developing a mine. This paper highlights the issues and information important to advancing exploration projects to production.

Keywords: Exploration, schedule , planning

1 INTRODUCTION

Mining is a temporary use of land. It starts with a green field, extracts the good materials from the ground and leaves behind a reclaimed land that can be used again. As it can be seen in Figure 1 during its "life" a mining project evolves by going through a number of lengthy development stages: exploration, evaluation, construction, operation, and closure. Although in consequences, exploration, evaluation and construction activities have many overlapping areas.

Mining, in general, is a risky business because it deals with unknowns and uncertainties to the end of its life. This most often produce complications. As the first segment in the chain of mining activities, exploration companies take most of the risks. Deposits are mostly buried, generally of unknown shapes and have to be sampled by expensive methods such as drilling. There are many other uncertainties and unknowns such as marketing, environmental and political issue that affect the destiny of a project. In addition to geology these types of risks are also need to be measured in exploration stage.

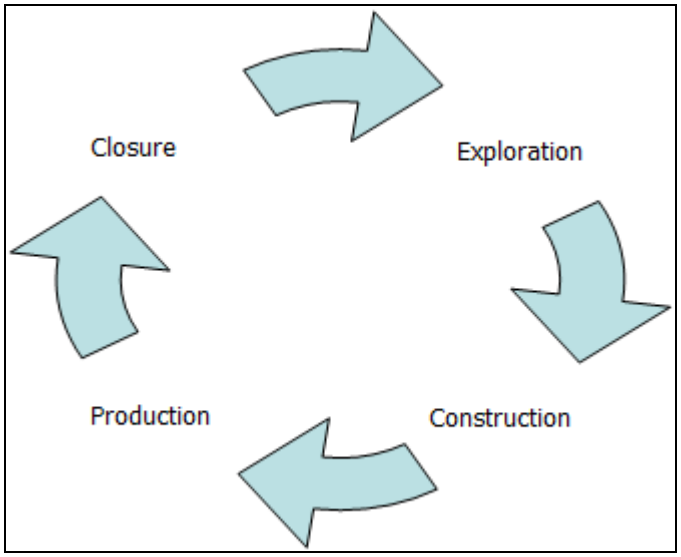

Figure 1. Mine development stages.

Exploration is art and science of collecting, analyzing and interpreting data. It is a business. Like any other business it spends

time and money and it is expected to return profit.

Not all exploration activities lead to constructing a mine. The success rate for exploration projects vary for different fields and operators. It is between 1 for each 200 in brownfield to 1 for more than 3000 in greenfield projects (Lord, et al.). In past several researches tried to explain the low success rate in mineral exploration and finding a way to improve it. For example Natural Sciences and Engineering Research Council (NSERC) of Canada in 2013 granted $5.1M the initiative researches aiming to increase the success rate of exploration projects in Canada.

Many researchers used statistics and probability distributions to understand and explain the exploration success rate (Kreuzer, et al.). Although exploration activities are associated with uncertainties however it is not entirely a game of cards. There are not many researches and studies that are focused on exploration planning (Mackenzie B.). Exploration planning can improve the economics of exploration activities. If implemented well, collectively, it can increase the success rate of exploration companies.

This paper tries to emphasize on the importance of exploration planning. It presents a generic work flow for activities in development stages and also discusses the importance of having an exit strategy for every exploration project.

2 MANAGING EXPLORATION COSTS

To be successful, every exploration company must overcome several challenges including financial, permitting, community relations, environmental, staffing and logistics. Among these hurdles funding a project can become the biggest challenge for most exploration companies. In addition sometimes exploration companies have limited access to skilled workers, expertise and equipment. For these reasons, managing the limited resources available is one of the most important keys exploration companies need for success.

A common approach to managing exploration costs is to do the work in sequences. The usual steps involved in developing mining projects are: scoping study/preliminary economic assessment (PEA), preliminary feasibility study (PFS), feasibility study (FS), and engineering/procurement (EP). As work progresses, the cost of development increases which usually results in a better understanding of the project. Due to knowledge improvements at every step of development, more accurate decisions can be made about the future of the project. It is expected that the results of a feasibility study will be more reliable than the results of a scoping study.

Although the sequencing of mine development is well accepted among the industry, its details and dynamics (exploration planning) are still not well defined and formulized. The main reason for this is the complexity of mining projects. It is impossible to copy the development plan of a mining project and simply apply it to any other deposit, even if they both look similar. Every project needs a well-defined and detailed individual development plan.

The main goal of sequencing exploration and mine development into stages is to control costs and lower the investment risk. Only the few projects that demonstrate positive outcomes at each stage can go through all these stages. Most projects will be stopped after showing signs of negative outcome or weaknesses. In the early stages of work, such as the scoping study when information is limited, it is difficult to make an accurate project evaluation hence using people that have both extensive experience and general business vision helps to reduce unnecessary iterations. Figure 2 shows the development stages of a mining project and the expected accuracy for each stage. Accuracy of studies varies from +/- 50% in scoping level to +/-10% for feasibility studies.

Based on the success rate of exploration projects figure 2 also suggests the minimum number of projects that exploration companies need to undertake to get to a

producing mine. A company sometimes may need to investigate 100s of grass root projects before it decides to spend millions of dollars in some of the promising ones. A project should NOT advance to higher stage if it doesn't demonstrate reasonable prospects for success. Advancing a project to higher level requires an honest internal due diligence and evaluation.

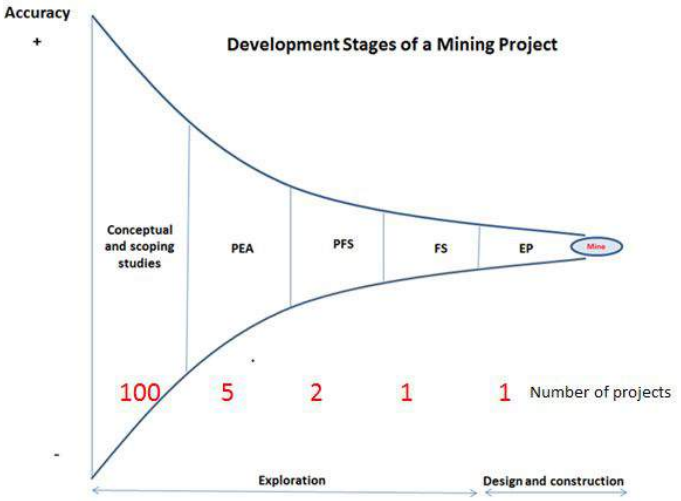

Figure 2. Development stages of a mining project

Exploration costs can vary a lot based on the location of the site, topography, complexity of geology and mineralogy. Therefore it is hard to formulize a budget that can be fit to all projects. To start an exploration project (prospect stage) probably less than a million dollar would be enough however to get the project to a PEA level at least several millions of dollars need to be spent including some initial drilling. Sometimes this may exceeds 10 million dollar. To reach to a PFS/FS level tens of millions of dollars need to be spent for drilling, tests and studies. Figure 3 shows approximate expected costs of developing a medium size base metal mine in today's market and in a well-developed mining region. As it can be seen by the cost of a FS one can cover at least 4 PEA. To reduce the risk of investment exploration companies need to adequately justify advancing each project to higher level.

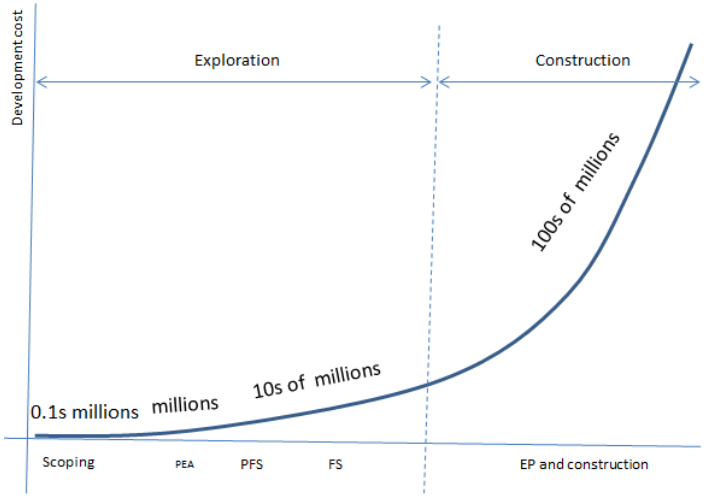

Figure 3. Approximate expected expenditure of a developing mining project

3 DATA COLLECTION CHECK LIST

To properly assess the value of a project a mineral exploration company needs to gather different pieces of data and information over stages of exploration. These fairly diverse pieces of information are collected not only from the ground but also from sources such as local communities, government and market.

Collecting data and information takes time and is costly. To control the cost and to be more efficient information should be collected according to a plan and in a sequence. Not all the information needs to be collected in first stage. Each step must be based on a thorough analysis of data collected in previous stage. For example it is just after geophysics and surface geology that a diamond drilling program should be developed. Even then drilling should start in large grids and in certain areas. Afterward based on the results of the first round of drilling, exploration can be followed with denser drilling and only in a few targeted zones.

Another example is geotechnical drilling that is usually done in more advanced phases when dimensions of the pit and the deposit are relatively known. Or it is premature to perform detailed tailing storage or waste dump design when the scale of mill operation is not known.

For every exploration project it is helpful to develop a check list of the information that is required to be collected in different

phases. Table 1 shows a simple example for data collection check list. In many exploration projects this table can become very sophisticated.

Table 1. Data collection check list,

Data collection task / studies	PEA	PFS	FS
Diamond drilling	✓		
In-fill diamond drilling		✓	✓
Geotehcncial drilling			✓
Metallurgical sampling and tests		✓	✓
Water sampling		✓	✓
Comunity engagement	✓	✓	✓
Strategic planning	✓	✓	✓
…			

4 MINING STUDIES WORK FLOW

Instead of focusing on a single project, exploration companies can be more successful if they work on a number of properties or interests. The properties must be prioritized in order to get investment funds, but the priority list must be dynamic and responsive as the values of the properties will change over time as exploration expenses are incurred and project data is collected.

As mentioned before it is important to realize that most properties have little chance of being developed as a producing mine in the near future. Besides the quality and quantity of the deposit itself, there are many other factors, such as environmental or community issues and poor infrastructure, that could bring a project to a halt. When project studies are planned and managed well, such issues can be detected in the early stages of development. This can help exploration companies allocate their limited resources better and focus on projects that have a better chance of progressing further into development. Making decisions about whether to continue working on a property, or to stop working and shift the focus to other projects, should be the top priority for management team of exploration companies. Shutting down work at a particular property doesn't mean the end for an exploration company.

Every exploration company has the potential to own a mineable deposit, or even to become a producing mining company, if it learns how to plan for it. In order to get there, a well-defined road map must be developed right from the initial step. Figure 4 shows the generic work flow for development stage of a mine. As it is implied from model in Figure 4 an exploration project goes through similar round of activities but in different level in its life. In each level the time and money we spent on the project increases. As a result it is expected to have higher level of accuracy (lower risk) in assessing the project as it goes forward.

Planning is the first and essential activity in all levels of exploration. In its core, an exploration road map includes three components: a work plan (budget and schedule), data collection (execution), and assessment.

The budget must be focused on only one phase and be as detailed as possible. Every expenditure must be well justified. Where, why, and when to spend the money, are the questions that need to be systematically investigated and answered. Every expense must help the company get closer to its target otherwise, the spending is a waste. In exploration planning we must keep in mind that the biggest question in early stages of exploration is whether to proceed to next phase or not.

The schedule must be practical and include all realistic parameters such as logistics, weather delays, and third parties' schedules (such as the availability of mineralogy laboratory). The tasks in a mining project need to be prioritized, because advancing in one task without completing its prerequisites may waste time and money. For example and as mentioned before, it is important to understand when is the right time to start geotechnical drilling or taking metallurgical samples.

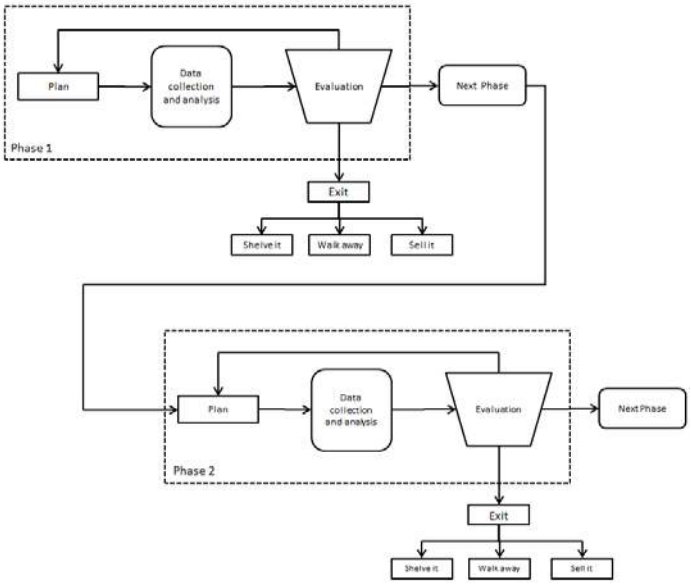

Figure 4. Generic work flow for a mine development phase

At the end of every phase, the project must go through an intensive evaluation. The evaluation must answer the crucial question: should the project be stopped or can it move forward to next phase? Based on the results of the evaluation there are three possibilities for the project:

a) Progress to the next phase
b) Redo the current phase
c) Stop the project

A positive result requires a more advanced investigation into the property. Every phase will point to a list of more specific questions that must be addressed in subsequent phases, where the evaluation process will be applied to a higher level of accuracy. However, until a project reaches the feasibility study phase, its chances of being halted remain high. Therefore, expenses must be carefully controlled to the end. The new plan and budget for each next phase must reflect the specific questions that have been raised in the previous phase(s).

In early stages project assessment or evaluation doesn't need to be complicated and expensive but rather should be robust and comprehensive. The project should be evaluated frequently—usually after major progress in data collection or when a new market outlook is adopted. Data should be collected under standardized procedures and adequate supervision. It is crucial to analyze data as they are being collected. After collection, the data must be well organized and converted into a meaningful format.

In many cases, especially in earlier stages of development, the studies may need to be updated. In such cases, it is necessary to revisit the study plan before making final conclusion for that phase. There are many reasons to do this, including changes in market outlook or company strategy. For example, a common occurrence at the scoping level is the discovery of better drilling targets. Therefore, before making a final decision about the property based on the old plan, it may be more appropriate to change the plan and wait for new drill results. When updating a study it is important to include all the information collected up to that point.

5 EXIT STRATEGY

If project evaluation shows weak result then the possibility of having to abandon the project should be considered. A key to success for exploration companies is often finding the right time to exit from a weak project as well as to find a right project to pursue.

A company's strategy and vision must be well understood and its team needs to be realistic about the company's capacities when a project is being evaluated.

When exiting a project, all possibilities for the property need to be considered. Some projects have the potential to be re-activated in near future, for example, in cases where the prices are higher or community relations are improved. In such a case, the company must understand in detail the costs of keeping all the licenses up-to-date for the shelving period, and be aware of other consequences of staying on the property. In other cases, the scale of project may be too big for the size of the company and the exploration company may consider selling the project or calling for a partner. In the worst case scenario, if there is no promising opportunity available for the project, it is better to walk away from the field as early as possible.

Exploration companies should focus on adding value to a project rather than advancing it at any cost. The value of an exploration property is related to the quality and quantity of knowledge that has been acquired about it. When it comes to an exploration project, “How much is it worth?” is equal to “How much do you know about it?”

6 STRATEGIC MINE PLANNING CAN HELP

Mine evaluation helps for early assessment of exploration projects. This can be done using strategic mine planning method. Strategic mine planning is mine simulation and economic analysis combined. For every phase of development, using knowledge that have been developed it is possible to simulate options that are conceivable for the project. Strategic mine planning is a technique that can help to make fundamental decisions. It is efficient way to guide an exploration or mining company through its development stages. Strategic mine planning can answer basic but fundamental questions such as:

-What should be the mining method?
-What is the optimum range for scale of operation?
-What are the sensitive and insensitive parameters?
-What are the weaknesses and strengths of the project?

In strategic mine planning, once enough information is collected, different production scenarios are simulated so that all the possibilities can be explored. Mine simulation studies the strengths and weaknesses of a project and provides practical advice for improvement. To be effective, strategic mine planning needs a thorough analysis of not only the mineral resources, but also of the company’s whole business and, therefore, requires the input of expertise from different fields.

7 CONCLUSION

The success of exploration companies are related to the amount of planning and evaluation efforts they put in projects. For every exploration project a road map is required to be developed in early stages. Road maps must include details about the data collection, budgets, schedules and evaluation systems. In order to stay on right track, evaluation must be done frequently and before proceeding to a higher level. While focusing on advancing the project to the higher levels, road maps must clearly mark the safe exit doors for every stage of the work.

An Alternative Multivariate Kriging Technique: Covariance Matching Constrained CoKriging

G. Ertunç, A.E. Tercan, F. Atalay
Hacettepe University, Mining Engineering Department, Ankara

ABSTRACT In predicting second-order stationary vector random fields, simple and ordinary cokriging techniques are widely used. In this study, an alternative multivariate kriging technique Covariance Matching Constrained CoKriging (CMCoK) is introduced and compared with ordinary kriging (OK) and its multivariate counterpart ordinary cokriging (CoK). For comparison, Meuse River data are used and results are discussed by means of local accuracy and spatial variability. From the results, it is seen that error variance for CMCoK is considerably less than CoK and OK.

Keywords: Kriging, CMCoK, OK, CoK

1 INTRODUCTION

Cokriging is the extension of kriging to more than one variable. The system is beneficial when the primary variable is under sampled with respect to the secondary variable(s) that are assumed to be correlated with the primary variable. In some applications there are only a few measurements of the samples of interest; the resultant predicated maps have poor resolution and the corresponding uncertainty may bevery large. In such situation it is critical to account for secondary, indirect information that may be more densely sampled (Goovaerts, 1997). If the two variables are spatially cross-correlated , this information can be used to make predictions of the primary variable (Bivand R.S. et al., 2008). Isotopic cokriging requires that the data for the primary and auxiliary variables be measured at all sampling locations. Heterotropic cokriging requires that only some of the sample points contain measurements of both primary and secondary variables (Wackernagel, 2003).

Depending on whether or not the mean of the vector random field is assumed to be known, estimation of a second-order stationary vector random field, i.e kriging, includes two alternatives namely simple and ordinary cokriging (Myers, 1982; Ver Hoef and Cressie, 1993; Wackernagel, 2003). Detailed derivation of cokriging equation systems is given in numerous publications such as Bishop, T.F.A. and Lark, R.M. (2006), Papritz, A. (2008) and Emery, X., (2012)

Multivariate geostatistical estimations are applied in wide range such as mineral resources evaluation (Journel and Huijbregts, 1978; Pan et al., 1993), environmental studies (Singh, V., 2011), remote sensing (Pardo-Iguzquiza, E., 2011), and geochemistry (Wackernagel, 1988; Lark, L.M. et al., 2014).

In this study, Covariance Matching Constrained CoKriging (abbreviated CMCoK in the sequel) is introduced and its performance is tested by means of spatial variability and accuracy. In previous studies, univariate case of covariance matching process based kriging showed promising tool and by this study the multivariate case of the method is compared with ordinary kriging (OK) and its multivariate counterpart ordinary cokriging (as CoK). Covariance Matching Constrained Kriging (CMCK) is an hybrid method that considers local accuracy property in kriging and preservation of spatial variability in stochastic simulation. The method estimates the unknown vector by adding the constraint to match the variance–covariance matrix of estimated values with the variance–covariance matrix of actual values under

unbiasedness constraint, introduced by Cressie and Johannesson, (2001). Various researchers made contributions to this method. Tercan (2004) applied CMCK to a lignite deposit in order to estimate the global recoverable reserve. The study also covers a comparison of CMCK with OK on estimation of quality tonnage curves. Hofer and Hofer and Papritz (2010, 2011) examined the performances of various techniques such as universal kriging (UK), conditional simulation (CS), constrained kriging (CK) and CMCK. Ertunç et. al., (2013) made a comprehensive comparison of techniques used in estimation of coal quality variables in 3D, including CMCK, OK, and CS.

2 METHODOLOGY

Multivariate estimation is useful when primary variable of interest is under sampled, compared with the cross correlated secondary variable. Thus, the cokriging estimate is a linear combination of both primary and secondary data values,

$$Z^*(x_0) = \sum_{i=1}^{n} a_i U(x_i) + \sum_{j=1}^{m} b_j V(x_j) \qquad (1)$$

Where $Z^*(x_o)$ is the predictor of $Z(x_0)$ at location x_0,

$U(x_i)$: a vector with elements of the measured values at location x_i, i=1,…,n,

$V(x_j)$: a vector with elements of the measured values at location x_i, i=1,…,m,

a_i: vector of kriging weights of primary variable, and

b_i: vector of kriging weights of secondary variable.

Exact formulas for cokriging are derived from unbiasedness condition Eq. (2) and minimization of error variance as given in Journel and Huijbregts (1978), Isaaks and Srivastava (1989), Cressie (1991), Goovaerts (1997) and Chiles and Delfiner (2012)

$$\begin{aligned} E\{\hat{U}_0\} &= E\left\{\sum_{i=1}^{n} a_i U_i + \sum_{j=1}^{m} b_j V_j\right\} \\ &= \sum_{i=1}^{n} a_i E\{U_i\} + \sum_{j=1}^{m} b_j E\{V_j\} \\ &= \tilde{m}_U \sum_{i=1}^{n} a_i + \tilde{m}_V \sum_{i=1}^{n} b_j \\ \sum_{i=1}^{n} a_i &= 1, \sum_{i=1}^{n} b_j = 0 \end{aligned} \qquad (2)$$

Minimizing error variance will lead the matrix form of cokriging Eq.(3) as follows:

$$\begin{bmatrix} \Sigma_z & 1 \\ 1' & 0 \end{bmatrix} \begin{bmatrix} \lambda \\ \mu \end{bmatrix} = \begin{bmatrix} C \\ 1 \end{bmatrix} \qquad (3)$$

Where

$$\Sigma_z = \begin{bmatrix} \Sigma_{11} & \Sigma_{12} \\ \Sigma_{21} & \Sigma_{22} \end{bmatrix}, \mu = \begin{bmatrix} \mu_1 \\ \mu_2 \end{bmatrix}, \lambda = \begin{bmatrix} a_i \\ b_j \end{bmatrix}, C = \begin{bmatrix} \Sigma_{10} \\ \Sigma_{20} \end{bmatrix},$$

Σ_{11}, Σ_{22}, Σ_{12}, Σ_{21} are covariance matrices for the primary, secondary data and between them respectively.

Σ_{10}, Σ_{20}: Covariance matrices among the primary, secondary data and target locations.

λ: the weights of primary and secondary variable;

μ: vector of Lagrange multipliers.

Solving for the weights yields,

$$\lambda = \Sigma_z^{-1}(C - 1\mu), \qquad (4)$$

Where,

$$\mu = (1'\Sigma_z^{-1}1)^{-1}(1'\Sigma_z^{-1}C - 1)$$

1, ‘, and $(.)^{-1}$ denote unity matrix, transpose and inverse of matrix respectively.

The CMCK method estimates unknown values such that the variance–covariance matrix of estimated values is matched with the variance–covariance matrix of actual values under unbiasedness constraint. The matching process is achieved by controlling K matrix (Tercan, 2004; Kukush, A. and Fazekas, I., 2005; Ertunç et. al. 2013).

By adding K matrix into multivariate case, the kriging weights can be calculated as follows:

$$\lambda = \Sigma_z^{-1}\left(C - \mathrm{K}(1'\Sigma_z^{-1}1)^{-1}(1'\Sigma_z^{-1}C - 1)\right) \qquad (5)$$

3 CASE STUDY

In this study, very well known Meuse river data is used for testing the performance of CMCoK. For the comparison, besides CMCoK, estimation is made by univariate ordinary kriging and multivariate variant, cokriging. The results are compared on the base of estimation map and prediction error map, more specifically, minimum squared prediction errors (MSPE) so that both spatial variability and local accuracy can be compared.

The meuse data is a set of data comprising of four heavy metals measured in the top soil in a flood plain along the river Meuse (Fig.1). This set is available with R Software package called gstat (Pebesma, E., 2004).

Two metal concentrations, having high correlation (Fig.2), Zn and Pb are used out of four available metals. Zn concentrations are used as primary variable and in order to create heterotopic case, 25 Zn samples are randomly discarded from total 155 sample locations (Fig. 2).

Prior to the estimations, both data are standardized and the Linear Model of Corregionalization (LMC) is fitted. Experimental and model direct and cross variograms variograms are presented in Figure 3. The LMC model includes a nugget effect and two spherical structures with the corresponding ranges 150 m and 1200 m respectively.

$$\begin{bmatrix} \gamma_{Zn} & \gamma_{Zn\text{-}Pb} \\ \gamma_{Zn\text{-}Pb} & \gamma_{Pb} \end{bmatrix} = \begin{bmatrix} 0.113 & 0.087 \\ 0.087 & 0.076 \end{bmatrix} nug + \begin{bmatrix} 0.062 & 0.048 \\ 0.048 & 0.049 \end{bmatrix} Sph_{150m} + \begin{bmatrix} 0.231 & 0.101 \\ 0.101 & 0.067 \end{bmatrix} Sph_{1200m}$$

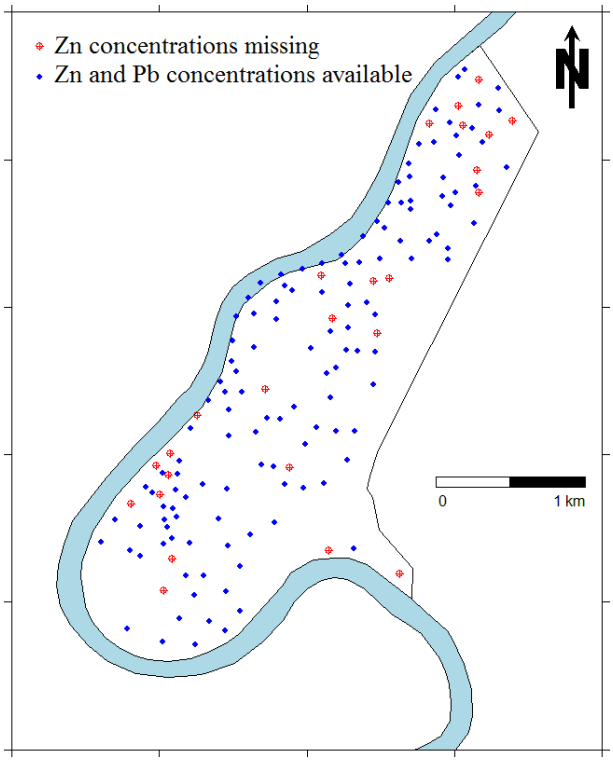

Figure 1. Meuse river and study area, sample locations.

Descriptive statistics of Zn and Pb concentrations are given in Table 1.

Table 1. Descriptive statistics of primary and secondary data.

	Pb	Zn
Count	155	130
Minimum	-0.902	-1.509
Maximum	1.084	1.368
Mean	0.000	-0.019
Variance	0.171	0.338

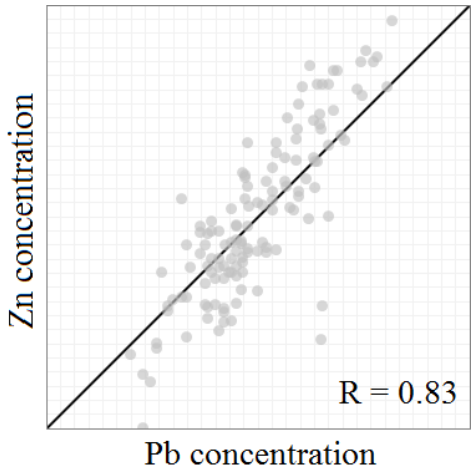

Figure 2. Scatter diagram of Zn and Pb concentrations.

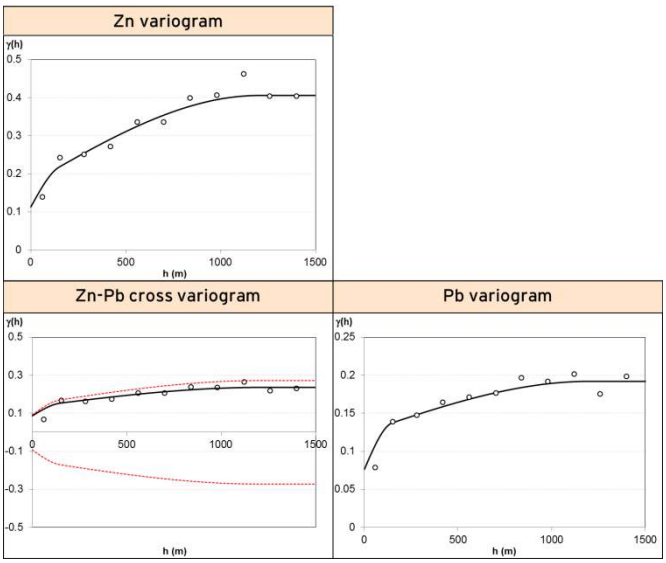

Figure 3. Model direct and cross variograms of Zn, Pb cocentrations. (Red dot line forms the hull of perfect positive and negative spatial correlation.)

In kriging with a moving neighborhood, each target point is estimated from a subset of data that varies with the target. In this study, moving neighborhood with a radius of 1500 m with nearest 8 points subsets are used. Results are given in next section by means of comparison of image maps, MSPE map, and swath plots.

4 RESULTS AND DISCUSSION

Image maps produced by three methods, OK, CoK, and CMCoK is given in the Figure 4. It is seen that, when compared with OK results Fig.4a, highly correlated secondary variable in the case of CoK Fig.4b slightly improved the spatial variability.

Covariance-matching based multivariate case CMCoK in Fig.4c is more sensible to low and high variation of attribute of interest, and this variation reflect as less smooth image map when compared to the OK and CoK. Since the most unavoidable phenomenon of kriging estimations is smoothing, the less smoothing behavior of constrained kriging can be used in further studies as an alternative.

As an other comparison tool, MSPE maps are used in comparison among three estimations (Fig. 5). CMCoK estimates MSPE map (Fig. 5c) shows that, points used in data are distinguishable rather than other methods. Although CoK produced image map almost same variability with OK; CoK MSPE map shows that, prediction errors are slightly lowered when compared to the univariate case OK. This is an indication of contribution of highly correlated secondary variable.

A swath plot is a graphical display of the attribute in interest from a series of slices, or swaths, generated in several directions through the study area. In this study, the slices are selected with same orientation with data, since regular Easting and Northing selecting might led misjudgement of results because of the irregular spread of data. The study area is divided into slices along with the direction under consideration and the weighted average of each slice for the respective attribute is calculated. The averages are plotted against the slice number. Swath plots are drawn for the target points and data in for three estimation methods. Results are represented in Figure 6.

From Figure 6, it is seen that OK estimates are locally much more accurate than multivariate estimations CoK, and CMCoK. When multivariate cases compared, CoK produced more accurate results than the covariance-matching processed variant.

Table 2. Descriptive statistics of results.

	OK	CoK	CMCoK
Count	3103	3103	3103
Minimum	-1.543	-1.629	-2.137
Maximum	1.482	1.530	2.240
Mean	-0.091	-0.096	-0.097
Variance	0.411	0.464	0.711

Table 2 gives the descriptive statistics of results of univariate OK, and multivariate cases CoK and CMCoK. From results, it is seen that CMCoK results lie in largest interval [-2.137, 2.240] when compared to ordinary kriging estimations. CoK results seem same characteristics with univariate case by means of similar interval, mean and variance, while CMCoK produced higher variance result.

It can be concluded that, covariance matching process is successfully adapted into multivariate case of kriging and seems promising tool since the technique is more effective to predict low and high values than univariate and multivariate ordinary kriging. Since the ordinary cokriging is an special case of an universal kriging (UK), the study shows that covariance-matching constrained equation and matrice systems can easily be adapted into cases which UK estimation is an altenative.

The Integration of Artificial Neural Networks and Geostatistical 3D Geological Block Modelling- a Case Study on a Mineral Sand Deposit

A.B. Jalloh

K. Sasaki
Kyushu University, Fukuoka, Japan

Y. Jalloh
London Mining Company, Freetown, Sierra Leone

ABSTRACT In this research, an Artificial Neural Network model was developed to predict metal content from drillhole data using the back propagation algorithm. For validation purposes, results between the actual and predicted mineral grades were compared, and regression analysis of the compared results indicate that the predicted mineral grades were in close proximity to the actual grades. The validated model was used to predict mineral grades at unsampled locations in order to determine the feasibility of drilling in those areas. The optimum results obtained from the neural network were fed to geostatistical techniques for developing a geological 3D block model for mine design. The generalized data from the Neural Network show that Artificial Neural Networks can be used to complement exploration activities and is an effective approach for mineral reserve estimation without worrying about spatial variability or other assumptions.

Keywords: Geostatistics, Artificial Neural Network, Geological block modelling

1 INTRODUCTION

Mineral deposits are very complex structures due to the geological processes involved in their deposition. The most important factor in reserve estimation is the distribution of the ore grades (Sathit, and Shigeru, 2013). The distribution of ore grades must be determined to enable the estimation of ore reserves. For the last five decades the mining industry has adopted and applied geostatistics (Kriging and Conditional Simulation) as an ideal and optimal tool for mineral reserve estimation. This is because geostatistics provide powerful tools for modelling most of the aspects of an ore deposit. The main steps involved mineral reserve estimation are as follows: (1) obtain the variogram model of the deposit, (2) fit a standard model to the variogram and (3) finally produce block estimates. However, geostatistics only considered spatial continuity as the main factor (Sathit, and Shigeru, 2013). There are other factors like mineral deposition environment, geological structure and deposit type which are not considered. To date, the biggest challenges on using geostatistics lie in the failure in variogram modelling, nonstationarity and normality of the data.

Developments in computing technologies have produced several machine learning algorithms, like, Artificial Neural Networks (ANNs) which have the ability to operate nonlinearly. With this technique, no assumptions are made about any factor or relationship. The ANNs learn the underlying functional relationship present in the data from the samples that are made available to them (Sathit, and Shigeru, 2013). Recently, despite the efficacy of geostatistics to reserve estimation, several researchers have opted for a neural network modelling approach for ore grade estimations, and the

utility and performance of this model in many practical applications have been demonstrated.

In this research, a neural network model is trained on the available drillhole data. The model was used to generalize in unsampled areas. The predicted and drillhole data were fed into geostatistics (OK) to produce gridded 3D geological block model. Figure 1 shows the schematic illustration of the research.

The data used in this study for training, testing and validating the model consist of 2880 composite samples. The samples include sample co-ordinates (easting, northing, and elevation), sample length and the rutile ore grade. The network is presented with this data for training, testing and validation. It is taught to recognize the relationship patterns between input and target and then generalize to interpolate ore grades. The performance of the neural network model was assessed by two estimation errors, namely, the mean squared error (MSE) and correlation coefficient (R^2). The performance of the ANN model is validated by comparing results with the traditional geostatitical techniques of ordinary kriging (OK).

2 CASE STUDY: GENERAL GEOLOGY AND DEPOSIT DESCRIPTION

The study area is located on the south Western part of Sierra Leone roughly at latitude 7°40'N and longitude 12°20'W. Figure 2 shows the location of the deposit overlain with some of the drillholes used in this study and the drillhole map.

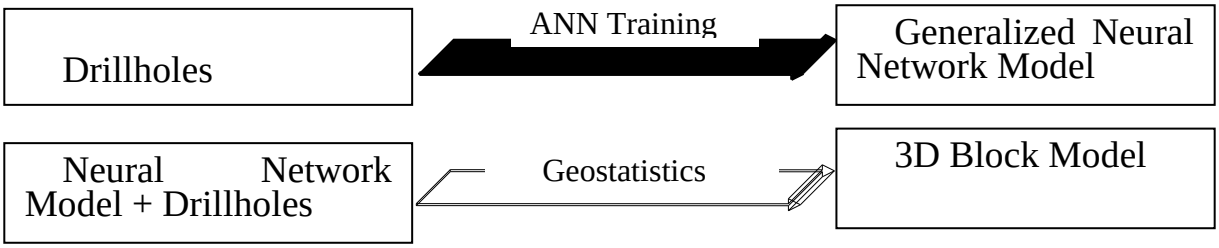

Figure 1. Schematic Illustration of the research outline.

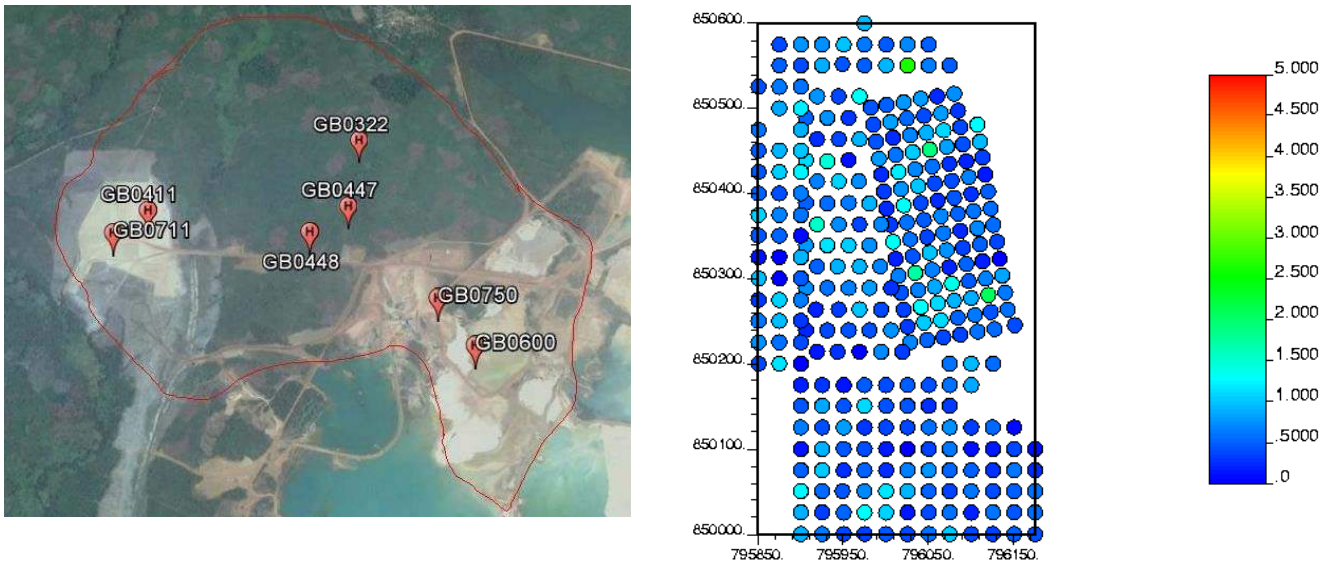

Figure 2. Location Map of drillholes in the studied Area

The deposit is one of the four largest developed in the area. The deposition is as a result of the rivers' tributaries crisscrossing all over the area stripping off materials from adjacent hills. The mineral distribution pattern comes in two folds and is mostly observed within the interfluves. The deposit show secondary surface enrichment averaging 1.99%HM, %RR of 0.81 with thickness being 8.9m.

2.1Data Analysis and Spatial Modeling

The assays include sample co-ordinates (easting, northing, and elevation), length of sample, and the rutile ore grade. The sampling was done at a regular grid interval. Preliminary statistical analysis conducted on drillhole composites from displayed a significantly large grade variation, with a mean and standard deviation of 0.84% and 0.43, respectively. The coefficient of variation is, however, less than one. For the sake of simulation, and network training, the grade was normal score transformed. Figure 3 shows the histogram plot and the normalized plot of the rutile grades. Table 1 shows the summary statistics.

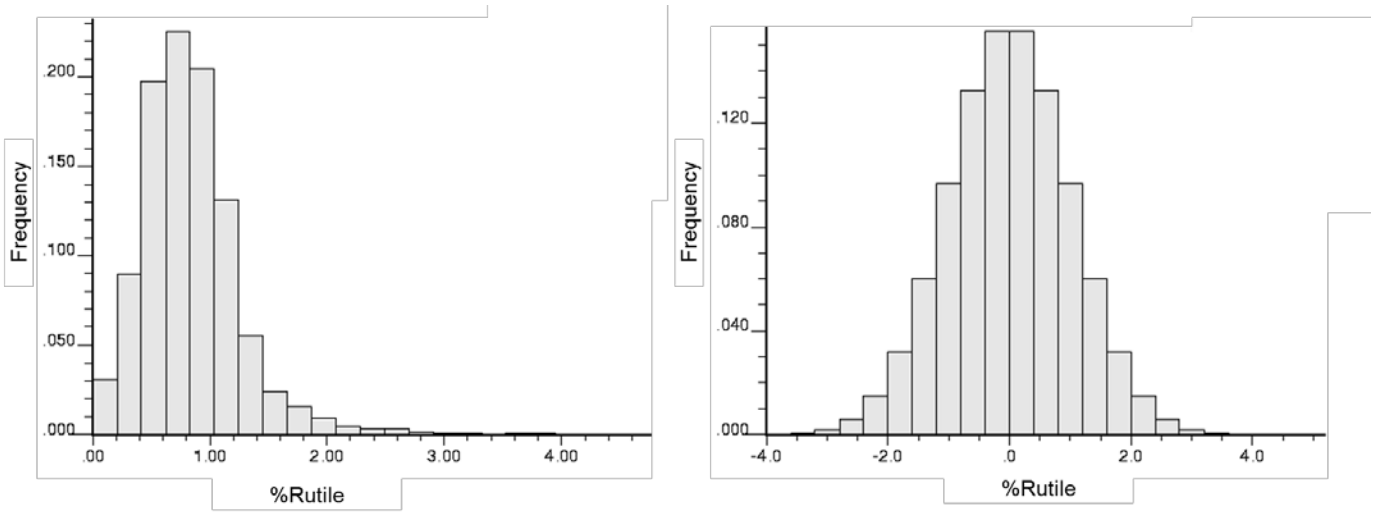

Figure 3. Histogram plot of raw data and normalized data respectively

Visual observation of the histogram plot reveals that the drill data is composed of a large proportion of low values and a minute proportion of extremely high grade values. For geostatistical estimation purposes and after preliminary analysis of the data, the spatial continuity of the data was explored by preparing the variogram models both directional and Omni-directional of the data. Spatial studies of the deposit show that the variograms reveal significant contribution from the nugget, thereby indicating difficult modelling conditions. The directional variogram model provided a better understanding and enabled to check for anisotropies in the deposit. Table 2 shows the parameters from which the directional variogram was constructed..

Large proportions of spatial variability occur from the nugget effect, indicating the presence of a poor spatial correlation structure in the deposit over the study area, and the variogram figure also indicate zonal anisotropy of the deposit. This anisotropy was taken into account during ordinary kriging.

3 PRICIPLES OF ARTIFICIAL NEURAL NETWORK USING BACKPROPAGATION

In 1986 David Rumelhart, Geoffrey Hinton, and Ronald Williams wrote a paper describing the use of several neural networks where the backpropagation algorithm works far faster than earlier approaches to learning, making it possible to use neural network applications to many areas. The attraction of neural networks is that they are best suited to solving problems that are the most difficult to solve by traditional computational methods.

Figure 5 explains the principle of the backpropagation technique in which each neuron receives a signal from the neurons in the previous layer, and each of those signals is multiplied by a separate weight value. The weighted inputs are summed, and passed through a limiting function (Sigmoid function) which scales the output to a fixed range of values. The output of the sigmoid function is then broadcast to all of the neurons in the next layer. So, to use the network to solve a problem, we apply the input values to the inputs of the first layer, allow the signals to propagate through the network, and read the output values.

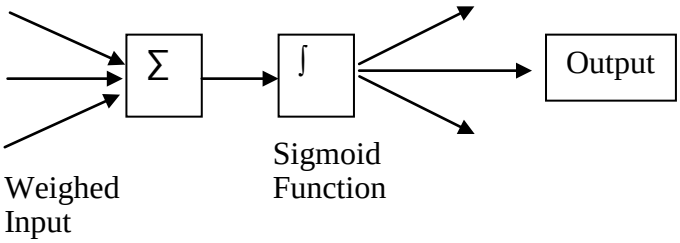

Figure 5. The structure of a neuron

The propagation error is calculated using the sigma transfer function. This function is derived as follows:

$$\frac{dx}{dy}\sigma(x)=\frac{d}{dx}\left(\frac{1}{1+e^{-x}}\right)$$

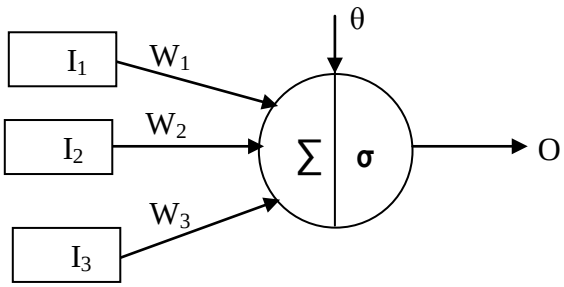
$$=\frac{e^{-x}}{(1+e^{-x})^2}=\frac{(1+e^{-x})-1}{(1+e^{-x})^2}$$

$$=\frac{1+e^{-x}}{(1+e^{-x})^2}-\left(\frac{1}{1+e^{-x}}\right)^2$$

$$=\sigma(x)-\sigma(x)^2$$

$$\sigma'=\sigma(1-\sigma)$$

To generate network output, elements in the input layer and the hidden layer of the neural network are manipulated by a weighing function as illustrated below.



$$O = \sigma\,(W_1I_1+W_2I_2+W_3I_3+\theta)$$

Where σ’ = the sigmoid transfer function
W = weight of input neurons
I = Input to the neurons

O = output

θ = Bias term

Given a set of training and target output data, also, and assuming that K= output layer, O_j =output node and T_j= target, then the error can be calculated thus:

$$E= ½ \sum (O_j-T_j)^2$$

The process of determining the weights is called training, and depending upon the output, the network adjust weights iteratively based on their contribution to the error. This process of propagating the effect of the error onto all the weights is called backpropagation (Dutta et. al, 2010).

The general architecture of neural network is made of an input layer consisting of inputs, two or more hidden layers consisting of a number of neurons, and the output layer consisting of outputs (Dutta et. al, 2010).

3.1 Model Training, Testing and Validation

Our neural network model for training, testing and validation is a two layer feedforward network with sigmoid hidden neurons. This network is presented with four input neurons which are X, Y, and Z coordinates, and sample length, consisting of two hidden layers with 20 neurons and one output layer, grade (%Rutile). Like (Dutta et. al, 2010), the number of hidden neurons chosen was based on the minimum generalization errors of the Neural Network model while experimenting with a different number of hidden nodes in the hidden layers. The network was trained using the Levenberg-Marquardt backpropagation algorithm. A MATLAB code was developed for the Neural Network modeling. Figure 6 shows the architecture of the feedforward neural network model.

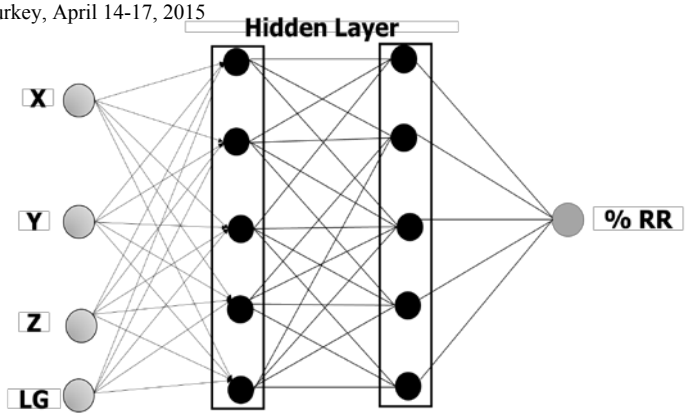


Figure 6. Architecture of the feedforward Neural Network Model

As mentioned earlier, to reach generalization, the data is split into three parts. Table 3 shows the data comprising each set for training, testing and validation of the model with their respective correlations.

The training data was used to train the neural net, the validation data was used to determine the performance of the network on the data that were excluded during training, and the test data was used for checking the overall performance of the neural net model.

Table 3. Data and model correlation results

Data	Samples	R^2	MSE
Training	2016	0.8925	0.2044
Validation	432	0.8805	0.2090
Testing	432	0.8807	0.2087

The predictions from the trained model were in agreement with the actual data with overall R^2 regression value of 0.889. This means that for the drillhole data used 88.9% of the variability can be explained by the neural net model. Figures 7 and 8 shows the regression plot for the training and validation, and overall regression R^2 plots of the model.

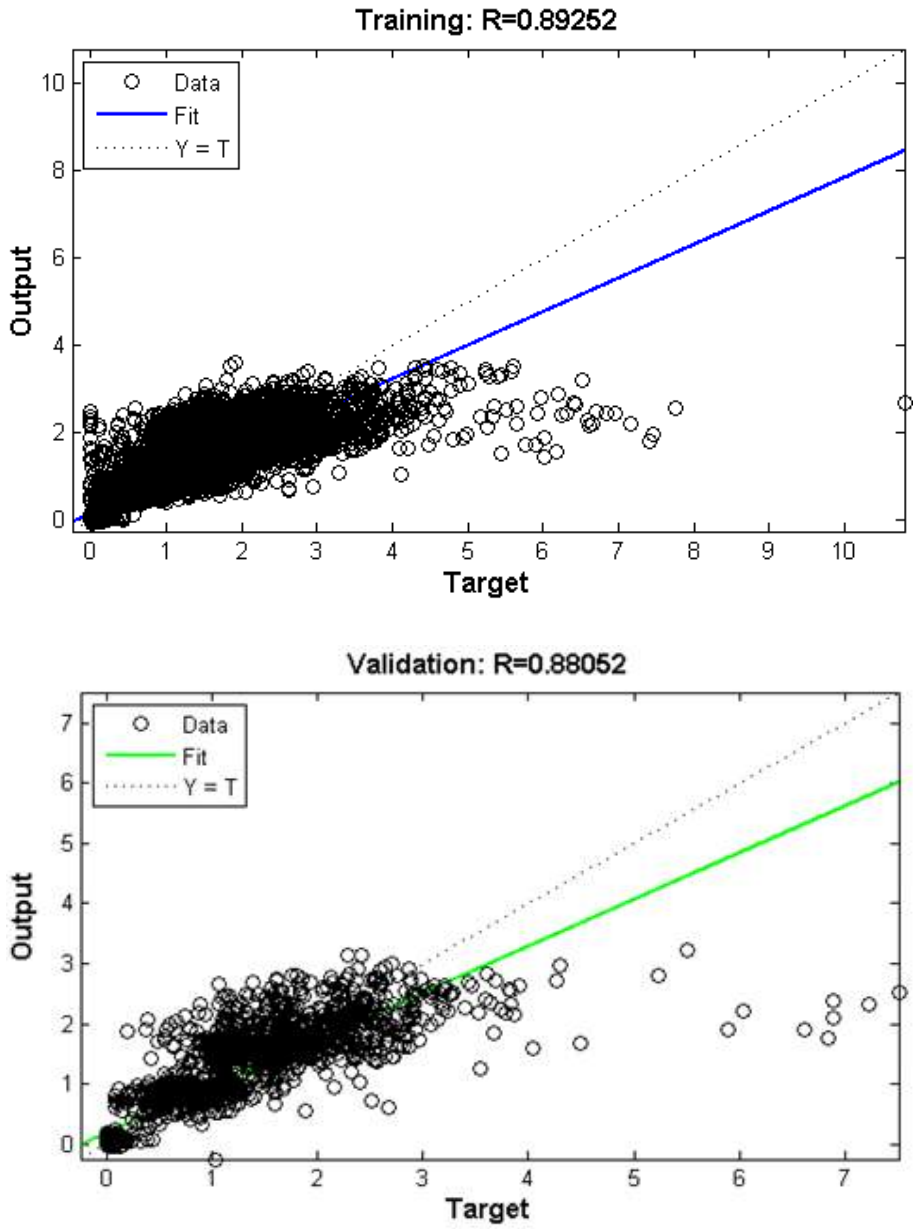

Figure 7. Output vs target for the training and validation data

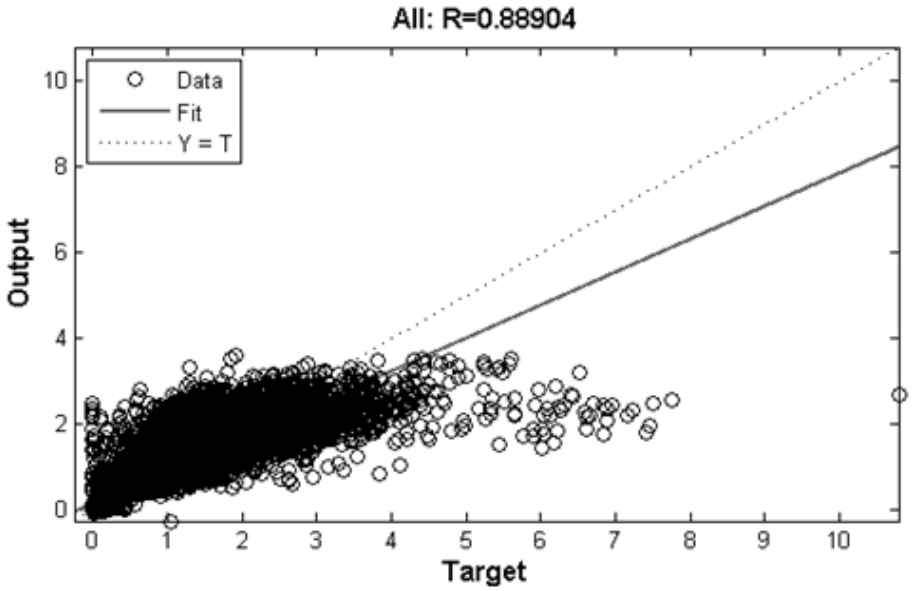

Figure 8. The correlation between outputs and targets of the Neural Network Model

4 GEOSTATISTICAL BLOCK MODELING

Appropriate dimensions were selected to construct 3D geological modeling grids from the neural network model. The dimensions were 60 m by 60 m by 5 m. GSLIB was used for variogram modelling and ordinary kriging.

Previously, (Wu and Zhou, 1993), estimated grades based on drillhole composite for a level in a surface mine with an assumed bench height of 12 m. In this study, the entire mineral deposit was estimated using composited drillhole data with a 1.5 m sample interval. After generating the optimum results from the neural net model, these results were fed in to the kriging algorithm for block grade gridding. Table show the results obtained from the kriging and neural net block grades.

Table 3. Data and model correlation results

	Neural Net	**Kriging**
Blocks	18000	18000
Variance	0.0121	0.0338
%Average	0.8039	0.7995

5 CONCLUSION

This study investigated ore reserve estimation capabilities of Artificial Neural Networks and applied it on a mineral sand deposit located in Sierra Leone.

The results show that the neural network can make accurate predictions of the grade and this is true within the zones of mineralization more than the edges. The artificial neural network tool can be used to assess grade distribution based on few available drillhole data. This techniques helps in determining the feasibility of the drilling program. When integrated with geostatiscs, the model produced provides realistic models take into account the available geological information at the time of modelling.

Application of Plurigaussian Simulation Technique to a Cement Raw Material Deposit

T.Y. Yunsel, A.Ersoy
Adana Science and Technology University, Adana, TURKEY

ABSTRACT The traditional simulation methods have serious limitations for applications to large numbers of domains, which have complex contact relations. Plurigaussian simulation is an effective method which can be applied to any number of domains, using both local and global geological information to infer the distributions of rock types. This study presents the application of the plurigaussian simulation method to the cement raw material deposit of Adana Cement Factory and assesses the spatially varying rock type proportions, and accounts for uncertainties between them. The method is able to incorporate cement quality parameters and geological logging from drill hole samples as well as prior geological knowledge as conditioning information for the realisations of rock types. The results indicate that the plurigaussian method correctly reproduces the different orientations of the individual rock types.

Keywords: Plurigaussian simulation, cement raw material

1 INTRODUCTION

Determination of uncertainty related to reserve classification plays an important role in mining applications especially raw material production in cement factories. Inability to construct a realistic geological model or insufficient geoinfomation generally results in high uncertainty. Main objective of this study is to reveal the underground rock type distribution to be used as raw material and fed to cement factory.

Geostatistical simulation procedures provide a solution for this uncertainty by incorporating multiple simulations at once for the mineral grades (Emery et al., 2008). Although the main concepts for the simulations include a single variable application, extended usage of the algorithm allow realizations of multiple variables simultaneously. This kind of application of simulations deals with geological domains and it requires an exhaustive simulation procedure. Here, geological domains stand for the preciously defined mineralisation zones. Dealing with the geological domains by simulation techniques requires categorical variables called rock types. There are several types of the simulations applied to characterize the geological domains. However, Gaussian based methods are well developed techniques and they include the advanced use of the old Truncated Gaussian simulations (LeLoc'h and Galli, 1996; De Almeida, 2010). Plurigaussian simulations exhibit better results in domains having complex transitive rock types and are becoming popular in recent years. Applications of plurigaussian simulations have found wide acceptance in the literature (Vargas-Guzman and Al-Qassab, 2006; Deraisme and Farrow, 2005; Yünsel, 2012). Complications and processes in dealing with geological domains to create the realistic geological structure as taking into account the proportions among related rock-types have been presented here. In this study especially a cement raw material field were chosen for application of the Plurigaussian Simulations. The case study aims to assess the spatial structure of the distributions of rock types for cement raw materials.

2 STUDY AREA AND GEOLOGICAL SETTINGS

Study area is located near to Adana City. The distance between the city centre and study area is approximately 10km (Figure 1). The cement factory is located next to the study area to avoid unnecessary transportation costs. Adana Cement Industry is the biggest cement producer of the Turkey. The factory has a wide range of cement production changing from Portland to pozzolanic cement. The majority of the production is put up on domestic market while remainder is exported to European and Middle-Eastern countries.

Geology of the study area exhibits a sedimentary lithology aged in Upper Miocene. Lithology consists of marl and limestone originated materials. Limestone covers the majority of the region and dominates the other formations. Thickness is relatively variable and gradually changing into related formations such as clayey limestone, marl may be observed. The rock is observed in different forms including microcrystalline calcite, clay minerals, microcrystalline quartz and fossil fragments. Geologically marls are formed by sedimentation of clay minerals and carbonate rocks at the same time. Marls are the most demanded formations by the factory since it naturally has the optimum mixture content and ready to process directly. Also, quartz carrying formations take place northern parts of the study area and related sandstone contains large amount of fossils. Raw material is removed by open pit mining methods in the field.

3 THE DATA

There are 43 drilling boreholes in the field and average depth is about 25m (Figure 2). All boreholes were drilled to 40m altitudes, because of problems with groundwater which is costly to drain. Different length of cores are logged and stamped at different sampling depths. Core logs include chemical analysis, sample length, coordinates, and rock type definitions. A representative 195 core samples were collected for the analysis. Although the boreholes have different variables, only rock types are used in the simulations.

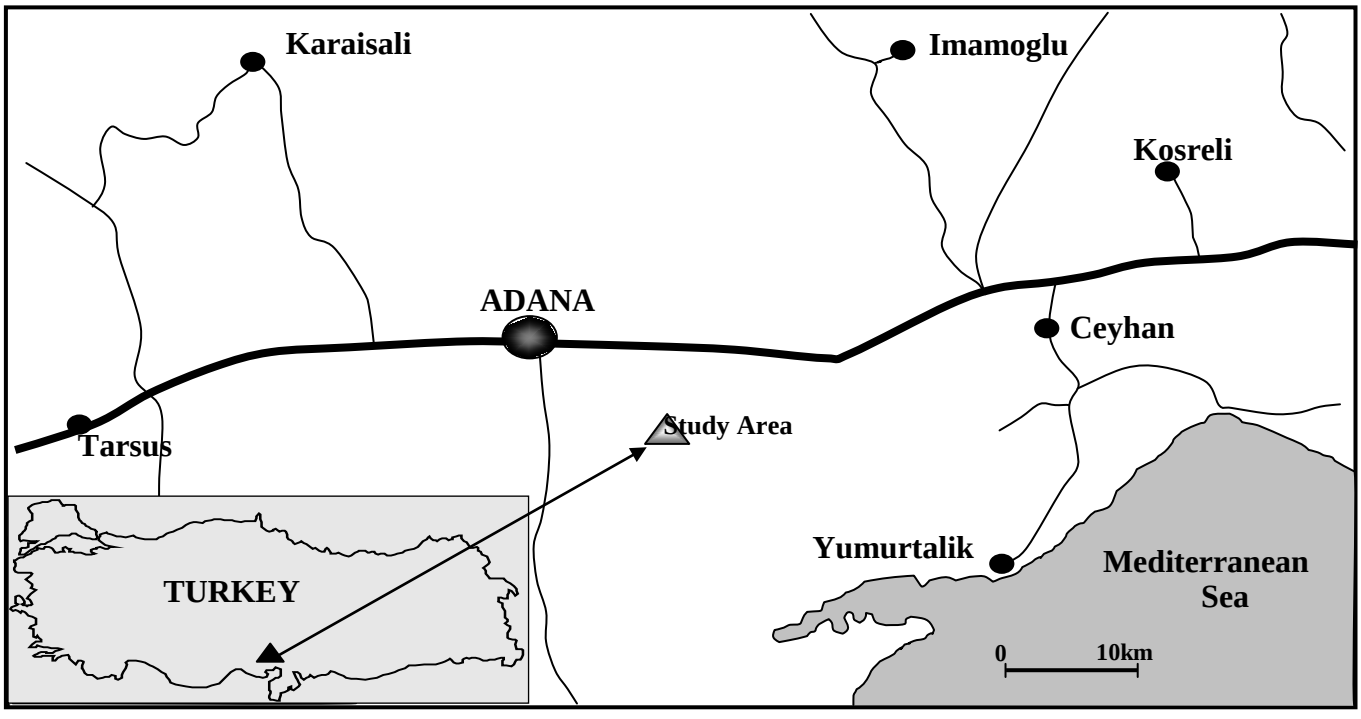

Figure 1. Location map of study area.

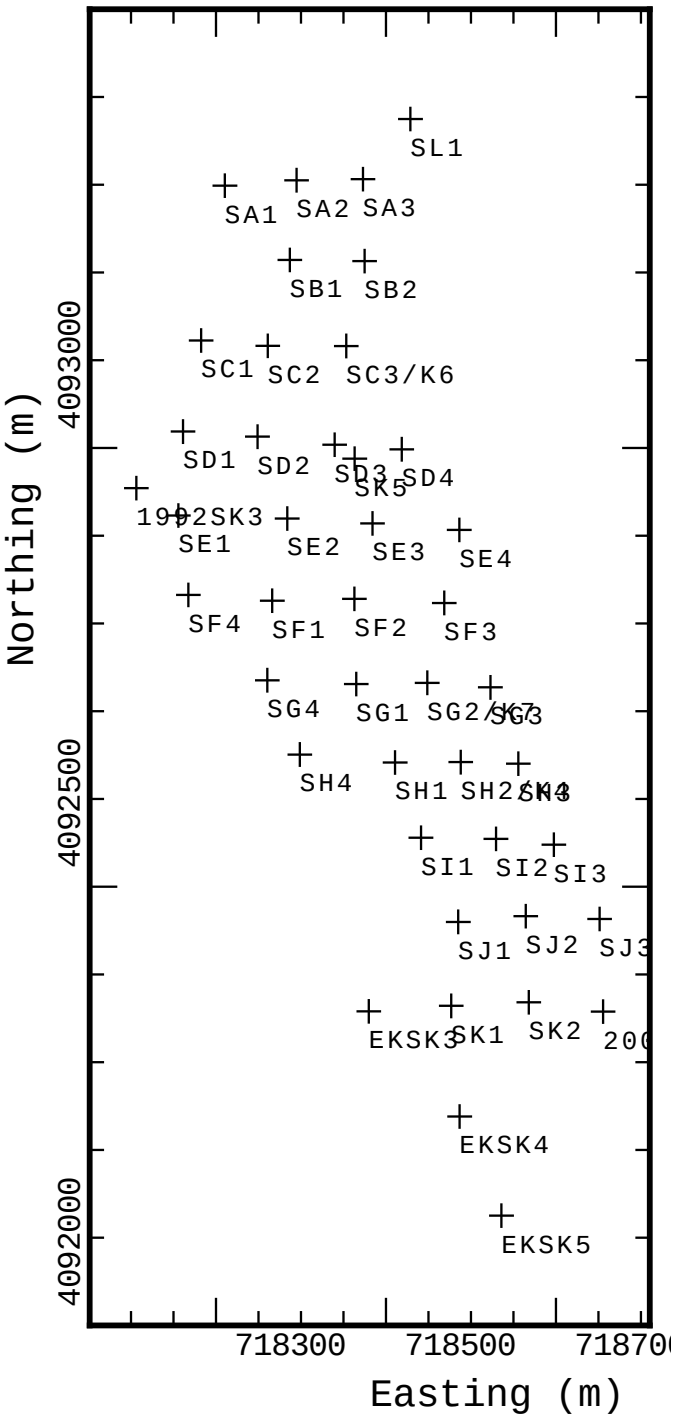

Figure 2. Drilling locations in the study area.

Chemical analyses include different oxides such as CaO, SiO_2, Al_2O_3, Fe_2O_3. These chemical compounds are used in calculation of the main cement modulus's including "Lime Standard", "Aluminium Modulus" and "Silica Modulus".

These standards play a vital role on optimal clinker production process by adjusting the chemical mixture content. The main rock types strongly affect the chemical contents of the samples. Thus, a correct characterisation of the field in terms of the rock types directly affect the clinker or cement production.

The rock types in the field are divided into three rock types. They are "Limestone", "Marl" and "Sandstone". In addition, limestone is divided into two groups according to their CaO contents. Limestones including lover than 45% CaO assigned as "Clayey Limestone". Finally, four rock types were used for the raw material deposits characterisation.

4 PLURIGAUSSIAN SIMULATIONS

Although it is similar in many aspects, Plurigaussian simulations is a different form of the Truncated Gaussian Simulations to be used for multiple realisations of the rock types. Detailed review of the methods can be found in relevant literature (Yünsel and Ersoy, 2013; Deraisme and Forrow, 2004; Armstrong et al., 2011). The basic procedure may be described under four steps:

1. Discretization and flattening is used to describe variables and the working grid system. Available data coordinates migrated to a working grid system to get better correlations between different rock types.

2. Vertical proportion curves are calculated for individual polygons created on the study field covering whole drilling boreholes. Each proportion curve is processed to get a representative geological structure in related polygon areas.

3. The following step includes the Plurigaussian variogram analyses. In this process, relations among rock types are modelled according to the described lithotype rules and correlation between Gaussian random functions and their variogram models.

4. The final step covers simply employing Plurigaussian Simulations and transferring the simulation results to its original space.

The rock types in the study are described as follows:

(1) Blue : Marl
(2) Yellow : Clayey Limestone
(3) Green : Limestone
(4) Red : Sandstone

According to the described colour, the positions of the rock types in 3D across the study area can be seen in Figure 3 (Z axis expanded by 10x).

A total of 20 polygons were created for the individual vertical proportion curves (VPC) (Figure 4). As it can be seen in the Figure 4, each polygon area has its own VPC to combine the related boreholes. Averaged within polygons designed to take into account lateral rock type changes. The vertical proportion curve counts the number of occurrences of each rock type distribution, and in validating the sedimentology interpretation. The data for the proportion curve are obviously related to the choice of the reference level used for the flattening step.

Next step includes the Plurigaussian variogram analysis of the categorical rock types to model the relation among them. The determination of the lithotype rule to identify the relation among rock types takes place at this stage. Multiple variogram analysis is carried out for each rock type at the same time in horizontal planes (X-Y) and vertical plane. This is the most important and time consuming phase of the process. Figure 5 shows the lithological rules defined from the transitions probabilities of the rock types, measured with the input dataset, and geological information about the rock type. In this diagram, the horizontal axis for the first Gaussian random function, including, marl. The vertical axis stands for the second Gaussian random function, including limestone, clayey limestone and sandstone. The application also produces a set of histograms showing the frequency of transitions between rock types along the wells. In the lithotype rule, the ore contact all rock types, have been imposed, according to the transitions probabilities. This is consistent with the real geology (borehole logs). Indicator vertical variograms for the rock types are presented in Figure 6. In the variogram graph, the thin continuous lines and thick continuous lines represent the experimental and modelled variograms respectively in a multigaussian frame.

Final process is the operating the Plurigaussian Simulation process using previously determined models and rules. As a post processing, low pass filtering and the median filtering methods are used to get a smoother rock type transitions as naturally should be in the field. In Figure 7 and 8 the distribution of the each rock type is presented. In these maps, the transitions, distributions, contacts and geometric positions of the rock types can easily be followed. Also rock type distribution in the field can be visualised in required lateral or vertical plane. This feature of the result provide invaluable information and flexibility for production planning and the process control in the study field.

Figure 7 is the vertical section of the field across the Y-Axis plane at the intersection of 718294th meter with the X-axis. Figure 8 shows the cross-section of the field taken at the level of 44m in horizontal plane. The following points may be drawn from an examination and interpretation of Figure 7 and 8.

- Marl is more abundant than the other rock types.
- Limestone proportions increases with depth.
- Approximately 10% of the cross sections area is covered by sandstone
- Limestone occurs in the northern part of the study area.
- There are contacts between all rock types. This is consistent with borehole logs.

Success of the simulation results can be validated by checking the input and the output information. The statistics of the simulated rock types are nearly the same as the input data statistics (Figure 9). Clearly, the plurigaussian simulations have been successful in reproducing the statistical and spatial character of the original data.

5 CONCLUSIONS

Plurigaussian simulation was shown to be effective in reproducing the characteristics of the different rock types and the main features of the geology at the cement raw material deposit. Such modelling is the basis of resource estimation for the raw material deposit. This may be explored in an operational context. Therefore, the work will help raw material operation, production planning, and economic decision making. Plurigaussian simulation relies hardly on the effective integration of geostatistical knowledge and geological experience. The case study was focused on geological models of a cement raw material deposit. The results of the analysis are likely to be potentially useful for a wide range of users, such as mining-resource researchers, practitioners, technologists, and decision makers for deposit planning and scheduling.

This kind of geostatistical simulation methods are very important in terms of geological understanding of the interested rock type domains. Result of the study revealed the distribution and the complex relation of the rock-type domains in the area. This is basic information for the particular industries such as cement factory. Identification of such domains play a key role for future production planning and used in decision making. Results of this study may be used in mining, petroleum, geological and other earth-related sciences.

ACKNOWLEDGEMENT

Authors extent their thanks to Adana Cement Industry for providing the data set for this study.

Characterization and Monitoring of Underground Cavities and Associated Disorders by Electrical Tomography

K. Hebbache, D. Benmeddour, M. Mellas, A. Mabrouki
Civil Engineering Laboratory, Biskra University, BP 145 Biskra 07000 Algeria

ABSTRACT The electrical tomography method is considered one of the best non-destructive geophysical methods for the detection, characterization and monitoring of underground cavities and associated disorders. The detection of cavities in urban areas is a very important tool to prevent different causes of accidents related to possible collapse. This study focuses on the assessment carried out in the framework of the construction of a project of buildings in the town of Tolga, Biskra province of southeastern Algeria. This field contains a plurality of cavities that are essentially of natural type, also of different dimensions and different depths. The procedures, using the electrical Tomography Wenner device to detect the cavities, are performed for depths ranging from 2m to 4m. These cavities result for most of the natural phenomenon of dissolution of carbonate material grounds. The electrical tomography results are calibrated, by the mechanical tests and trials dynamic penetrometer.

Keywords: Electrical tomography, underground cavities

1 INTRODUCTION

The methods of geophysical prospecting are used in the preliminary studies, for projects of construction that cover large surfaces. They can quickly and inexpensively obtain an overall assessment of the subsurface. Practically, there are several methods such as the electrical, gravimetrical, seismically, and the electromagnetically methods. The electrical method is the most commonly used to resolve geological and geotechnical problems. Many works have been made by this technique to present, applications of underground cavities detection (El Khammari *et al*, 2007; Emin and Irfan, 2006; Fehri *et al*, 2011; Metwaly and Alfouzan, 2013; Van schoor, 2002), the archaeological investigation (Muztasa *et al*, 2012) and environmental and hydrogeologically studies (Martinez *et al*, 2009; Sumanovac, 2006). This technique is not the only one used to discover the subterranean cavities. Gravimetrical and electromagnetically methods for geological radar are also used, to obtain a good recognition of the subsurface (Park *et al*, 2010; El Khammari *et al*, 2007; El-qadi *et al*, 2005).

In the present study, the technique of electrical panels is implemented for the detection and delimitation of underground cavities within foundation soil layers. The electrical tomography is non destructive method. Spatially integrative technique has recently been introduced into the geotechnical studies. The mechanical tests and trials dynamic penetration tests are used to confirm the geophysical measurements.

In the town of Tolga, willaya of Biskra situated in South east Algeria, there are underground cavities of natural origin, that are formed by the process of dissolution of limestone. The presence of these cavities influences the stability of constructions.

The objective of this work is to analyse the subsoil resistivity in the city of Tolga, to assess the potentiality of the geo-electric method to detect underground cavities.

2 PROCEDURE OF INVESTIGATION

Electrical tomography makes use of a multi-electrode device that enables acquiring a large number of measurements corresponding to the various four-electrode combinations. The principle of the electrical

resistivity panels is to inject in the ground an electric current of intensity (I) between two electrodes C1 and C2 and measuring the difference of potential (V) induced between another pair of electrodes P1 and P2 (Fig. 1).

From the value of the injected current (I) measuring the potential difference (V) and the spacing between the different electrodes. The apparent electrical resistivity of the subsurface can bee determined by the Ohm's law:

$$\rho_{app} = \frac{\Delta V}{I}.K \qquad [1]$$

K: Factor of geometry depends on the distance between electrodes.

ΔV : Difference of potential

I: Intensity of current

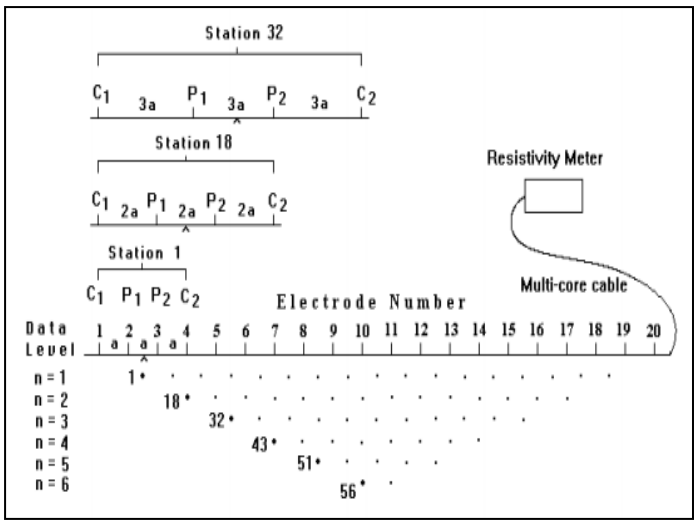

Figure 1. Classification of electrodes according to Wenner's method (*manual RES2Dinv*).

3 METHODOLOGY

The main objective of the present study is to implement the technique of tomography for the detection and delimitation of underground cavities, within urban area.

In the present study, series of two dimensional tests (resistivity measurement of the ground) have been carried out with the apparatus of resistivity meter SARIS (Scintrex Automated Resistivity Imaging System) of the company (Scintrex Ltd).

The program of geophysical recognition contains eight (8) electrical panels; their characteristics are represented in the Table 1.

Table 1. Electrical profiles characteristics.

N° of profiles	Number of electrodes	spacement (m)	Direction
1	30	2	W-S
2	29	2	N-S
3	30	2	W-E
4	25	1	W-E
5	25	1	W-E
6	25	1	W-E
7	25	0.5	N-S
8	24	0.5	N-S

The optimal disposal of profiles allows collecting maximum of information about the experimented zone (Fig. 2). The Wenner configuration was adopted for all the electrical profiles (Dahlin and Loke, 1998). This configuration has a horizontal sensibility, and it is recommended to discover horizontal structures; however, it is misadvised for vertical structures (Dahlin and Zhou, 2004). After the collection of data, the following stage concerns the inversion of data.

Figure 2. Disposal of the group of the electrical panels.

The inversion of data obtained from the electrical imaging is made by the code of inversion RES2Dinv (Loke and Barker, 1996), which determines automatically in two dimensions: the model of resistivity and the polarization provoked by the subsoil (Grifiths and Barker, 1993). The inversion

code is able to calculate the values of apparent resistivity by the technical optimization of nonlinear least squares (DeGrout and Constable, 1990; Loke and Barker, 1996; Sasaki, 1992). For the modelling, the RES2Dinv program distributes data by considering rectangular meshes on all the investigation depth (Edwards, 1977).

4 RESULTS AND DISCUSSIONS

4.1 Geophysical Investigations

The electrical tomography results are presented as pseudo-sections or electrical panels. The apparent resistivities values obtained for all electrical panels vary between 10 to 500 ohms - m, and indicate that the subsurface is very heterogeneous. The inversion code RES2Dinv represents three pseudo-sections, the first is the apparent resistivity measured, the second is the calculated apparent resistivity and the last is the proposed inversion model.

In this study, only the inversion models are shown in figures (3, 4, 5, and 6) for illustrative purposes. Figure 3 shows three electrical panels corresponding to the profiles P1, P2 and P3. The electrical panel P1 shows that the ground consists of a layer clay measured approximately 16m in length and 1.3m in width, with an apparent resistivity ranging from 35 to 40 ohms - m. Also, below the upper layer clay, there are carbonate formations, corresponding to limestone characterised by high resistivities of the order of 200 ohms - m, which are located at 3m in depth. The first and the second panels contain approximately similar characteristics (clay, clayey carbonates, and carbonate formation).

The electrical panel P3 indicates the presence of three formations in the subsoil, which are clay layer near the surface, clay carbonates layer at a depth of 3m and carbonate formation presents the deep layer.

The profiles P4, P5 and P6 were performed in the longitudinal direction at the excavation bottom. The results are shown in Figure 4. The panel P4 shows a carbonate formation covering the entire study parcel, and the resistivity is of the order of 200 ohm - m. Also, there is a highly conductive clay laver of resistivitv 20 ohm - m.

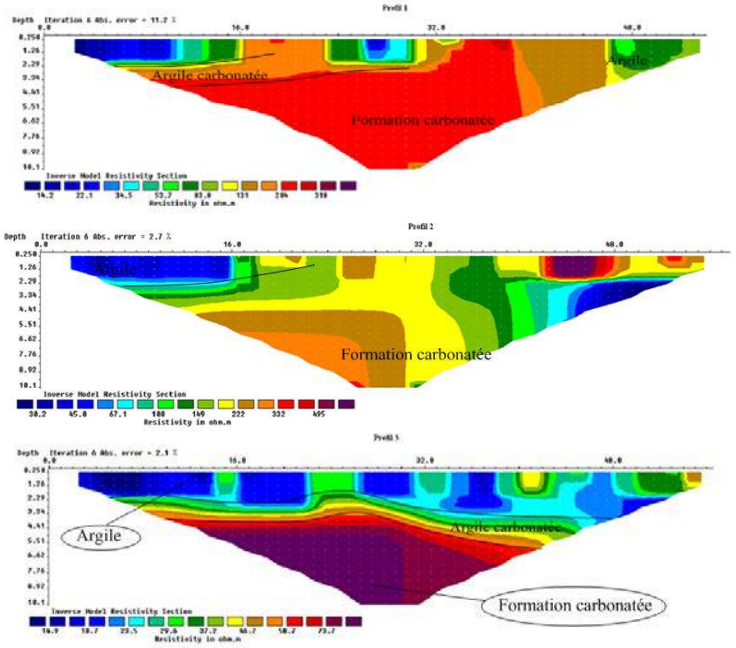

Figure 3. Geophysics measurement results of profiles P1, P2 and P3.

The electrical panel P5 shows the existence of a highly resistive region, that reveal a resistant body whose core is located at approximately 1.5 m; this can be explained by the presence of a horizontally elongated cavity. Both P4 and P5 profiles have similar characteristics, corresponding to carbonate formations. However, the electrical panel P6 is characterized by carbonate formations; in addition, there is a conductive area in the center of the panel, and its apparent resistivity equals to 20 ohm-m. This area corresponds to a clay formation.

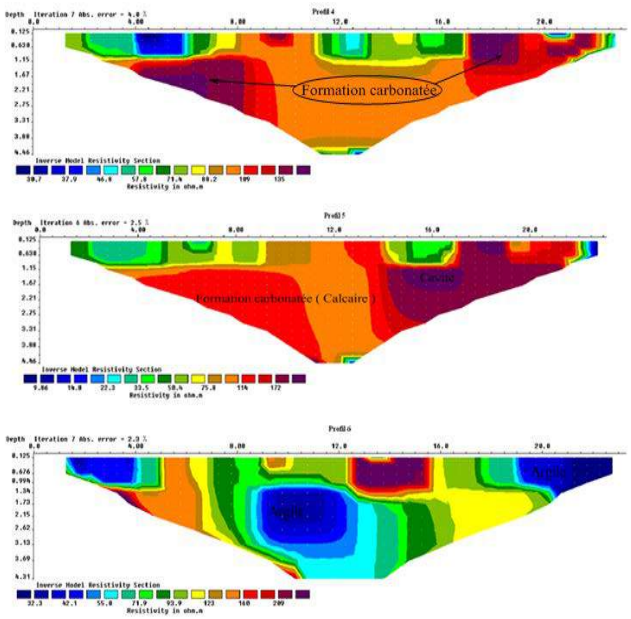

Figure 4. Geophysics measurement results of profiles P4, P5 and P6.

Figure 5 shows the Geophysical measurement resulting of profiles P7 and P8. These profiles are performed in the transverse direction at the excavation bottom. These electrical panels show that the foundation soil contains carbonate formations (limestone) that spreads in depth and the soil surface. The results clearly show an electrically resistive basement; moreover, it can be concluded that the electrical tomography method allows characterizing the existing formations in the study site.

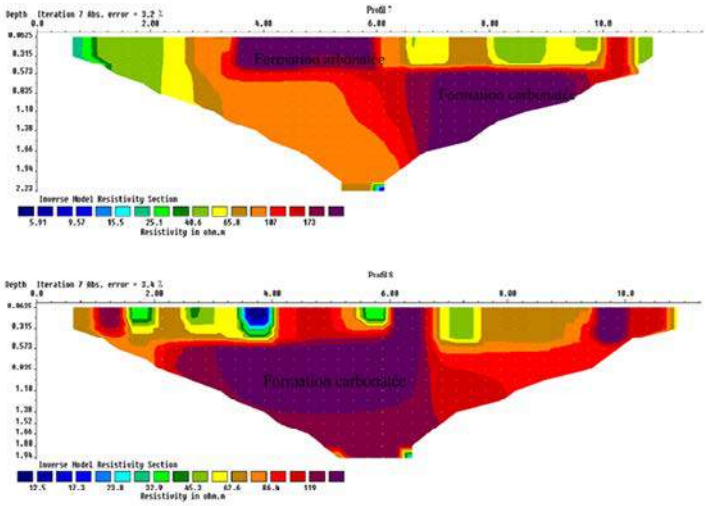

Figure 5. Geophysical measurement results of profiles P7 and P8.

4.2 Geotechnical investigations

To confirm the existence of the subterranean cavities and assess the performance of the geo-electrical method, the mechanical tests, and dynamic penetration tests were conducted. The excavation confirms that, within this geological context, for the most part can be classified as carbonate, dissolution phenomena have engendered the appearance of a complex system of underground cavities of variable size and highly irregular shape. Figure 6 illustrates the type of subterranean cavities encountered after excavation of 2.5m in depth.

The results of mechanical tests clearly show the continuity of carbonate formation of the ground. Finally, the site contained a white porous limestone, silty clays, clays highly carbonates, gravelly and stony tuffs with sandy silt passages.

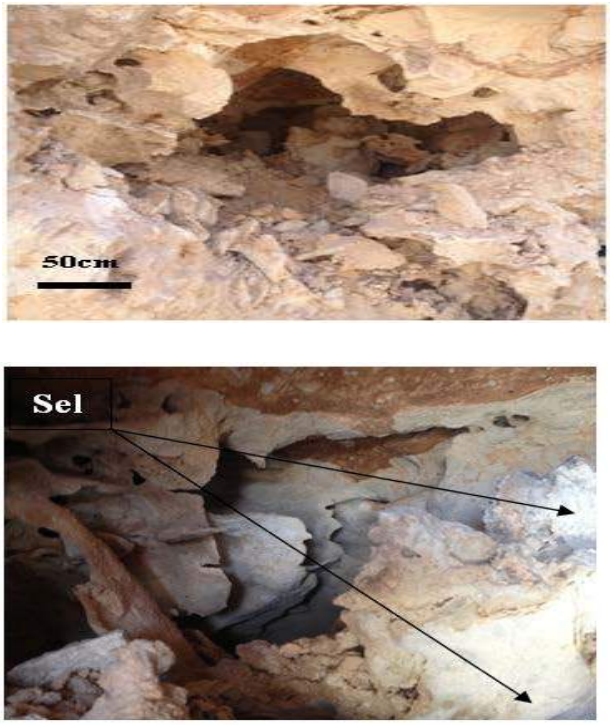

Figure 6. Illustration of subterranean cavities (city of Tolga)

5 CONCLUSION

The geophysical prospecting by electrical tomography allows detecting the subterranean cavities and their extension. The presence of cavities in the Tolga region

is mainly due to the dissolution of the material in the limestone. The electrical panels gave vertical section below realized profiles; these panels contain information necessary for correct interpretations.

The applicability of the present technique is illustrated by a comparison with the results from mechanical tests. Tests performed by dynamic penetration gave very satisfactory resistances of the foundation soil.

The solution proposed to realize the infrastructure, is a total excavation and reconstruction of the soil foundation, treated with a hydraulic binder, for example 15% cement, and compacted layer by layer of depth of 20 to 30 cm. Cavities and voids localized according to their dimensions can be filled with mortar of cement or concrete.

ABSTRACT: Detection of optimized geochemical pattern requires Orientation Survey (O.S.) in which one of its important layers is selecting an effective data analysis method. In order to detect favorable potentials in Gulan area, discrimination of mineralized and blind ore zones using advanced techniques with presenting a suitable geochemical pattern and relative pathfinders is the scope of this study. In this respect 233 stream sediment samples were collected from the area and analyzed for base metals (Cu, Mo, Cr, Co, Ni, Pb, Zn, As, Y …) and their indicator elements.

The anomalous zones in the area were detected using two systemic methods such as principle component analysis (PCA) and Fractal (F) methods. Application of F method on geochemical data leads to detection of two anomalous zones of Cu in Gharachilar and west of Loutkeh, with Mo appearance in Namnigh. The separation of these two anomalous zones (Cu& Mo) probably is due to acidity of area formed by solubility of sulphides from outcrops and migration of Mo in the form of Molibdat which caused the precipitation of Cu and Mo in two different zones.

Results shows in spite that both the methods (F& PCA) have similar detection zones but the capability of PCA in enhancement of halos and detection of blind ore zones is more effective than F method. As in this case it could detect strong blind anomalous zone of Mo in Namnigh in addition to Cu & Mo trend. Overall the characterization of methods also revealed that the PCA is more reliable in rejecting the syngenetic effects and the results can be more precisely used in the area.

1 INTRODUCTION

Mineral exploration is a multidisciplinary task that requires the simultaneous consideration of numerous disparate geophysical, geological, and geochemical datasets (Knox-Robinson, 2000). Furthermore, it needs spatial modeling using observations regarding the association of mineral occurrences with various geological features in a qualitative manner.

In exploratory studies, singular geological processes result in elemental enrichments (or depletions) and geochemical distribution patterns representing mineralized zones.

Therefore, in order to identify promising areas, assessment of the elements distribution pattern in different environments is essential.

One of the most important fundamental issues in exploration geochemistry is the separation of anomalies that are associated with mineralization from background concentrations of elements which results from geological processes (Gałuszka, 2007; Hawkes and Webb, 1962). The relationship between anomalies and background concentrations especially for ore-forming elements is an important issue in spatial data analysis(Hawkes and Webb, 1962).

In exploratory data analysis it is well known that geochemical data are characterized by their spatial positions, which means that the element concentration varies spatially. Thus, the traditional methods emphasize only the frequency distribution of the element concentration and ignore spatial variability. In addition, these methods are only applicable to situations where geochemical data follow a normal distribution(Ahrens, 1954a; Ahrens, 1954b). Many statistical methods that have used to enhance geochemical anomalies include probability graphs, univariate and multivariate analysis, moving averages, fractals methods (Cheng, 1999; Govett et al., 1975; Miesch, 1981; Sinclair, 1974, 1991; Sinclair, 1976; Stanley and Sinclair, 1989). Various characteristics of geochemical data are considered in these statistical methods: 1) The frequency distribution of elements is applied in most methods; 2) Both the content and spatial position of samples are considered in moving average, kriging and spatial factor methods and 3) in addition to element contents and spatial position of samples, the geometrical characteristics of anomalous areas are used in fractal and multifractal methods (Changjiang et al., 2002; Changjiang et al., 1995; Cheng, 1995; Cheng et al., 1994; Cox and Wang, 1993; Sun et al., 2006; Xu and Cheng, 2001; Yuhua, 1994; Zhangdong et al., 1998). Due to the natural uncertainty and nonlinear behavior of elements in this study, it was attempted to apply a comparative optimization based on multivariate statistical method (PCA[1]) and spatial analysis method (fractal) for quantify spatial relationships of elements and discriminating anomaly from background in order to enhance mineralization zone in the Gulan area.

1.1 Geological Settings

Gulan area is located between ($46^{\circ}15'-46^{\circ}30'$) longitude and ($38^{\circ}45'-39^{\circ}$) attitude in 50 km north of Tabriz,70 km from W-Ahar city in Azerbaijan province, NW of Iran (Figure 1). Geochemical exploration background in the area represents the Gharahchilar area as a promising area for Cu-Mo mineralization (Alavi, 1991).

Based on the Siahrood geological map (Figure 1), the oldest rock unit is disrupted collection of metamorphic rocks and its main outcrop is visible in the NE of the area. Further, it consists of alternating layers of slate, mica schist, metatuff, metaandesite, calcschist and quartzite. These rocks have also undergone a further change under the intrusion of igneous masses. During the Upper Cretaceous, activation of sedimentary basins has led to form the variety of volcanoclastic facies which are transformed into each other laterally. Moreover, Oligocene magmatic activities have the important role in the geology of the area. Middle Alpine tectonic activities could also appear as faults and folds by influencing in the sedimentary and igneous deposits and the related outcrops are visible in the southern part of geological map. The main faults trend is in NW-SE and E-W directions. Paleogene volcanic series which is known as a process of Alpine tectono-magmatic cycle, is able to host significant mineralization of Cu, Mo, Pb, Au and Ag around the Ahar city, NW of Iran. It seems that this mineralization is accordance with the Alp- Himalaya copper belt and faulting of the area is continued from NW to SE towards Sungun copper deposit.

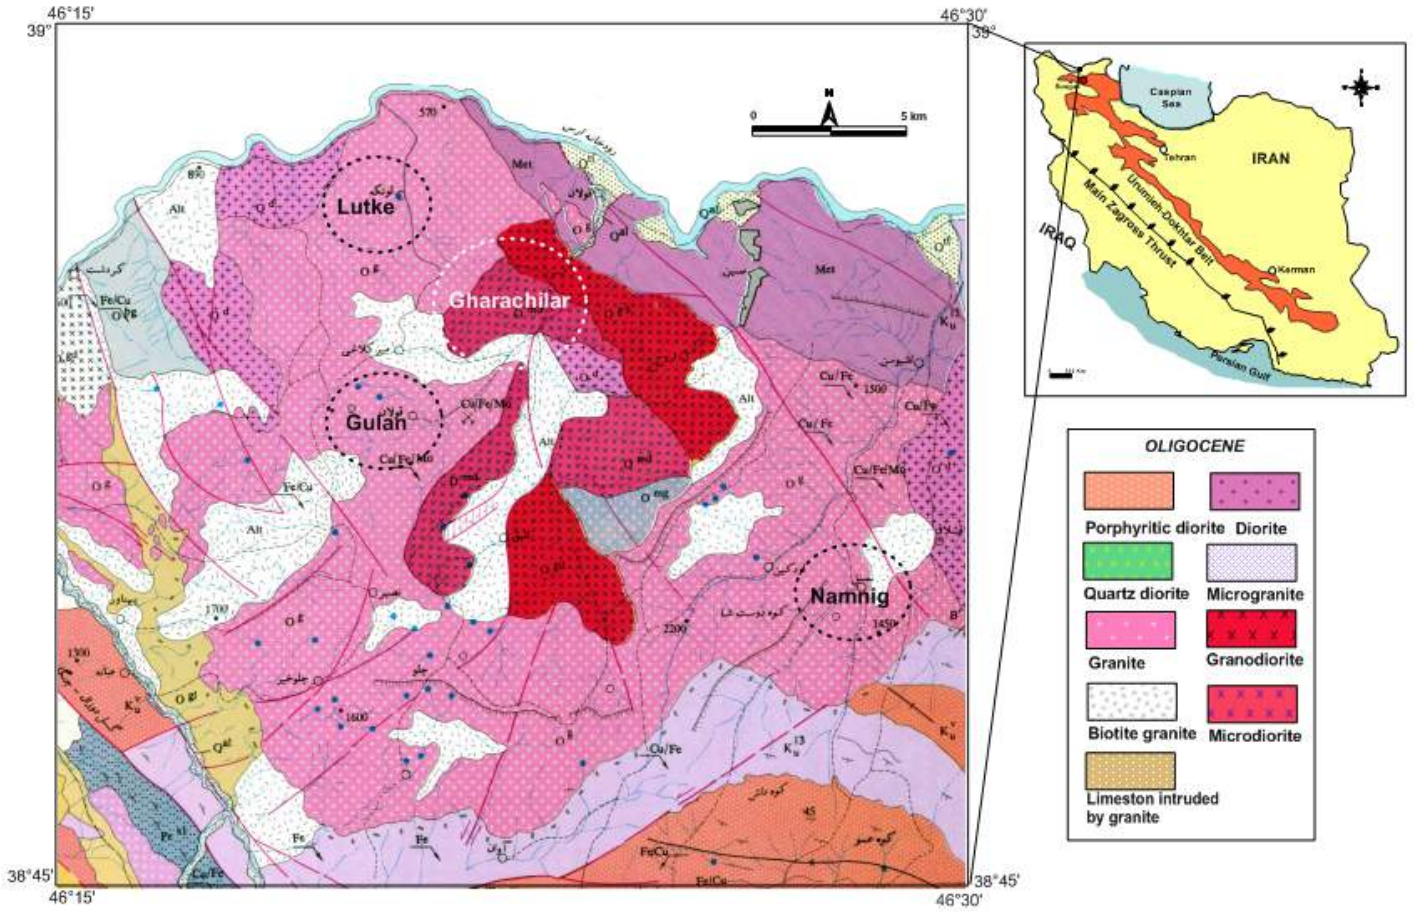

Figure 1. Modified and simplified geology map showing the location of study area

Stream sediments sampling was attempted in the area with the aim of detecting promising area for Cu mineralization by employing the systemic optimized methods.

2 MATERIALS AND METHODS

2.1 Sampling

Sampling operations were performed by three expert teams and total of 233 stream sediments were collected from the area. Each sample covers approximately an area of 1-2 kilometers square based on streams density in the catchments and had maximum compatibility with topology center method. The higher density of sampling was carried out for important zones such as intrusive and extrusive bodies, alteration zones, vicinity of faults and their intersections.

After preprocessing, the samples were converted to -200 mesh and analyzed for Cu, Mo, Cr, Co, Ni, Pb, Zn, As and Y by different analytical methods specially XRF-Sequential method. Figure 2 presents the stream sediments sample location map in Gulan area.

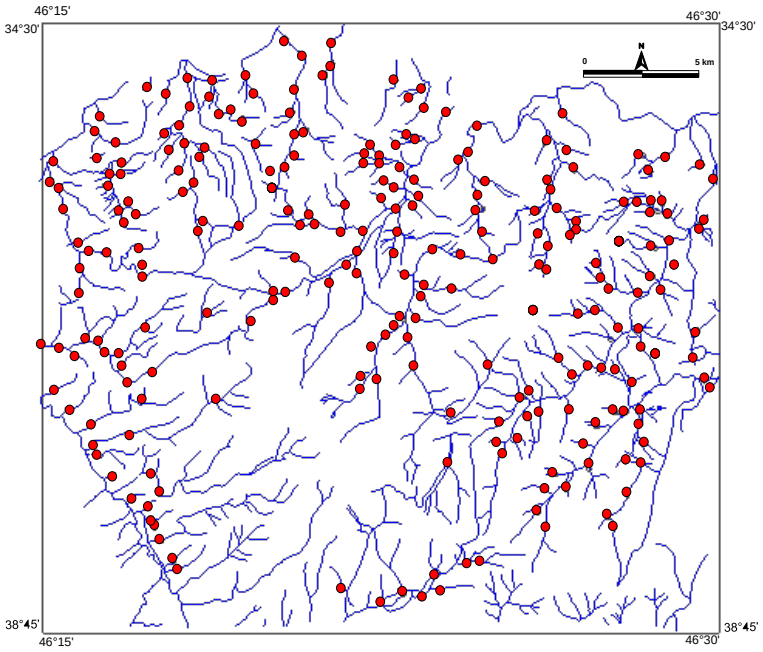

Figure 2. Stream sediments sample location map in Gulan area

2.2 Data Analysis

2.2.1 Principal Component Analysis(PCA)

Multivariate analysis methods have been used in mineral exploration for characterizing interrelationships occurring in large multi-element geochemistry datasets. Large datasets simplifying and analyzing process often becomes complicated and difficult when dealing with more variables. Therefore it is essential to apply dimension reduction methods in multivariate analysis. Principal component analysis (PCA) - as a multivariate statistical method- is a well mathematical method to reduce the dimensionality of the variable space based on the reduced factor solution. In the present study, PCA proceed in four steps: 1) computing the correlation matrix for all variables, 2) extracting factors, 3) rotating factors and 4) calculating scores between the original values and the extracted factors.

During this process, the obtained factors were subjected to orthogonal rotation by the varimax method to minimize the medium loaded elements in the extracted factors and to maximize low and high loadings of the elements. Since PCA with varimax normalized rotation was performed, each PC score contains information on all of the metal elements combined into a single number, while the loadings indicate the relative contribution of each element makes to that score. The PC loadings were plotted and accordingly the anomalous zones were detected (Figures 4& 5).

In order to assess the performance of the PCA for anomaly detection, we made a comparison of the results obtained from PCA with that of Fractal (F) over the same data.

2.2.1 Fractal method

This section contains a description of the Fractal construction and its application in discriminating anomaly from background in Gulan area. In this regard, the spatial distribution of elements values in a frequency domain was characterized and distinct patterns were separated using the concentration-area fractal method, which has been developed originally for anomaly separation in a spatial domain (Cheng, Agterberg, and Ballantyne, 1994; Cheng, 1999 asfollows:

$$A(\rho \le \upsilon)\alpha\rho^{-\alpha_1} \; ; \quad A(\rho \ge \upsilon)\alpha\rho^{-\alpha_2} \qquad (1)$$

Where $A(\rho)$ denotes the area with concentration values greater than the contour value ρ; υ represents the threshold; and α_1 and α_2 are characteristic exponents (fractal dimension).

All the resulting data from 233 stream sediment samples of the study area were analyzed using the aforementioned model for enhancing for enhancing and separating the anomalies from background, especially those week anomalies with relatively low concentration values.

The most important issue for calculating the fractal dimension in the studied area is to calculate concentration and grid area in gridded system. In this regard, there are several methods for interpolatingof data depending on the type of data. Due to the nature of the stream sediments data and considering the fact that each sample is only representative of its upstream thus radial estimation method was employed. After preparing gridded map(1000*1000 m^2), it was attempted to consider the area and concentration(C & A) for each cell. Ultimately, concentration-area log–log plot was constructed and then the threshold value was estimated based on the plot.

3 RESULTS AND DISCUSSION

Since multivariate techniques are sensitive to non-representative data, such as censored data, missing values and outliers, which impart strong variations in a dataset therefore prior to application of these techniques, a careful univariate analysis of the data set is required (Reimann et al., 2002). Accordingly, outliers were detected and replaced with Q method prior to data normalization and entering to PCA.

3.1 PCA Results

After pre-processing, univariate and bivariate statistical methods such as correlation coefficient was applied on the data. Considering the appropriate association of elements, PCA was conducted and the relevant maps were shown in Figures 4& 5 with their statistical parameters in Table1. This table shows the major loading of variables on each component in Gulan area. Further, a number of statistical parameters such as cumulative variance of each PC presented in the table, which can be used to judge the quality of a principal components analysis. Figure 3 a scree plot of the eigen values against their indices for different principal components (PC1 to PC8) indicating the importance of each component. The principal components calculated from a correlation matrix and only the first three components have eigen values above 1. These three components altogether account for 88.12% of the total variation in the original variables. The first principal component accounts for 38.88% of the variance including most of the variation in Zn,CO,Cu and Ni.

Table 1. Total variance and component matrixes for stream sediments samples in Gulan area

Element	PC_1	PC_2	PC_3
Cu	0.577	0.391	-0.486
Mo	-0.309	0.773	-0.341
Co	0.846	-0.328	0.143
Zn	0.817	-0.11	0.252
pb	-0.082	0.816	0.264
As	0.242	0.557	-0.015
Ni	0.632	0.335	-0.065
Zr	0.189	0.103	0.847
Cumulative (%) Variance	38.88	68.5	88.12

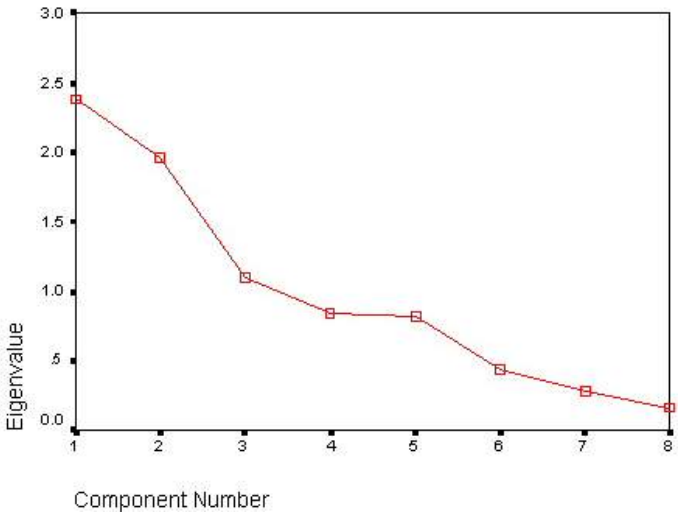

Figure 3. Diagram shows a scree plot of the eigen values against their indices for different principal components (PC1 to PC8) in Gulan area

Figure 4 shows a map of PC1 loading factor which indicates equal distribution of the elements in the area. Geochemically, it can be said that this distribution is the result of the weathering process. During this process, the elements have high mobility in aqueous solutions and can migrate for a long distances with relatively high stability. Depletion of Pb mobility in the area has been marked with intensity of Mo with extended secondary halos. In contrast positive correlation between Mo, Pb was observed in PC2 (with 29.62% of the total variance) that's why PC2 can not be used in geochemical interpretation of elements and determination of Mo and Pb anomalies. The third principal component (PC3) accounts for 19.62% and has high negative loadings score on Cu and Mo. Figure 4 shows the geochemical distribution map of (-PC3) which indicates high correlation between Cu, Mo in Namnig and Garehchiler zones. But the concentration of Cu, Mo in Namnig is more prominent compare to Garahchilar.

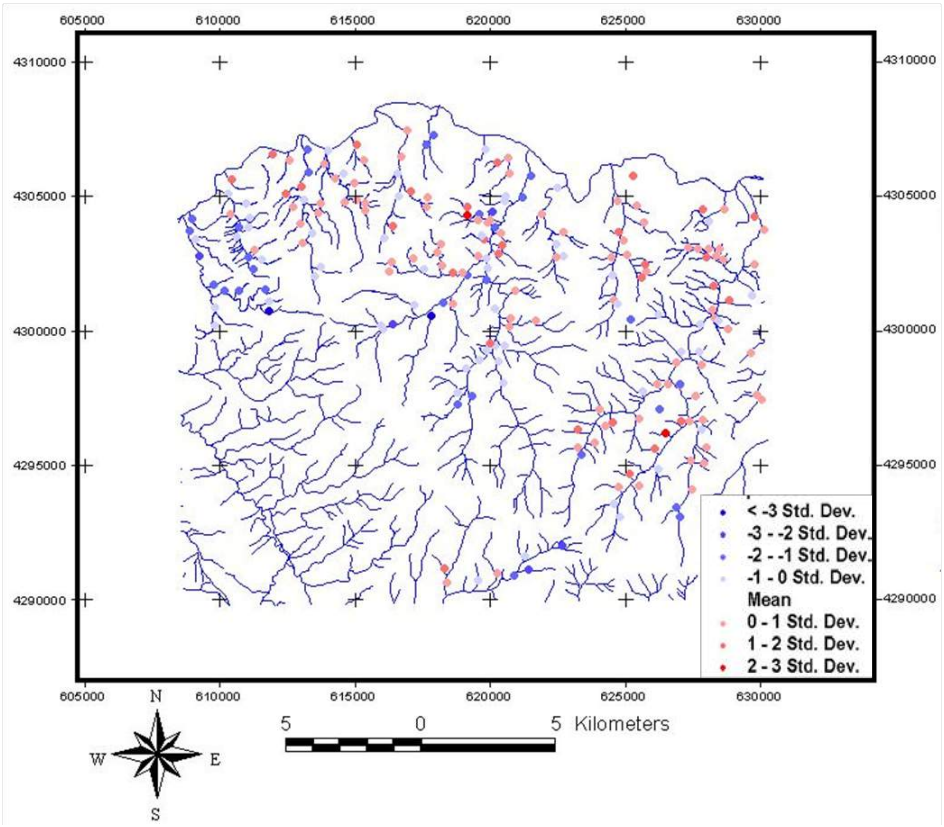

Figure 4. Mapping of the first (PC1) principal component in Gulan area.

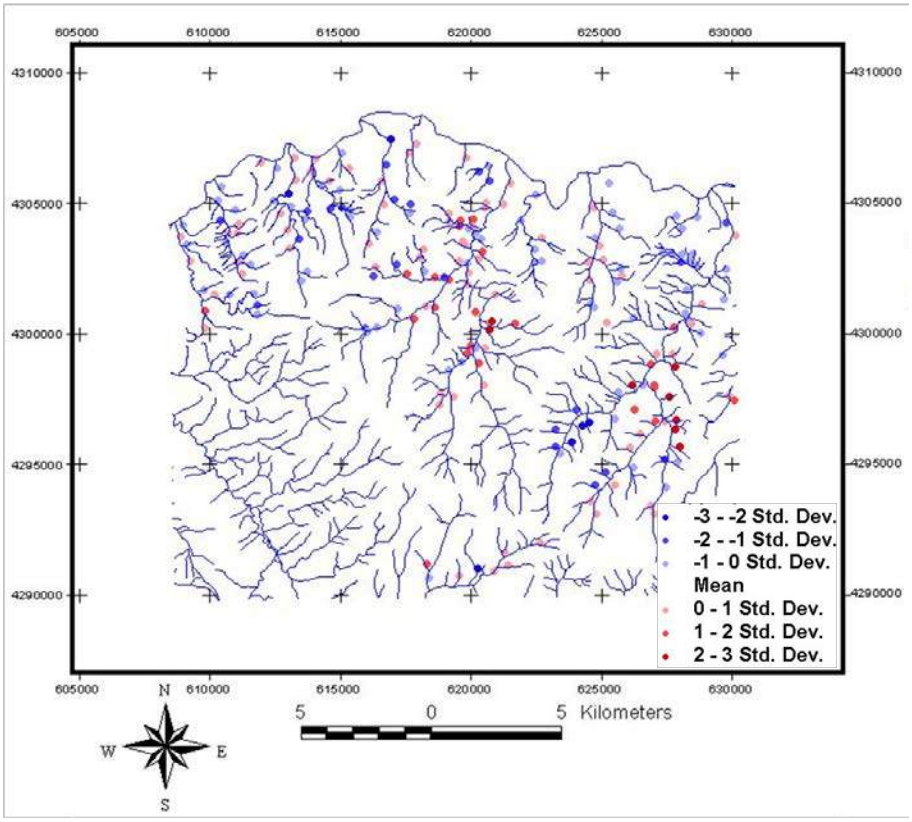

Figure 5. Distribution pattern map of (-PC3) showing high correlation between Cu and Mo in Namnig and Garahchilar.

3.2 Fractal Results

Figure 6 shows the grid pattern and catchment basin boundaries in Gulan area. Accordingly, most of catchments are overlapping in a cell. This issue was considered in calculating the final grade of each cell. After calculating the final grade for each cell, all log–log graphs were plotted (Figures 7& 8). To achieve this goal, the concentration-area fractal method was implemented for separating geochemical anomaly from background in the studied area. Distinct patterns separated by different straight-line segments with different slopes fitted to the elements values. Two line segments were fitted to the Cu and Mo values in Figures 7& 8, yielding a threshold value of 70ppm for Cu and 26 ppm for Mo respectively.

It can be seen that the areas with Cu values greater than 70ppm represent the Cu anomalies and the areas with 30 ppm for Cu as background value which may correspond to the average concentration of Cu in granodiorite and the effects of Cu mineralization. Figure 9 represents the geochemical distribution pattern of Cu anomaly population in the area. Based on this figure, three zones of West of Lutkeh, Gharachilar and Namnig were detected as promising areas for Cu mineralization. Similarly, figure 10 shows the anomaleous geochemical distribution pattern of Mo trending NW-SE of Gharachilar. This element manifested as molybdenite in the area and due to its high mobility, the corresponding secondary halos have expanded in the area. Therefore it can be used regional guide for prospecting. The lack of overlapping between secondary halos of Cu and Mo in Namnig and W of Lutkeh probably is due to acidification of the area by pyrite and Chalcopyrite presence from the outcrops. Thereby causing Mo to be transported in the form of molibdates in acidic environment concentrate its halo in Garachilar somehow discriminated from the Cu halos located in Namnig.

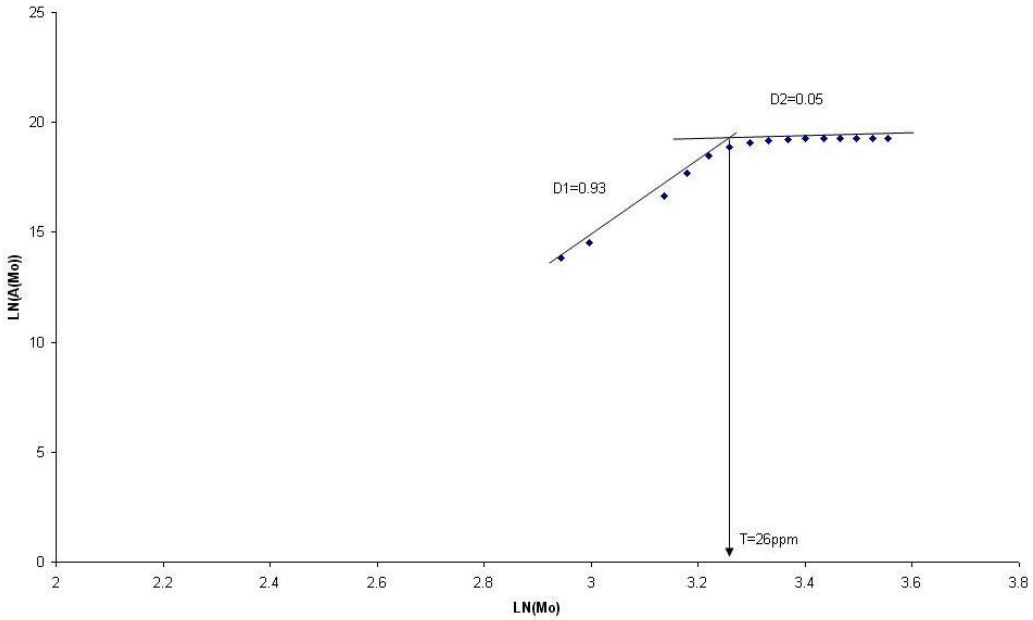

Figure 8. Log-log plot showing the relationship between frequency and Mo threshold value in Gulan area.

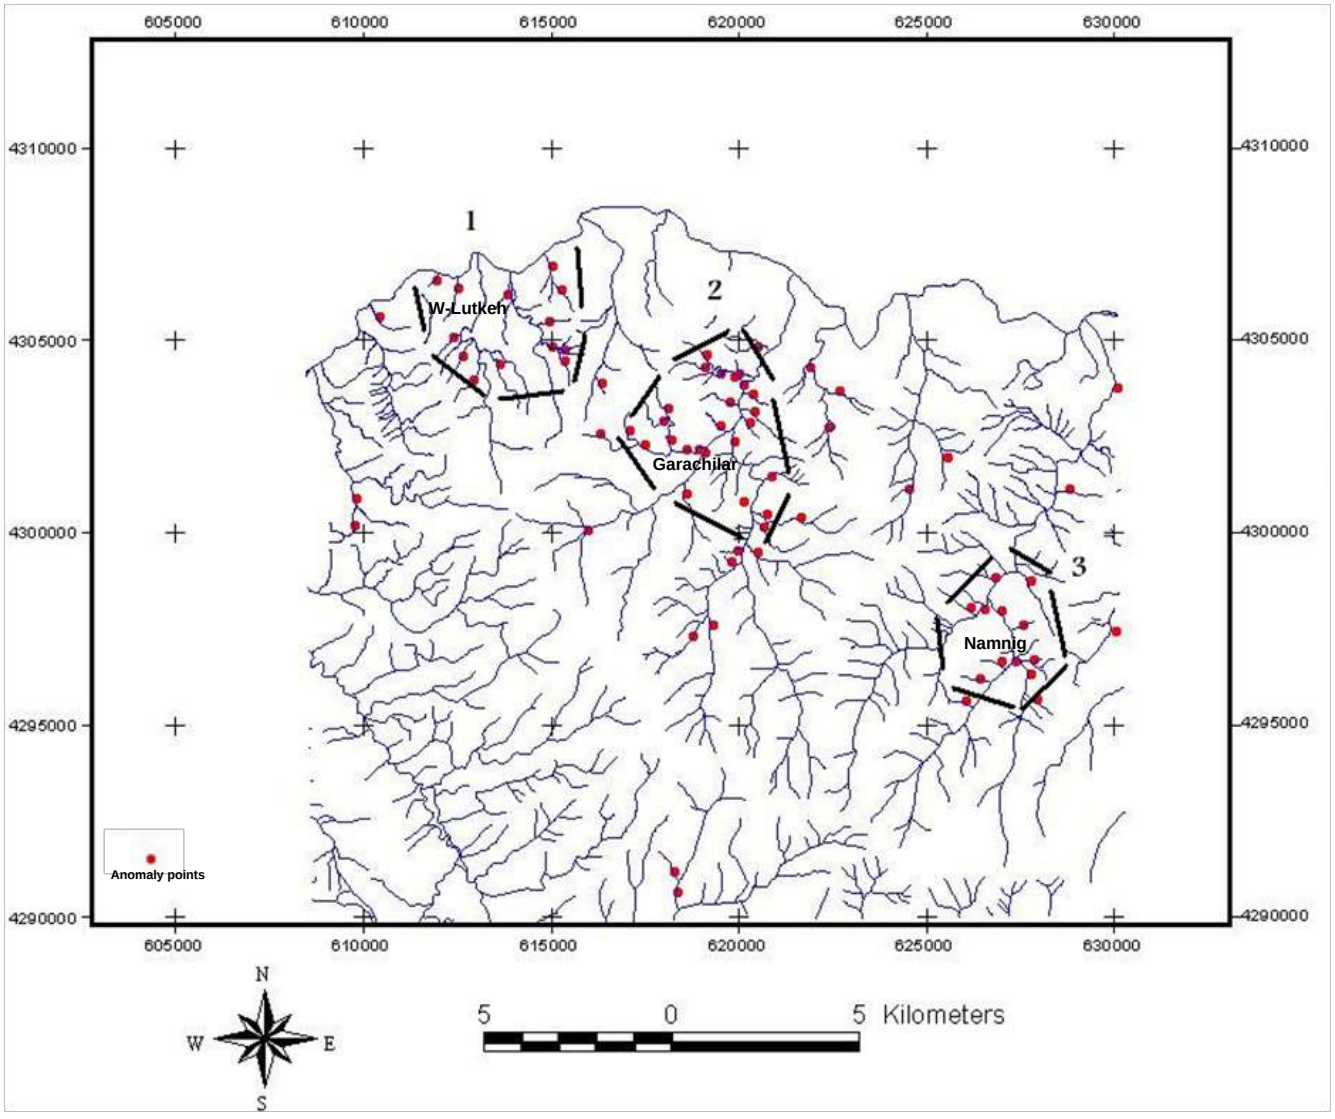

Figure 9. Cu anomaly delineation based on C–A model

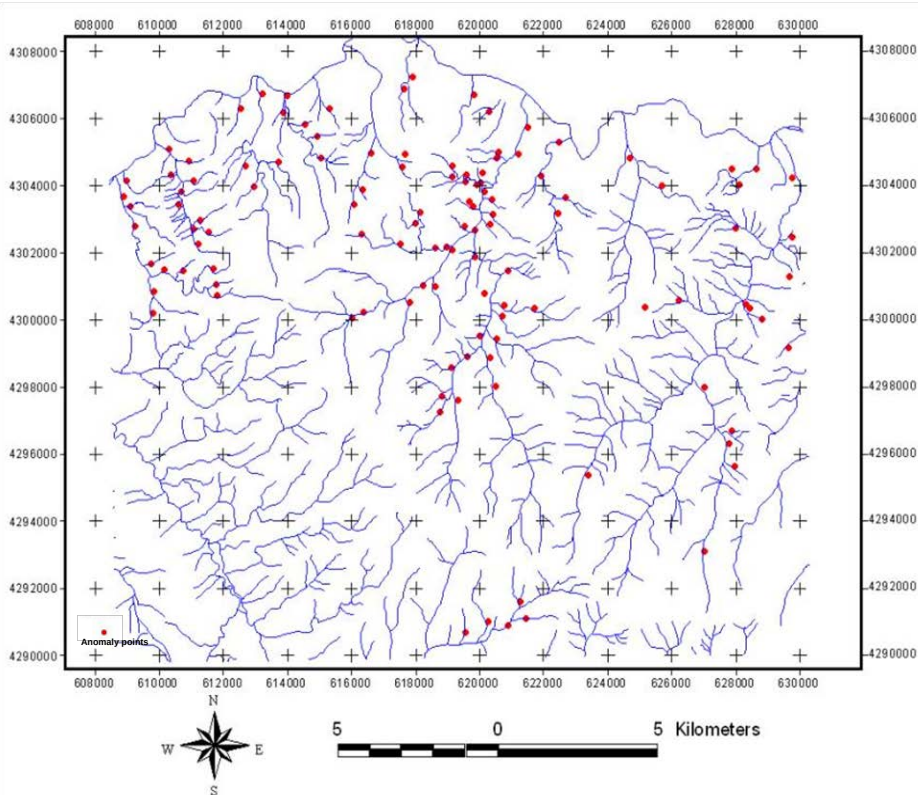

Figure 10. Mo anomaly detection based on C–A model

4 CONCLUSION

1) The results from PCA implementation in Gulan area reveals three parts of studied area as potentially promising zones for Cu- Mo prospecting in NW-SE direction. Application of this method enabled to detect more prominent anomalous zone in Namnig with higher intensity compared to Garachilar ad west of Lutkeh.

2) The intensity of Cu-Mo mineralization in the study area influenced by Caucasus tectonics and volcano-plutonic system of Shiyvar - Shahjahan-Ordubad orogeny trending with higher intensity toward NW-SE part of the area. This mineralization zone complying Alp-Hymalian Cu metalogenic belt trending toward famous Sungun copper mine –Anjerd and Kighal area.

3) Application of C-A fractal model in Gulan area indicate western part of Lutkeh, Gharachilar and Namnig for Cu prospecting while it proposed Gharachilar area for prospecting of Mo blind anomalous zone.

4) Results shows in spite that both the methods (PCA& F) have similar detection zones (western part of Lutkeh, Gharachilar and Namnig) but the capability of PCA in enhancement of halos and detection of blind ore zones is more effective than F method in this region. As in this case it could detect strong blind anomalous zone of Mo in Namnigh in addition to Cu – Mo general trend of mineralization. Overall the characterization of methods introduce PCA as a reliable method in rejecting the syngenetic effects and detecting anomalous zones with more accuracy and precision in Gulan area.

ACKNOWLEDGEMENT

Senior exploration engineer Hadi Fathi is hereby appreciated for his useful discussions and constructive advises in fractal data analysis. Furthermore, the authors also would like to acknowledge their sincere thanks to anonymous reviewers for their precious time and comments including all the organizers of the conference and other well wishers of the program

Digital Borehole Camera Technology and Its Applications in Mining Geology Exploration

H. Zengqiang, W. Chuanying, H. Sheng
State Key Laboratory of Geomechanics and Geotechnical Engineering, Institute of Rock and Soil Mechanics, Chinese Academy of Sciences, Wuhan 430071, CHINA

ABSTRACT Taking geological engineering exploration in Tangshan mining area of Kailuan Coal Mine as the engineering background, Digital Borehole Camera Technology is used to obtain discontinuities characteristics of rock mass in borehole. Further, a new method, rock mass integrity index (RMDI), is proposed to describe rock mass integrity. This article put forward a new technique and analysis method for geological survey of mining area. The research shows that: (1) The high resolution borehole image gives superior discontinuities information for geological survey of mining area; (2) The use of rock mass integrity index (RMDI) to evaluate rock mass quality is feasible, accurate and effective.

Keywords: Borehole camera technology, rock mass integrity, integrity index, geological survey

1 INTRODUCTION

With the rapid development of economy, the exploitation of mineral resources has entered a new stage with the increasing scale and strength of mining. However, this development also brings a series of problems to the geological disasters in mining area, making detailed geological survey of mining area become the main task of the mining work. For a long time, drilling core has become an important method of all kinds of geological survey work, which plays a huge role in the engineering geological survey. However, because of the complexity and particularity of the geological conditions of mining area such as the weak bedding, fault, fracture zone, the void region etc. and limitations of drilling technique such as low or zero rate of core caused by mechanical disturbance, this method loses its accuracy and sometimes even leads to wrong results.

It's one of the basic engineering geological survey works to collection of joints information, statistical analysis and assessment of the integrity of rock mass in mining area. At present, collection information on are mainly carried out in the outcrops of rock mass, and various geometric parameters of joints are artificially observed and measured with a huge workload and inaccurate results. On evaluation methods of rock mass integrity, RQD (rock quality index) method proposed by American Deere is the most widely used, however, this method also exist many problems in the process of actual application. In view of the above insufficiency, based on digital borehole camera technology, this article focuses on collecting and analyzing joints information and presents a new method for evaluation of rock mass quality—RMDI. Then, this research applies to geological engineering of Kailuan coal mine in Tangshan mining area survey work and has been achieved good results.

2 DIGITAL BOREHOLE CAMERA TECNOLOGY

Digital borehole camera technique is an advanced exploration method with a set of electronic technology, video technology and digital image technology which can realize 360° continuous panoramic imaging of borehole wall. Moreover, the borehole images superimpose on the range and depth of information that geological conditions of the whole drilling can be judge initially.

Problems which engineering geology concerned such as broken belt, joints can implement measurement, calculation and analysis. This technique has been successfully applied in water conservancy, civil engineering, energy, mining and other fields.

Figure 1. Digital panoramic borehole camera system

3 INVESTIGATION AND STATISTICAL ANALYSIS OF JOINTS

3.1 Calculation Of Joint Parameters

Assuming the relationship of joint and borehole is completely cutting, the geometric shape of joint in expansion graph is a sine curve as shown in Fig.2.

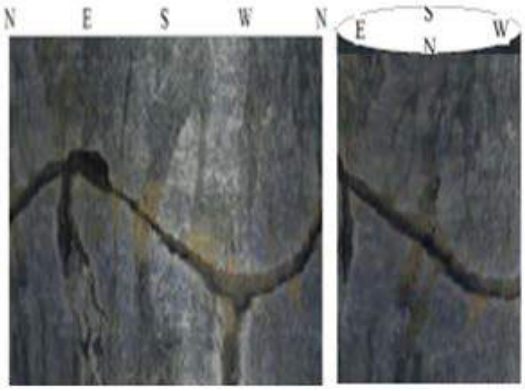

Figure 2. The expansion graph and three dimensional core graph of borehole wall

Through the calculation of the sine curve in the setting coordinate, multiple joint parameters can be obtained. In a borehole image, joint parameters mainly include: (1) Position depth. Joint position along the direction of borehole; refer to the distance from ellipse center point which formed by joint and borehole intersection to the orifice center point. (2) Dip direction. The angle between the line's drop shadow on the horizontal plane and the geomagnetic north direction; the line refers to link the highest point and the lowest point in joint cutting borehole. (3) Dip angle. The angle between the line and the horizontal plane; the line refers to link the highest point and the lowest point in joint cutting borehole. (4) Width. The vertical distance from the upside to underside of joint; mean values of multiple points when the two interfaces are not parallel.

3.2 Statistical Analysis Of Joints

Kailuan coal mine of Tangshan mining area has been 120 years of mining history with an annual output of raw coal 4×106t. Because of the large thickness of exploitation coal seam, repeated mining in multiple coal seams produce large surface subsidence and cause many social and environmental problems. For this reason, the group starts processing the subsidence caused by mining. For the further investigation into the engineering geological conditions of mining area, digital borehole camera technology is used to investigate joints, structural indications, the main discontinuities and fault structural fracture zone.

Twelve boreholes were arranged in the survey area, and with the imaging survey from top to bottom of the borehole wall, joints parameters can be obtained such as depth, occurrence and width. Through reasonable statistical methods to analyze these parameters, we can obtain some statistical rules. In No. ZK2 borehole as example, we get the following statistical results: First, drawing the whole joints occurrence distribution graph as shown on Fig.3, All joints can be divided into three groups according to the occurrence with the dominant occurrence are respectively N28° E∠37° , S24° W∠62° and N82° W∠78° .

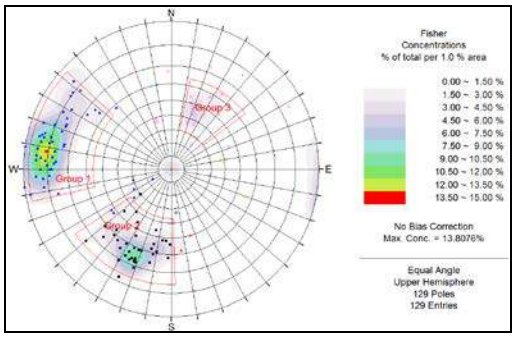

Figure 3. Occurrence distribution graph

Second, making classification statistic according to the different joint width as shown in Fig.4, the results show that joints with width of 5-10mm are in the largest number.

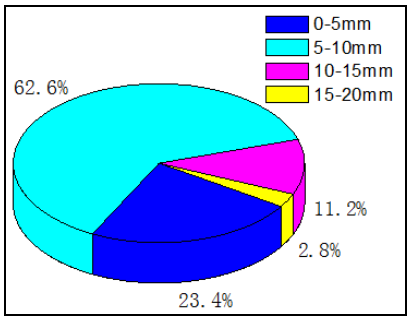

Figure 4. Width distribution graph

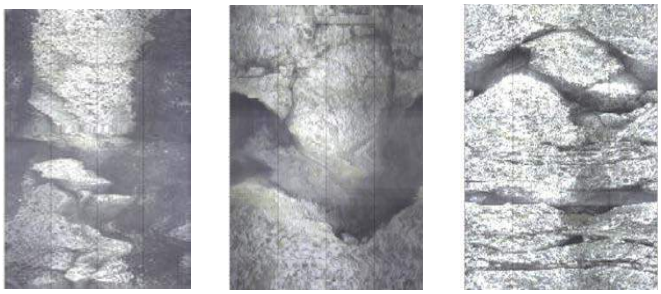
Third, making summary statistics of abnormal zones such as broken zone and cavity zone as shown in Fig.5, the results show that there are three abnormal zones should pay attention to.



183.4-183.8m 202.5-202.8m 226.7-227.2m

Figure 5. Abnormal zones

4 INTEGRITY EVALUATION OF BOREHOLE WALL ROCK MASS

4.1 The Evaluation Method

In order to realize the accurate evaluation on the borehole wall rock integrity, an integrity index density function is established. In this function, the concept of integrity and broken are defined based on digital borehole image with the reason that there is a direct relationship between the geological structure and integrity or broken in borehole image. For example, all kinds of closed interface have very little effect of rock integrity and the color, texture of borehole image is well-distributed, showing integrity characteristics; open joints and fault fracture zones make the rock mass break and the color, texture of borehole image is varies greatly, showing broken characteristics. Therefore, we can define two rock mass characteristics reflected in the borehole image: broken and non-broken.

Integrity index density function (DIDF) is a single variable function changing along the borehole axial, expressing as f(z) which z represents the depth. The function is shown as follows:

$$f(z)=\begin{cases} 0 & \text{Fractured Rock Mass} \\ \alpha\times 1 & \text{Non Fractured Rock Mass} \end{cases}$$

In the formula, α is the size reflection of rock block. About the determination of rock integrity block size reflection coefficient, based on grading standard of joints spacing ISRM recommended, α is defined as shown in Table 1.

Table 1 Rock mass size and corresponding size effect coefficients

Standard	Structure Types				
	Integrity	Block	Lamellar	Fracture	Granular
ISO/WC 182/WGI/SC	>0.6m		0.2-0.6m	<0.2m	
Block size as α	>1.0m	0.6-1.0m	0.3-0.6m	0.1-0.3m	<0.1m
α	1.0	0.8	0.5	0.2	0.1

On the basis of integrity index density function (DIDF), rock mass integrity index (RMDI) is proposed to evaluate the integrity of rock mass. Rock mass integrity index (RMDI) means scale complete rock block degree occupies within a given range expressed as a percent. If the depth range is given as [h1, h2], RMDI can be indicated by

the definite integral of DIDF in the range. The expression is shown as follows:

$$\mathrm{RMDI} = \frac{\int_{h_1}^{h_2} f(z)dz}{\int_{h_1}^{h_2} 1dz}$$

4.2 Case Analysis

Taking borehole No.ZK2 for example, borehole wall rock integrity is evaluated combined with the joints statistical analysis. The test range of borehole No.ZK2 is 175.5～245.5m. By dividing structure types and determining the effect coefficient, integrity index density function (DIDF) is established. Based on DIDF, RMDI in different deep range is analyzed. Results are shown in Table 2.

Table 2 Results of RQD and RMDI

Depth/m	RQD/%	RMDI/%
175.5-185.5	97.94	92.58
185.5-195.5	95.43	91.87
195.5-205.5	92.65	90.53
205.5-215.5	88.56	87.49
215.5-225.5	99.91	97.36
225.5-235.5	91.69	86.79
235.5-245.5	98.73	79.39

Through the above analysis and calculation, the value of RQD is generally bigger than the value of RMDI. This result mainly because RQD is only the cumulative length, however, RMDI is the definite integral of DIDF which considers the effect of size effect of rock block.

5 CONCLUSION

The article researches the application of borehole camera technology in geological survey of mining area, combined a project case to show how this research to carry out. The results show that: (1) Borehole camera technology makes up for the lack of core drilling; (2) The high resolution borehole image gives superior discontinuities information for geological survey of mining area; (3) Using RMDI method for the evaluation of rock mass integrity is feasible.

Estimating the Reserve of Chelkureh Copper Deposit Using Ordinary Kriging Method

A. A. Daya
Department of Mining Engineering, University of Sistan and Baluchestan, Zahedan, Iran

ABSTRACT This paper presents a reserve estimation of Chehelkureh copper mine by ordinary kriging method. The case study consists of borehole samples measuring the Cu concentration. This deposit was explored principally by 48 boreholes totaling to 2976.7 m of drilling. In order to estimate the deposit, 1351 input data gained from 48 boreholes were used. To estimate the Cu grade, ordinary kriging was used. For application of ordinary kriging, a spherical model was fitted over empirical variogram. Then the model was verified through cross validation method and proved to be valid with a very good coherence coefficient between the estimated and real data. Plotting the empirical variogram in different directions showed geometric anisotropy for the deposit. Results showed that ordinary kriging can be used for estimating and modelling the Cu concentration in the Chelkureh mine.

Keywords: Ordinary krigging method, Chelkureh copper mine, reserve estimation

1 INTRODUCTION

Geostatistics provides a coherent framework for spatial prediction and uncertainty assessment spatial prediction or interpolation is concerned with how to estimate the variable under study at an un-sampled location, given sample observations at nearby locations. This question aims at finding a single number, termed the 'estimate', at the un-sampled location. Estimation is possible due to spatial correlation, i.e. the underlying biophysical phenomenon causes observations that are measured closely to be dependent on one and another (Zhang and Yao 2008). If the unknown values at the un-sampled location were dependent on the known sample value at another location, then those sample values carry information about the unknown (Zhang and Yao 2008).

An important problem in mineral exploration is the estimation of two- or three-dimensional regional variables in a studied area, especially ore grade distribution. According to this problem, which is known as spatial interpolation, several methods were proposed which consist of linear and non-linear kriging methods, inverse distance weighted (IDW), interpolating polynomials, splines, and power and Fourier series fitting (Shahbeik et al. 2013). Ordinary kriging is now well accepted method in mining grade control and mine reserve estimation.

The aim of this study is to evaluate the potential and applicability of ordinary kriging method, as a tool for estimating the reserve of Chelkureh copper deposit. To estimate, all of the exploitable blocks with dimensions 20 m * 20 m * 10 m were block estimated within the estimation space. Ordinary kriging was used to estimate the regionalized variable (Cu Concentration) at unsampled locations. After that a three dimensional model of estimated value is presented by ordinary kriging. The study shows that ordinary kriging can be applied successfully for modeling the grade of an ore deposit. Results showed that the correlation between the estimated value and the real value at locations is 82.9%.

2 GEOLOGICAL SETTING OF CHELKUREH DEPOSIT

The Chehelkureh deposit is located in the Nehbandan- Khash zone (eastern Iran) between the Afghan block to the east, the Neh Fault to the west, and the Bashagard Fault to the south (Stocklin et al. 1972). This

zone, also known as the Sistan suture zone of eastern Iran (Tirrul et al. 1983), represents a narrow, short-lived strip of oceanic lithosphere that was consumed in the Sennonian and Paleogene and, in part, obducted during the Eocene continental collision (Tirrul et al. 1983).

Dikes and lavas from the Chehelkureh ophiolitic mélange are plagioclase-phyric basalts with chemical compositions that indicate that they were mid-ocean ridge and marginal basin tholeiites (Desmons and Beccaluva 1983). There is no metasedimentary rock older than Cretaceous in the Sistan suture zone (Maanijou et al. 2012). The Cretaceous facies consists of flysch (turbidite) sediments and volcanic rocks (Stocklin et al. 1972) up to 3 km thick. The turbidites are strongly tectonized and underwent low-grade metamorphism (e.g., zeolite-subgreenschist facies) during the Cretaceous, which converted them to slate, phyllite, and schist. The N-S–trending Lunka-Malusan Mountain Range is the highest in the region, with Kuh-e-Lunka (2,300-m elevation) comprising metaturbidites (Fig.1) and Kuh-e-Malusan (2,425-m elevation) comprising gabbro (Maanijou et al. 2012). The study area is divided into three lithotypes on the basis of rock components: igneous rocks (younger than ophiolites), sedimentary rocks, and the ophiolitic mélange (Fig. 1). Each of these lithotypes is described below, relative to its age (i.e., from the oldest to the youngest unit). Sedimentary layers, which consist of graywacke, shale, and limestone, are tightly folded, steeply dipping, and faulted (Maanijou et al. 2012). Cretaceous turbidites have faulted contacts with the ophiolitic complex and are composed of phyllite and small lenses of marble (Maanijou et al. 2012). Paleocene turbidites are composed of shale and sandstone with rare limestone layers (Fig.1). Eocene turbidites are up to 1 km thick and widespread. In metamorphosed turbidites the basal conglomerate is the oldest unit. The western turbidites, which are altered, host the Chehelkureh ore deposits (Maanijou et al. 2012). Several granitoid stocks and dikes intruded the sedimentary sequence where they are oriented parallel to the major NWSE– trending fault set (Fig.1). Plutonic rocks crop out mostly to the west of the Chehelkureh Fault in the Lunka-Malusan Mountain Range (Valeh and Saeedi 1989).

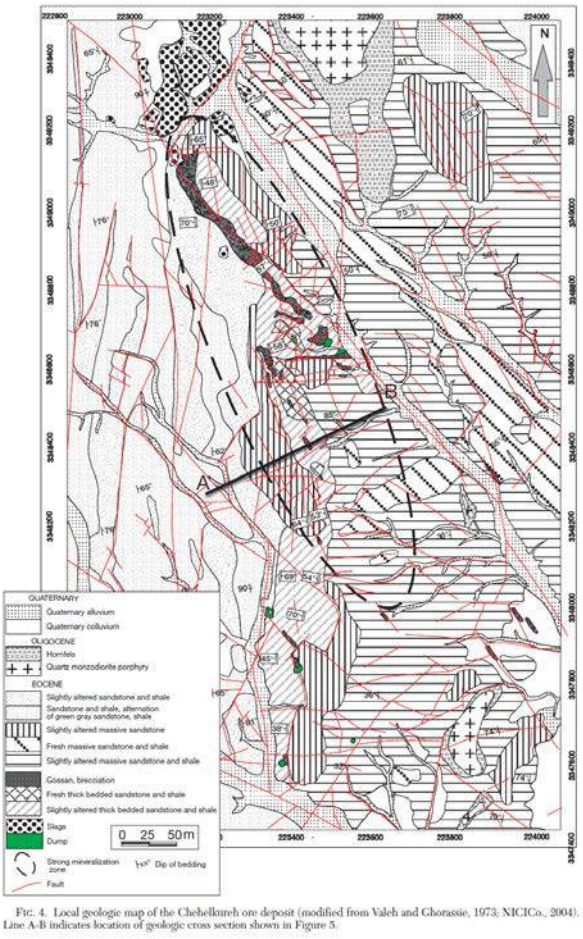

FIG. 4. Local geologic map of the Chehelkureh ore deposit (modified from Valeh and Ghorassie, 1973; NICICo., 2004). Line A-B indicates location of geologic cross section shown in Figure 5.

Figure 1. Regional geologic map of the Chehelkureh ore deposit (Maanijou et al. 2012)

Intrusive bodies consist of quartzmonzodiorite and granodiorite at the Chehelkureh deposit. Exposures of rock in the vicinity of the Chehelkureh deposit are controlled by major N-S– and NW-SE–trending faults, based on air photo lineaments, surface traces, and offsets of geologic features (Maanijou et al. 2012). The strata in the western part of the area, as well as the enclosing faults belonging to the Neh fault system, have an N-S trend. The Neh fault system is a dominantly right-lateral strike-slip set of faults that have been recently active. The N-S–trending Khanibeyk Fault (the eastern branch of Neh Fault) and northwest-southeast Chehelkureh

Fault are the most important faults in the area (Maanijou et al. 2012).

The Chehelkureh deposit comprises numerous lenses and veins. There were two stages of mineralization, the first of which consists of metallic mineralization concentrated along the brittle, finely fractured parts of the beds of sandstone, siltstone, and shale. The second stage of mineralization formed along fractures that crosscut sandstone, siltstone, and shale, displacing them by several millimeters.

3 STATISTICAL ANALYSIS ON DATA

This deposit was explored principally by 48 boreholes (Fig. 2) totaling to 2976 m of drilling. In general, the drilling grid is irregular; the distance between two boreholes varies from 50m to 100m (Fig. 2). Borehole samples were analyzed by ICPMS method. They were of unequal length. It is very important in estimation to work with equal support (volume) samples. This is why the data were composited to equal lengths (Daya 2013; Daya and Bejari 2014).

Statistical studies were performed on the raw data, the results of which are shown in Fig. 3 for Cu concentration values more than 0.20 %. The histogram of the raw data (Fig. 4) was generated by GSLIB Software (Deutsch and Journel. 1998). This regionalized variable (Cu %) can be modeled using a second- order stationary random function. There is no trend of Cu concentration in any directions; it means that Cu concentration does not depend on the coordinates of samples (Fig 4, 5, 6). Assumptions of stationary thus appear to be tenable (Daya 2014). Since the Gaussian kriging method was not used in this study, the data were therefore not normalized and raw data can be utilized (Shahbeik et al. 2013).

4 DISCUSSION

Variogram modelling and estimation is extremely important for structural analysis and spatial interpolation (Burrough and McDonnell 1998). They are widely used tools for spatial interpolation, which are the fundamental parameters for geostatistical modeling (Shahbeik et al. 2013; VerHoef and Cressie1993; Calder and Cressie 2009). The experimental variogram displays several important features (Burrough and McDonnell, 1998). The variogram models may consist of simple models, including: Nugget, Exponential, Spherical, Gaussian, Linear, and Power model or the nested sum of one or more simple models (Burrough and McDonnell 1998; Pebesma 2004; Webster and Oliver 2001). The most commonly used model in mining industry is spherical model. In the current study the spherical model was used. In this study, the non-directional and directional variograms were generated by GSLIB Software (Deutsch and Journel. 1998) in the Chelkureh deposit, as shown in Fig. 7.

After studying of variograms in different direction (Fig 7: B, C, D) it was found out that the ore deposit has no anisotropy, because in most of the variograms same ranges were obtained. The best fitted variogram model (Fig. 7 D) is considered for ordinary kriging estimation. Cross-validation was used to evaluate the accuracy of the variogram model for kriging (Fig. 8). In this procedure, every known point is estimated using the values at the neighborhood around it, but not itself (Isaaks and Srivastava 1989). After trial and error process of the cross validation a variogram with the best summary statistics is chosen. Model consists of a pure nugget effect with 0.30 plus a spherical scheme with sill 1.10 and range 30 m. This model is required since ordinary kriging estimation will be based on.

To estimate the Cu %, the ordinary kriging method was used to get estimates at points on a grid 20m x

20m x 10m. These points may be taken as the center-points of cubes of dimension 20m x 20mx 10m. The estimation and 3-D modelling process commenced from the elevation of 1280m above the sea level to 1670m above the sea level in the mine. It also began from 223075m to 223575m in the east direction and from 334755m to 3348850m in the north direction (Fig 9, 10). For the application of OK, GSLIB Software (Deutsch and Journel. 1998) has been used. Fig.9 and Fig.10, respectively, show estimates and kriging errors of Cu concentration in different elevations above sea level computed by OK.

Three dimensional modeling of grade in an ore deposit has a lot of advantageous. Therefore if this process is done carefully, evaluations and judgments about different parts of ore deposit would be better.

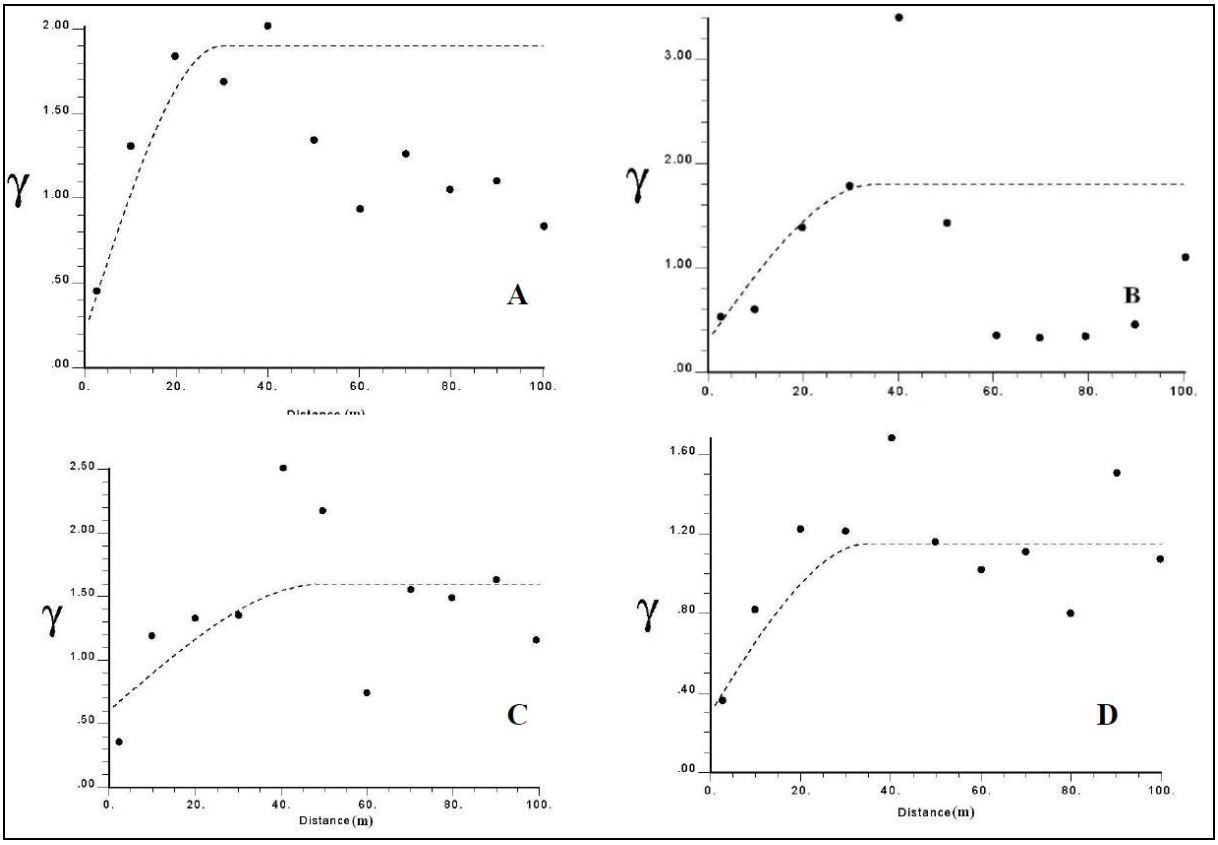

Figure 7. Non-directional and directional variograms: A non-directional, B North-South direction, C East-West direction, and D Vertical direction

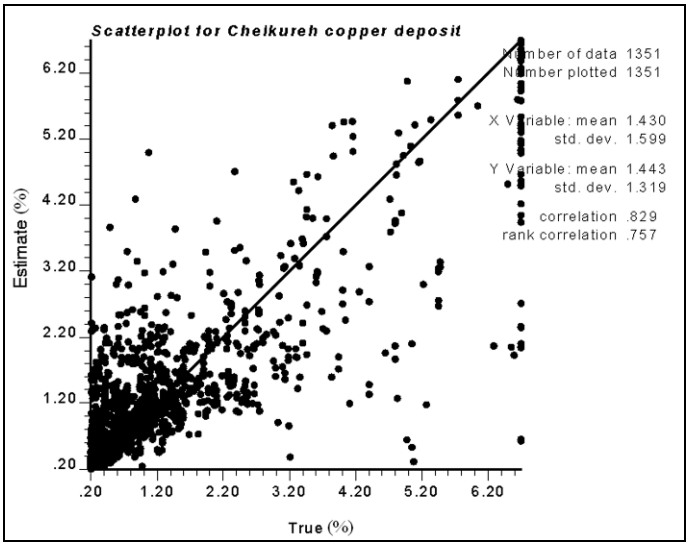

Figure 8. Cross validation diagram for real and estimated values of Cu in Chelkureh copper ore deposit.

In ore estimation it is necessary to calculate the error of each voxel and the classification of reserves. The following formula for calculation of the estimation error is used (Noppé 1994):

$$\% \text{ Error} = ((Z.S)/ (X.\sqrt{N})) \times 100 \quad (1)$$

(1)

S, X and V are the standard deviation of each voxel, assay of each voxel and the number of samples that are participating in the grade estimation, respectively. Z is the integer constant, which is 1.96 if the confidence level is 95% or 1.64 if the confidence level is 90%. In this study, the confidence level assigned to Z was 90% hence a Z of 1.64 was used.

The reserve estimated by OK method was classified based on error estimation. The JORC (2012) method was selected to classify the reserve, as shown in Table 1. The classification framework based on the prepared code by the Joint Ore Reserves Committee of the Australasian Institute of Mining and Metallurgy, Australian Institute of Geoscientists and Minerals Council of Australia (JORC code), which is one of the international standards for mineral resource and ore reserve reporting, provides a template system that conforms to

international society requirements (Li et al. 2008; Asghari and Madani 2013).

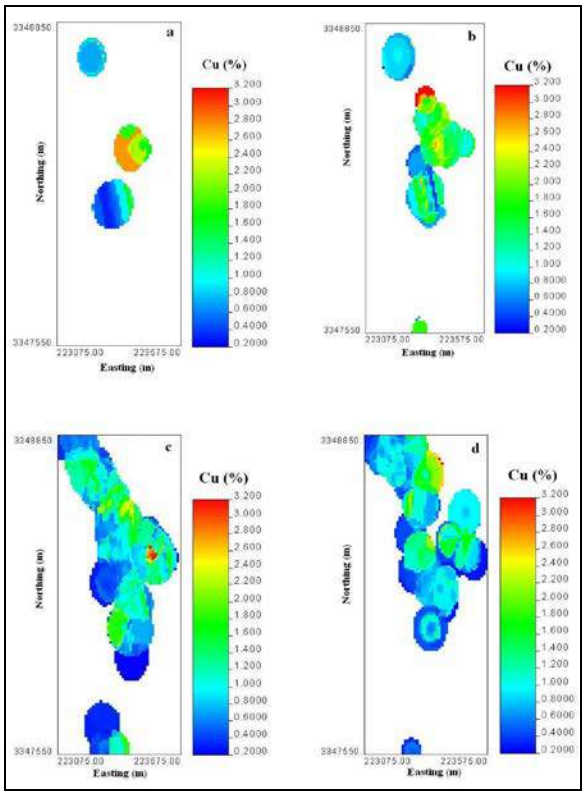

Figure 9. Estimates of Cu concentration by ordinary kriging in different elevations (a=1330m, b=1380m, c=1480m, d=1580m above the sea level) in Chehelkureh deposit

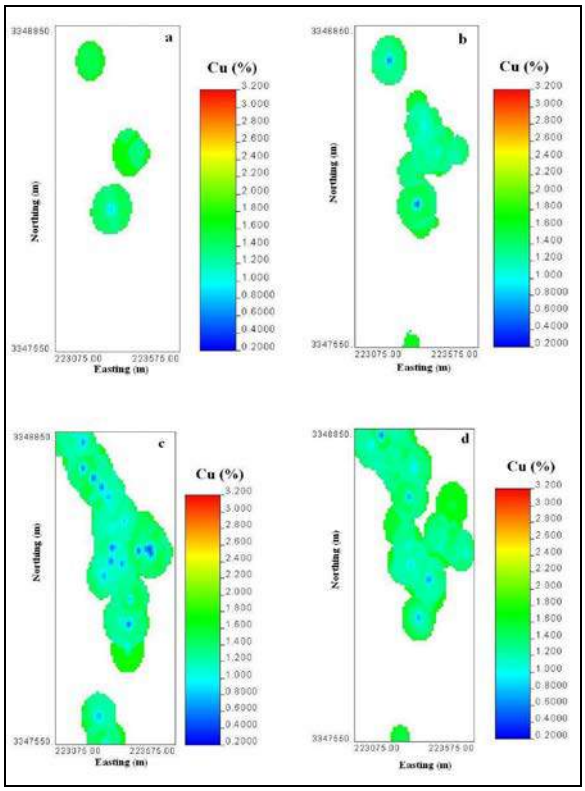

Figure 10. Ordinary kriging errors of Cu concentration in different elevations (a=1330m, b=1380m, c=1480m, d=1580m above the sea level) in Chehelkureh deposit increasing the cut-off grade the amount of deposit decreases.

Most parts of the estimated block model derived via the OK method (higher than 92.66%) were classified in the A category based on JORC standard (Table 1). And, 7.34 % of the estimated tonnages by the OK method were categorized in the B class (Table 1).

Grade-tonnage curves are one of the tools which enable the mine managers to determine the correct long-time, mean-time and short-time parameters for ore producing. Drawing grade-tonnage curves needs to finding the tonnage of different grades. To find the tonnage of each block, the specific gravity of ore and core recovery percent is required. So according to this data, we could calculate the deposit based on different cut-off grades. Fig. 11 shows the grade-tonnage curve of Choghart north anomaly copper ore deposit. It could be seen that with reducing the cut-off grade of copper the amount of deposit increases and with

Table 1. Reserves classification based on JORC standard

Error (%)	Average Grade (%)	Tonnage (%)	Class
0-20	1.12	92.66	A
20-40	0.41	7.34	B
40-60	-	-	C
>60	-	-	Possible
Total	1.054	100

5 CONCLUSION

Choosing the proper method for estimation of reserve with a minimum error is very important in geostatistical operations in mining engineering. The case study presented in this paper shows that ordinary kriging is a useful method in the estimation of reserves or resources of vein type deposits, such as in Chelkureh copper deposit. After trial and error a variogram with the best summary statistics was chosen. Model consists of a pure nugget effect with 0.30 plus a spherical scheme with sill 1.10 and range 30 m. The cross validation results show that the correlation coefficient between estimated and real data is 0.829. The total tonnage of the ore deposit based on various cut-off grades is different and with 0.20% cut-off grade are 200,000 tones, with 0.5% cut-off grade are 150,000 tones and with 0.80% cut-off grade are 100,000 tones. Classification of reserve has been carried out successfully by JORC standard. High-grade reserves including 92.66 % of reserve have errors less than 20 % based on estimation by OK technique. Based on results obtained by OK method, parts of the high-grade reserves that include 7.34 % of reserve have an error between 20 to 40 %. It is hoped that this example taken from very different application fields will encourage practitioners in applying ordinary kriging with variety of ore deposits.

Fuzzy Analytical Hierarchy Process for Mineral Exploration Potential Mapping: a Case Study in Kamoshgaran Region (NW, Iran)

A.A. Daya, H. Bejari
Department of Mining Engineering, University of Sistan and Baluchestan, Zahedan, Iran

ABSTRACT: Selection of potential areas for mineral exploration needs many diverse criteria. Analytic hierarchy process (AHP) modeling provides an effective means for studies of mineral potential mapping evaluation. Fuzzy AHP is an extension of conventional AHP and by using fuzzy theory is obtained the advantage rather AHP method. In this paper to provide, potential mapping for elemental mineralization used fuzzy AHP in the Kamoshgaran region, several criteria, such as geology, geochemical, alteration, and faults were used. Each criterion was evaluated with the aid of fuzzy AHP. The method allowed a mixture of quantitative and qualitative information with group decision. The results and its validation demonstrate the acceptable outcomes for mineral exploration.

Keywords: Fuzzy, Analytic hierarchy process (AHP), Kamoshgaran

1 INTRODUCTION

Localization is one of the spatial analyses that have great effect on reducing the costs of creating and construction of various activities. Today, finding a suitable place or places for the creation of an activity in a specific geochemical field is an important step. Over the past decades, many methods such as simple additive weighting (Hwang and Yoon 1981), the technique for order preference by similarity to ideal solution (Hwang and Yoon 1981), analytical hierarchy process (Saaty 1980), data envelopment analysis (Cooper et al. 2000), and so on have been developed to deal with a multiple decision making problem. One of the most powerful and flexible method of decision-making means is analytical hierarchy process (AHP) method which was initially presented by Saaty (1980) for use in solving multiple criteria decision problems. Analytic hierarchy process (AHP) is one of the most commonly used multi-criteria decision-making (MCDM) methods, which integrates subjective and personal preferences in performing analyses. Fuzzy logic, resembling human reasoning in its use of approximate information and certainty to generate decisions, is a better approach to convert linguistic variables to fuzzy numbers under ambiguous assessments. This method under fuzzy environment has been used for a variety of specific application in decision making problem (Önüt and Soner 2008; Torfi et al. 2010; Erensal et al. 2006; Dağdeviren et al. 2009; Khademi Hamidi et al. 2010; Bejari et al. 2010; Aalianvari et al. 2012; Ataei et al. 2012; Rafiee et al. 2013; Fattahi et al. 2014 and Pazand et al. 2014), nevertheless its application in selecting the best geochemical fractal anomalies has not been reported yet.

Fractal theory has been established and developed by Mandelbrot (1983), as an important branch of nonlinear mathematical sciences has been applied in different fields of geosciences since 1980s. Cheng et al. (1994)'s studies show that geochemical dispersion patterns of different elements are fractals. Several fractal models have been developed and applied to geochemical exploration for separate anomalies from background. One of the most important method for separating anomaly from background is the number–size model (N–S model) proposed by Mandelbrot (1983), which has been widely used by many

geoscientists (e.g., Agterberg, 1995; Turcotte, 2002; Zuo et al., 2009c; Wang et al., 2010).

In this paper, first Cu, Au, As, and Mo anomalies were delineated by number–size fractal model and then selecting the best anomalies was done using fuzzy-AHP method.

2 NUMBER-SIZE (N-S) MODEL

Number–size (N-S) method proposed by Mandelbrot (1983) can be utilized to describe the distribution of geochemical populations (Sadeghi et al., 2012). In this method, geochemical data do not undergo any pre-processing (Mao et al., 2004). This model shows a relationship between desirable attributes (e.g. elemental concentration in this study) and their cumulative numbers of samples (Sadeghi et al., 2012). A power-law frequency model has been proposed to explain the N–S relationship according to the frequency distribution of elemental concentrations and cumulative number of samples with those attributes (e.g., Li et al., 1994; Sanderson et al., 1994; Shi and Wang, 1998; Turcotte, 1996; Zuo et al., 2009a; Sadeghi et al., 2012). The model is expressed by the following equation (Deng et al., 2010; Mandelbrot, 1983):

$$N(\geq \rho) = K\rho^{-D}$$

where ρ denotes elemental concentration, N(≥ρ) denotes the cumulative number of samples with concentration values greater than or equal to ρ, *K* is constant, and *D* is the fractal dimension of the distribution of elemental concentrations. According to Mandelbrot (1983) and Deng et al. (2010), log–log plots of *N* (≥*ρ*) versus ρ show straight line segments with different slopes – *D* corresponding to different concentration intervals (Sadeghi et al., 2012).

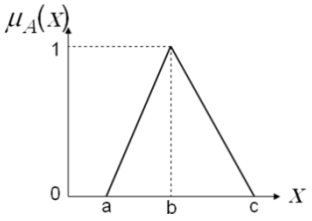
3 FUZZY ANALYTIC HIERARCHY PROCESS (F-AHP)

Analytic hierarchy process (AHP) is a useful approach for evaluating complex multiple criteria alternatives involving subjective judgment. The AHP structures the decision problem in levels which correspond to one understands of the situation: goals, criterion, sub-criterion, and alternatives. By breaking the problem into levels, the decision-maker can focus on smaller sets of decisions. In AHP technique, the elements of each level compared to its related element in upper level by pairwise comparison method. Though the aim of AHP is to capture a decision maker's knowledge, the conventional AHP cannot fully reflect the human thinking style. Linguistic and vague descriptions could not be solved easily by AHP until the recent development in fuzzy decision-making (Cheng 1999). Fuzzy set theory first proposed by Zadeh (1965) as a means representing uncertainty using set theory.

The traditional AHP employs exact numbers such as 1–9 to score. However, much decision-making involves some uncertainty. The traditional AHP does not take into account the uncertainty associated with the mapping of one's perception (or judgment) to a number (Cheng 1996).

Fuzzy set theory, resembling human reasoning in its use of approximate information and certainty to generate decisions, is a better approach to convert linguistic variables to fuzzy numbers under ambiguous assessments (Zadeh 1975). By incorporating fuzzy set theory with AHP, fuzzy AHP allows a more accurate description of the decision-making process. So, the use of fuzzy numbers and linguistic terms is more suitable since the traditional AHP approach is somewhat arbitrary. A fuzzy number describes the relationship between an uncertain quantity x and a membership function μ_x, which ranges between 0 and 1. A fuzzy set is an extension of the classical set theory (in which x is either a member of set A or not) in which an x can be a member of set A with a certain membership function μ_x. Different shapes of fuzzy numbers are possible (e.g., bell, triangular, trapezoidal, Gaussian, etc.). In order to simplify the implementation, in this

paper, triangular fuzzy numbers (TFNs) are used. TFN is represented by three points (a, b, c) on the universe of discourse (scale X on which criterion is defined), representing the minimum, most likely, and maximum values, respectively. Figureure 1 illustrates a triangular fuzzy number (TFN).



$$\mu_A(x) = \begin{cases} 0 & if\ x \le a \\ \dfrac{x-a}{b-a} & if\ a < x \le b \\ \dfrac{c-x}{c-b} & if\ b < x \le c \\ 0 & if\ x > c \end{cases}$$

Figure 1. A triangular fuzzy number

This paper proposes a seven-step procedure for F-AHP which is schematically given in Figure. 2. These seven steps are followed through a simple hierarchical structure example shown in Figure. 3. A step-by-step description of the methodology is presented as following.

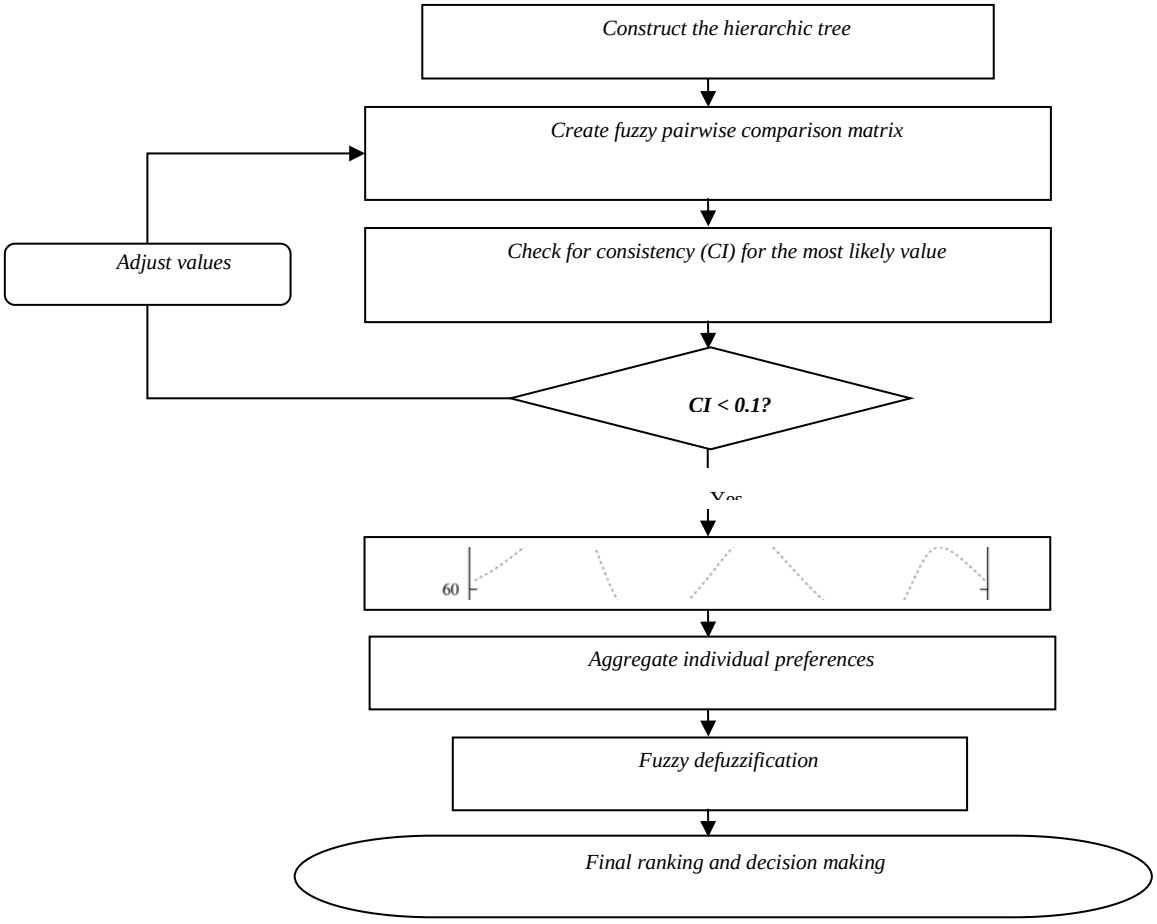


Figure 2. Proposed methodology for fuzzy AHP

3.1 Construction Of Hierarchical Structures

Constructing the hierarchical model includes the decomposition of a complex decision problem into smaller manageable elements of different hierarchical levels. The first level of the hierarchy corresponds to objective or goal, and the last level corresponds to the evaluation alternatives (options), whereas the intermediate levels correspond to criteria and sub-criteria.

Development Of Fuzzy Judgment Matrix Using Pairwise Comparisons

Within a hierarchical structure, the elements of a particular level are compared pairwise with a specific element of an upper level. A fuzzy judgment matrix ($\tilde{J}$) is generated using fuzzy pairwise comparison index ($\tilde{j}_{ij}$).A relative importance of the pairwise comparison is assigned using a scale of 1–9 (Saaty 1977, 1980), which are fuzzified to capture vagueness in perception and meaning (Table 1). For *n* number of comparison items, the fuzzy judgment matrix $\tilde{J}$ is:

$$\tilde{\mathrm{J}} = \begin{bmatrix} \tilde{j}_{11} & \tilde{j}_{12} & \cdots & \tilde{j}_{1n} \\ \tilde{j}_{21} & \ddots & & \tilde{j}_{2n} \\ \vdots & & \ddots & \vdots \\ \tilde{j}_{n1} & \tilde{j}_{n2} & \cdots & \tilde{j}_{nn} \end{bmatrix} \quad (1)$$

Table 1. Fuzzy scales for pairwise comparisons

For diagonal entries, i.e., i = j, $\tilde{j}_{ij} = 1$. Upper right-hand triangle entries $\tilde{j}_{ij}$ are comparison items needs to be defined by decision maker, whereas for lower left-hand triangle entries are derived by taking reciprocals, i.e., $\tilde{j}_{ji} = 1/\tilde{j}_{ij}$. For illustration purpose, a comparison is performed between three items in Figure. 3, C31, C32 and C33, using the relative importance given in Table 1; let the level of importance of C31 to C32 is a fuzzy number $\bar{3}$; C31 to C33 is $\bar{5}$ and C32 to C33 is $\bar{4}$. Hence the judgment matrix is populated as:

$$\tilde{\mathrm{J}} = \begin{bmatrix} \bar{1} & \bar{3} & \bar{5} \\ 1/\bar{3} & \bar{1} & \bar{4} \\ 1/\bar{5} & 1/\bar{4} & \bar{1} \end{bmatrix}$$

The concept of fuzzification factor δ is introduced in Table 1. For this example, the value of fuzzification factor δ is assumed "1", i.e., $\bar{3}$ meaning a TFN (2, 3, 4).

3.2 Check For Consistency

Consistency is important in human thinking, which enables us to order the world according to dominance (Saaty 2005). It is important to ensure that there is consistency in the pairwise comparisons. Therefore, it would be useful to have a measure of inconsistency associated with the pairwise comparison matrix J. In order to measure the degree of consistency, one can calculate the Consistency Index (CI). Consistency index therefore, indicates whether a decision maker provides consistent values (comparisons) in a set of evaluation. The CI is calculated as:

$$\mathrm{CI} = (\lambda_{\max} - \mathrm{n})/(\mathrm{n} - 1) \quad (2)$$

where $\lambda_{\max}$ is the maximum eigenvalue and n is dimension of the judgment matrix.

The final inconsistency in the pairwise comparisons is solved using consistency ratio $CR = CI/RI$ where RI is the random index, which is obtained by averaging the CI of a randomly generated reciprocal matrix (Saaty

1980). The values of RI are tabulated in Table 2. The threshold of the CR is 0.1, and in case of exceedance a three-step procedure should be followed (Saaty 2005): (1) identify the most inconsistent judgment in the decision matrix, (2) determine a range of values the inconsistent judgment can be changed to so that would reduce the associated inconsistency, and (3) ask the decision maker to reconsider the judgment to a 'reasonable value'. In this paper, though the pairwise comparison indices of the judgment matrix are TFNs, however, the CI is evaluated for the most likely value.

Table 2. Random inconsistency indices (RI)

No. of criteria	**1-2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**
RI	0	0.58	0.9	1.12	1.24	1.32	1.41	1.45	1.49

Following the example of the judgment matrix illustrated in Step 2, the CI is computed. The maximum eigenvalue evaluated is ($\lambda_{max} = 3.086$). Thus, for n=3, the CI from Eq. 2 is (CI=0.043) and the random index from Table 2, RI=0.52. Finally, the consistency ratio CR is computed to be 8%.

3.3 Calculation Of The Fuzzy Weights

Various techniques are used to compute the final fuzzy weights, such as, computation of the eigenvector (as described in Step 3), arithmetic mean, geometric mean, etc. In this paper, for the ease of implementation the geometric mean is adopted to estimate the weights. Some commonly used fuzzy arithmetic operations are listed in Table 3.

Table 3. Common fuzzy arithmetical operations by two TFNs

Operators	***Formulae**	**Results**

Scalar product	Q·B	$(Q*b_1, Q*b_2, Q*b_3)$

* A= (a_1, a_2, a_3); B= (b_1, b_2, b_3)

Fuzzy arithmetic operations are utilized over matrix $\tilde{J}$ to compute the fuzzy weights. Following the previous example for $\tilde{J}$, the geometric mean is computed for each row $\tilde{J}_i$. Given $\tilde{J}$ from Eq. 1, the corresponding fuzzy weights are computed as:

$$\tilde{J}_i = (\tilde{j}_{i1} \otimes \cdots \otimes \tilde{j}_{in})^{\frac{1}{n}} \quad (3)$$

$$\tilde{w}_i = \tilde{J}_i \otimes (\tilde{J}_1 \oplus \cdots \oplus \tilde{J}_n)^{-1} \quad (4)$$

where $\tilde{w}_i$ is the fuzzy weight (where i =1 to n). Therefore, for C31, C32 and C33, the fuzzy weights are computed as:

$$\tilde{J}_1 = (\bar{1} \otimes \bar{3} \otimes \bar{5})^{\frac{1}{3}} = [(1,1,1) \otimes (2,3,4) \otimes (4,5,6)]^{\frac{1}{3}} = (2.0, 2.5, 2.9)$$
$$\Rightarrow \tilde{w}_1 = \tilde{J}_1 \otimes (\tilde{J}_1 \oplus \tilde{J}_2 \oplus \tilde{J}_3)^{-1} = (0.43, 0.63, 0.89)$$

similarly

$$\tilde{J}_2 = (1/\bar{3} \otimes \bar{1} \otimes \bar{4})^{\frac{1}{3}} = [(1/4, 1/3, 1/2) \otimes (1,1,1) \otimes (6,4,5)]^{\frac{1}{3}} = (0.32, 0.37, 0.44)$$
$$\Rightarrow \tilde{w}_2 = (0.19, 0.28, 0.42)$$

and

$$\tilde{J}_3 = (1/\bar{5} \otimes 1/\bar{4} \otimes \bar{1})^{\frac{1}{3}} = [(1/6, 1/5, 1/4) \otimes (1/5, 1/4, 1/3) \otimes (1,1,1)]^{\frac{1}{3}} = (1.58, 1.73, 1.87)$$
$$\Rightarrow \tilde{w}_3 = (0.07, 0.09, 0.14)$$

Sum of the most likely values of weights $\tilde{w}_i$, i = 1, 2, 3, equals to 1 (=0.63+0.28+0.09), which is the basic axiom of AHP. Therefore, crisp AHP is a special case of F-AHP, when fuzzification factor reduces to zero.

3.4 Establishment of Global Preference Weights

The local priorities at each level are aggregated to obtain final preferences of the alternative. This computation is carried out from the evaluation alternatives to the top level (Goal). As depicted in Figure. 3, each of the three alternatives (level 4), A_i, i = 1, 2, 3 are aggregated through level 3, level 2 and finally to level 1 (Goal). Therefore, following Figure. 3 at each level k of hierarchical tree, the fuzzy global preference weights ($\tilde{G}_k$) are computed as:

$$\tilde{G}_k = \tilde{w}_k \cdot \tilde{G}_{k-1} \quad (5)$$

The final fuzzy AHP score ($\tilde{F}_{Ai}$) for each alternative A_i is obtained by carrying out fuzzy arithmetic sum over each global preference weights:

$$\tilde{F}_{Ai} = \sum_{k=1}^{n} \tilde{G}_k \text{ for each alternative Ai.} \quad (6)$$

3.5 Ordering the Alternatives Using Fuzzy Ranking Methods

The defuzzification entails converting the final fuzzy AHP score $\tilde{F}_{Ai}$ into a crisp value. Once the final fuzzy AHP score ($\tilde{F}_{Ai}$) of each alternative is defuzzified, the crisp numbers are compared and ranked accordingly. In this paper the most common centroid index method developed by Yager (1980) is employed. The index is a geometric center $x_O(A_i)$ of the fuzzy number of alternative A_i, where for a given TFN (a_1, b_1, c_1) is formulated as follows:

$$x_O(A_i) = \frac{\int_0^1 A_i \mu_{Ai}(x)dx}{\int_0^1 \mu_{Ai}(x)dx} = \frac{(b_1 - a_1)(a_1 + \frac{2}{3}(b_1 - a_1)) + (c_1 - b_1)(b_1 + \frac{1}{3}(c_1 - b_1))}{(b_1 - a_1) + (c_1 - b_1)} \quad (7)$$

Where A_i is treated as a moment arm (weight function) measuring the importance of the value *x*. The value of $x_O(A_i)$ may be seen as the weighted mean value of the fuzzy number A_i. Hence, the bigger the $x_O(A_i)$ values are, better will be the ranking of an alternative.

4 STUDY AREA

Kamoshgaran region is located in the southwest of Ghorveh, east of Kurdestan province, northwest of Iran, in the Sanandaj-Sirjan zone (Figure. 1) and covers the area of about 600 km^2. The studied area has been important for Au mineralization occurring in the fault zones. Most of the large and known Iranian Au deposits are located along the Sanandaj–Sirjan metamorphic-structural zone, which hosts upper Paleozoic to upper Mesozoic volcano-sedimentary sequences of lower green schist to lower amphibolite metamorphic facies (Aliyari et al., 2012).

Sanandaj–Sirjan zone (SSZ) is a track from the southwest of central Iran, which is located immediately on the northeast of the main thrust of Zagros. Structural and rock features of SSZ indicate a deep valley between Arabian-Iranian Precambrial Shield. Thus, its geological features are clearly different from those of the adjacent zones (Aghanabati, 2004). Agreement of structural trend, equality of structural pattern, and dominance of thrusts, especially admitting the standard pattern of orogenic areas in collision zones, have led geologists like Falcon (1961), Farhoudi (1978), and Alavi (1994) to consider SSZ as a subzone of Zagros Orogen. Thiele et al. (1968) believed that Hercynian phase in this zone was accompanied by metamorphism. Except in rare cases, Permian rocks are covered by Upper Triassic-Jurassic Schist and the available evidence indicates that metamorphism has occurred in the Middle Triassic, as a result of which SSZ rocks have undergone dynothermal metamorphism (Aghanabati, 2004). According to the available information, it can be acknowledged that SSZ has a main structural field, starting from Late Precambrian by rifting and ending in Early Cimmerian orogeny by tectonic inversion.

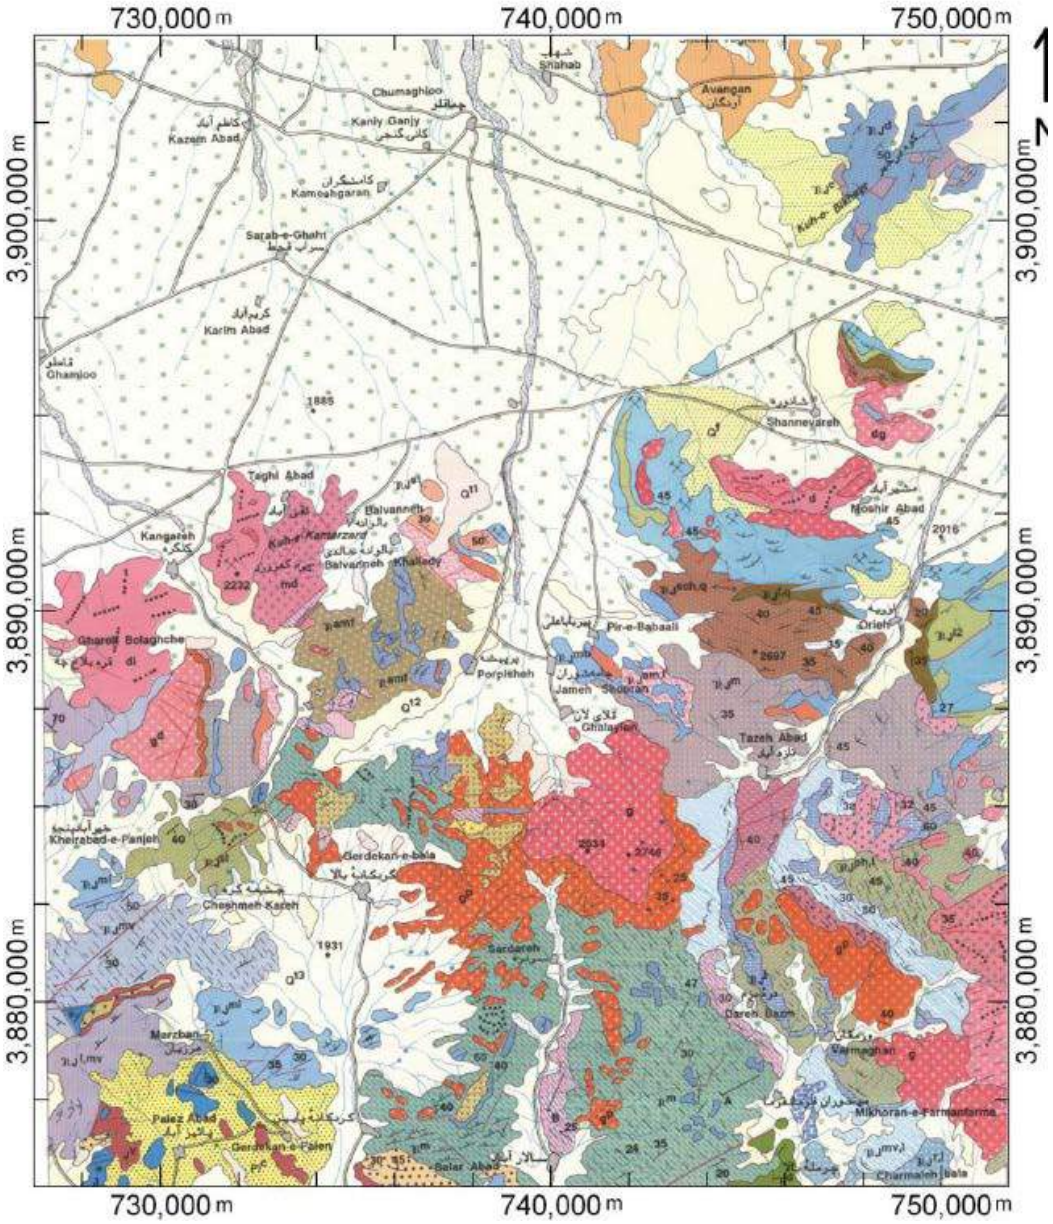

Figure 3. Geological map of Kamoshgaran region (based on the 1:100,000 geological map of Qorveh) and geology of Iran showing the location of the studied area in metamorphic–magmatic Sanandaj–Sirjan zone (compiled and simplified by Sahandi et al. (2005) based on the 1:2,500,000 geologic map of Iran)

The studied area consisted of metamorphic rocks including sch;ist, marble, amphibolites, and gneiss along with massive intrusive rocks with different chemical compositions. A geology map of Kamoshgaran region is shown in Figure. 1. Lithological sequences include Triassic, Triassic-Jurassic, Jurassic metamorphic, and Eocene non-metamorphic rocks, respectively (Hosseiny, 1999). There are also massive intrusive rocks with the compositions of gabbrodiorite, diorite, granodiorite, and granite in the region.

5 DISCUSSION

Four elements (As, Au, Cu, and Mo) from 317 stream sediment samples were used to identify number-size geochemical anomalies. Stream sediment samples of the −80 mesh (0.18mm) fraction were collected from the center of the streams. Kamoshgaran region was modeled using 10,323 cells. The area was gridded by 250×250 m cells, which were determined based on the geometrical properties of the studied area and sampling spacing (David, 1977). Arsenic, Au, Cu, and Mo distribution models were obtained via ordinary kriging (Ok) method using GSLIB software (Deutsch and Journel, 1998). The elemental concentrations were sorted based on decreasing concentrations and cumulative numbers were calculated for the concentrations. Finally, N-S log-log plots were generated for As, Au, Cu, and Mo (Figure. 4). Based on the N-S plots, there were five enrichment steps for As, four enrichment steps for Au and Cu and three enrichment steps for Mo (Figure. 4). Various enrichment steps derived by N–S method represented different geological factors and lithological differences.

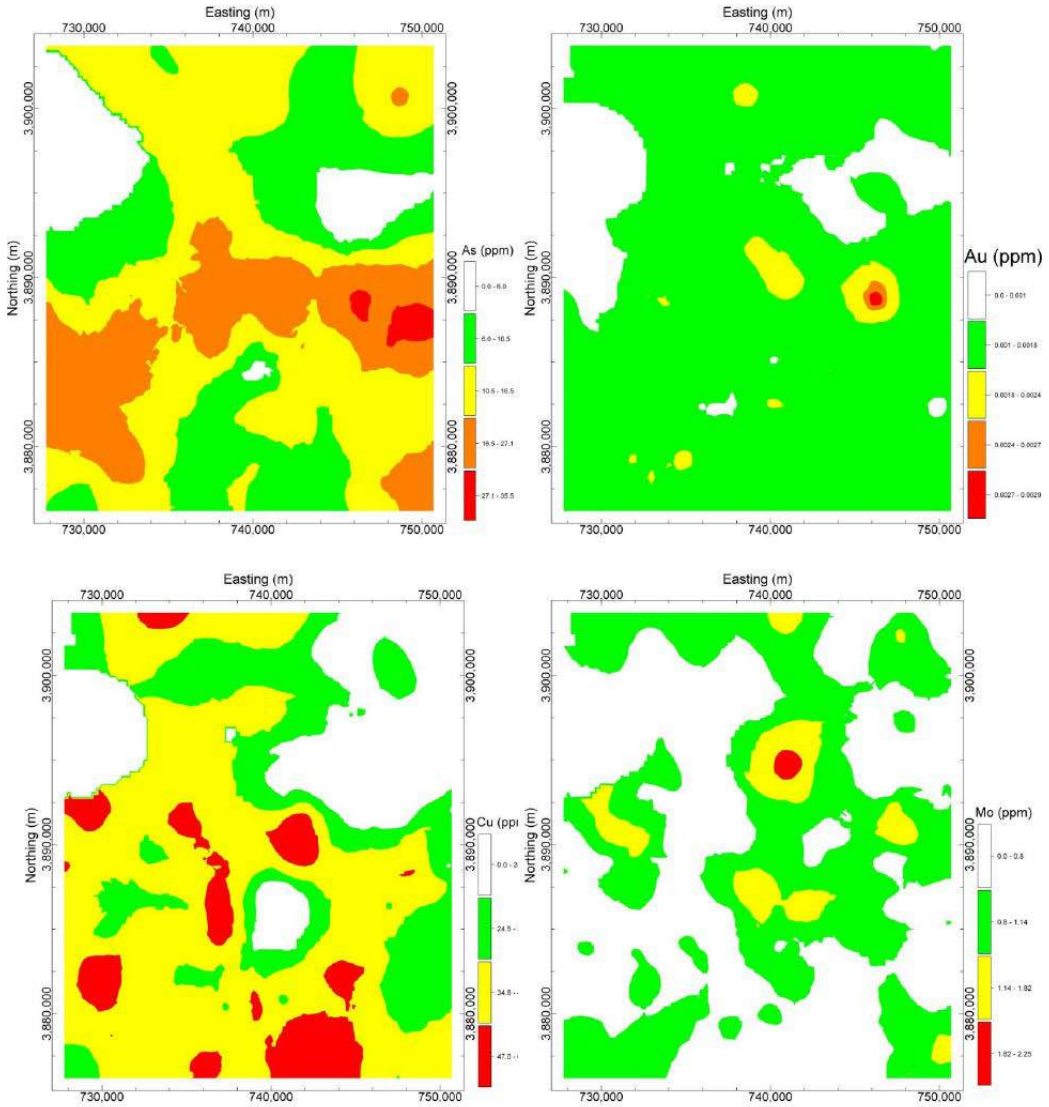

Figure 4. N-S log–log plots of As, Au, Cu, and Mo

Geochemical maps of the elements were obtained using RockWorks 15 software package. Based on the results of the N-S method, As, Au, Cu, and Mo anomalous maps were drawn (Figure. 5). According to the elemental anomaly map resulted from N-S plot, the high intensity of As values existed in the eastern part of the area and correlated with Au anomalous location (Figure. 5). Most of the Au anomalies were located in the eastern and central parts of the area, especially very high-intensity Au anomalies (> 0.0024 ppm). Few parts of these anomalies were also located in the southwestern and northern parts of the studied area. From Figure.5 it can been seen that there are a lot of anomalous area. It is very difficult to visually select the best anomalous areas. This process was done using fuzzy-AHP method. The data used in this study were selected based on the relevance with respect to Au exploration criteria. The five main criteria as input map layers including rocks, stream sediment geochemical data, altered units, structural data, and mining index were used. At the first step, the criteria for Au potential were determined and placed in a hierarchic structure. Each layer in this hierarchic structure was evaluated in pairwise comparisons related to each of the elements at the level directly above. The level of the structure was established by analyzing the relationship of each index.

Relative importance of the criteria was analyzed by called Expert Judgment System. In this research, we invited experts with Au backgrounds to give the corresponding relative importance of each factor and then analyzed all the opinions, and finally, gained the rank of relative importance for each factor by nine basic terms as shown in Table 4.

Table 4. Membership function of linguistic scale (example)

Fuzzy number	Definition	Scale of fuzzy member
9	Perfect	(8, 9, 10)
8	Absolute	(7, 8, 9)
7	Very good	(6, 7, 8)
6	Fairly good	(5, 6, 7)
5	Good	(4, 5, 6)
4	Preferable	(3, 4, 5)
3	Not bad	(2, 3, 4)
2	Weak Advantage	(1, 2, 3)
1	Equal	

In this paper, the computational technique is based on the following fuzzy numbers defined by Gumus (2009) in Table 4. Here, each membership function (scale of fuzzy number) is defined by three parameters of a symmetric triangular function of fuzzy numbers, the left point, middle point, and right point of the range over which the function is defined. Pairwise comparisons of all the related attribute values were used for establishing the relative importance of hierarchical elements. Pairwise comparison matrices were calculated. These matrices are shown for rocks (e.g. Table 5), stream sediment geochemical data, altered units, structural data, mining index and main criteria.

Table 5. Pairwise comparison among rocks

	C11	C12	C13	C14
C11*	(1 1 1)	(2 3 4)	(6 7 8)	(8 9 9)
C12*	(1/4 1/3 ½)	(1 1 1)	(2 3 4)	(5 6 7)
C13*	(1/8 1/7 1/6)	(1/4 1/3 ½)	(1 1 1)	(3 4 5)
C14*	(1/9 1/9 1/8)	(1/5 1/6 1/7)	(1/3 1/4 1/5)	(1 1 1)

*C11= Methamorphosed Igneous Rocks, *C12= Contact Methamorphic Rocks, *C13= Intrusive Rocks, *C14= Others

To determine the final score, Saaty (1980) uses the hierarchic composition principle; this results in the production of the vector regarding all the decisions at every level of the hierarchic structure. The final potential map for Au mineralization, using the obtained score, indicates appropriate areas for Au mineralization (Figure. 5).

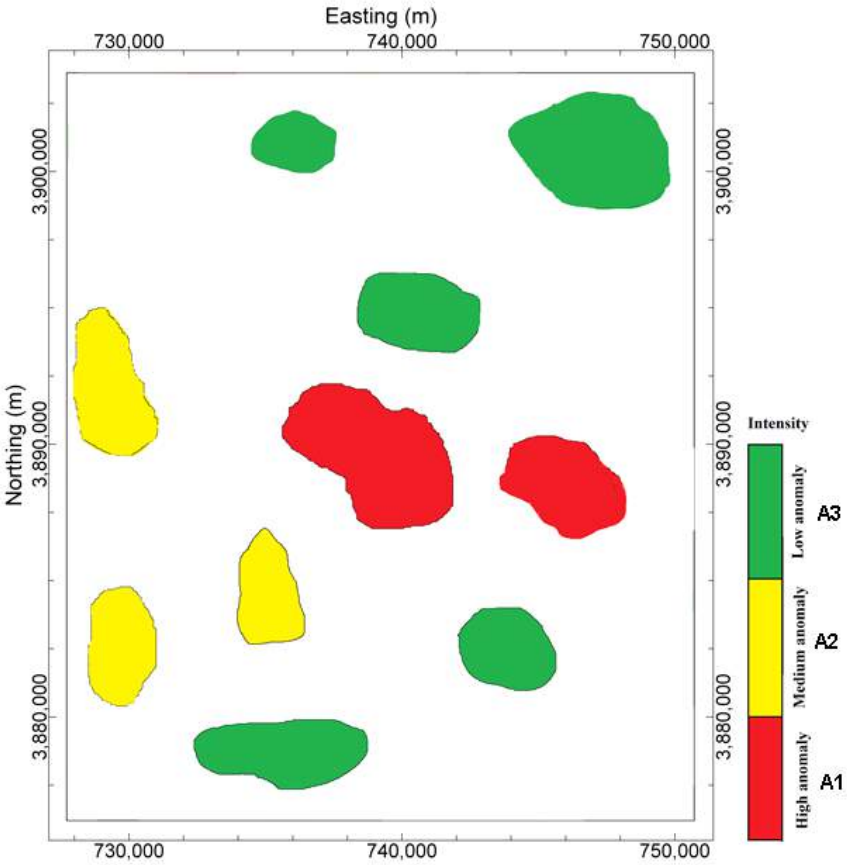

Figure 5. The final potential map for Au mineralization, using the obtained score.

6 CONCLUSIONS

Exploration strategies for nonrenewable resources have been changing rapidly along with the accelerating innovations in information processing technology. The aim of this research was to construct a fuzzy AHP model to select the best anomalies. This methodology allowed us to have a deeper understanding of the problem and helped us follow a systematic approach to evaluate the potential alternatives. The application of the AHP method for selecting the best anomalies provides a strong theoretical framework for handling the complexity of modeling multiclass anomalies maps in a scattered and widespread anomalies areas.

ABSTRACT Separation anomaly from background is one of the most important purposes of geochemical exploration studies. Many methods have been used for this purpose. Methods based on fractal geometry are common for separation anomaly from background. Geochemical anomaly separation using the number-size (N-S) method at Nakhilab region, SE Iran, is studied in this paper. Stream sediments data sets were used in this geochemical survey which was conducted for the exploration for Au and Cu mineralization in Nakhilab region. The study shows threshold values for elements are being a consequence of the occurrence of anomalous accumulations of silicification and alterations rocks. The obtained results were compared with lithological unit patterns reveals a positive direct correlation between mineralization in anomalous areas and the related lithological units present in the region.

Keywords: Anomaly separation, Number-size (N-S) fractal model, Nakhilab

1 INTRODUCTION

Identification and recognition of anomalies from background is an essential issue in geochemical exploration. In the last century, customized statistical methods usually assumed that the concentration of chemical elements in the crust follow a normal or log-normal distribution. A geochemical anomaly as defined is a region where the concentration of a specific element is greater than a certain threshold value by statistical parameters, such as mean, median, mode, and standard deviation (Li et al. 2003; Daya 2014a,b). But, statistical methods, e.g., by histogram analysis or Q–Q plots assuming normality or log-normality, do not consider the shape, extent, and magnitude of anomalous areas and disregard spatial distribution (Cheng et al. 1994; Agterberg 1995).

Fractal theory has been established and developed by Mandelbrot (1983), as an important branch of nonlinear mathematical sciences has been applied in different fields of geosciences since 1980s. Bolviken et al. (1992) and Cheng et al. (1994)'s studies show that geochemical dispersion patterns of different elements are fractals. Several fractal models have been developed and applied to geochemical exploration for separate anomalies from background. One of the most important method for separating anomaly from background is the number–size model (N–S model) proposed by Mandelbrot (1983), which has been widely used by many geoscientists (e.g., Agterberg, 1995; Turcotte, 2002; Zuo et al., 2009c; Wang et al., 2010).

In this paper, Cu, Au, As, and Ag anomalies are studied and delineated by number–size model in Nakhilab area, SE Iran. Consequently, a general discussion is argued whereby the anomalous threshold values are correlated to the relevant structural and lithological units.

2 NUMBER-SIZE (N-S) MODEL

Number–size (N-S) method proposed by Mandelbrot (1983) can be utilized to describe the distribution of geochemical populations (Sadeghi et al., 2012). In this method, geochemical data do not undergo any pre-processing (Mao et al., 2004). This model shows a relationship between desirable attributes (e.g. elemental concentration in this study) and their cumulative numbers of samples (Sadeghi et al., 2012). A power-law frequency model has been proposed to explain the N–S relationship according to the frequency distribution of elemental concentrations and cumulative number of samples with those attributes (e.g., Li et al., 1994; Sanderson et al., 1994; Shi and Wang, 1998; Turcotte, 1996; Zuo et al., 2009a; Sadeghi et al., 2012). The model is expressed by the following equation (Deng et al., 2010; Mandelbrot, 1983):

$$N(\geq \rho) = K\rho^{-D} \qquad (1)$$

where ρ denotes elemental concentration, N(≥ρ) denotes the cumulative number of samples with concentration values greater than or equal to ρ, K is constant, and D is the fractal dimension of the distribution of elemental concentrations. According to Mandelbrot (1983) and Deng et al. (2010), log–log plots of N (≥ρ) versus ρ show straight line segments with different slopes –D corresponding to different concentration intervals (Sadeghi et al., 2012).

3 GEOLOGICAL SETTING OF THE NAKHILAB REGION

The study area is located in northwestern of Zahedan city, SE of Iran. The study area is located in boundary of Loot Block and eastern flitch zone In Iran. It is probably a part of Iran's eastern flitch zone. Loot Block in contact with Iran's eastern flitch zone occurred in a very metamorphosed, faulted, sheared, and brecciated zone. From the upper cretaceous to quaternary the study area experienced different mountainous phases including Laramide and Alpine. These mountainous phases have an effective impact in developing the geological setting of the study area. Another important feature of the study area is that it is near the active Nehbandan fault system. Loot Block is more dynamic in its eastern part where the study area is located. The study area is highly brecciated and has faults with general trend of NS and NE-SW. The folding systems in the study area are normal anticline and normal syncline. Their trend is NW-SE to NS.

In the study area lithological units comes from upper cretaceous to quaternary ages. The study area occurred in a tectonic regime that Ophiolites complex was present. The lithological units according to 1:250,000 geological map of Nakhilab sheet divide into three parts which are metamorphic, sedimentary and igneous rocks (Fig 1). Metamorphic unit itself divides into three parts. The first consists of serpentine and harzburgite. Their trend is NS and generally occurred in a folded, fractured, and transformed units. The second group consists of marble, phyllite, serisite, and schist. Theses metamorphic rocks are widespread and its strike in the study area is NS. The last (third) group of metamorphic rocks consists of chlorite, epidote, schist, and mica schist. Their strike in the region is NS. This unit is affected by tectonic activity and as a result is highly fractured. Sedimentary rocks are very widespread in the study area. The most abundant of them are shale, sandstone, limestone, marl, and conglomerate (Fig 1). There are many igneous rocks in the study area. The most important of them comes from Oligocene. It consists of granite, granodiorite, and monzonite. Alteration phenomena are obvious in the igneous rocks and these rocks are much altered (Fig 1).

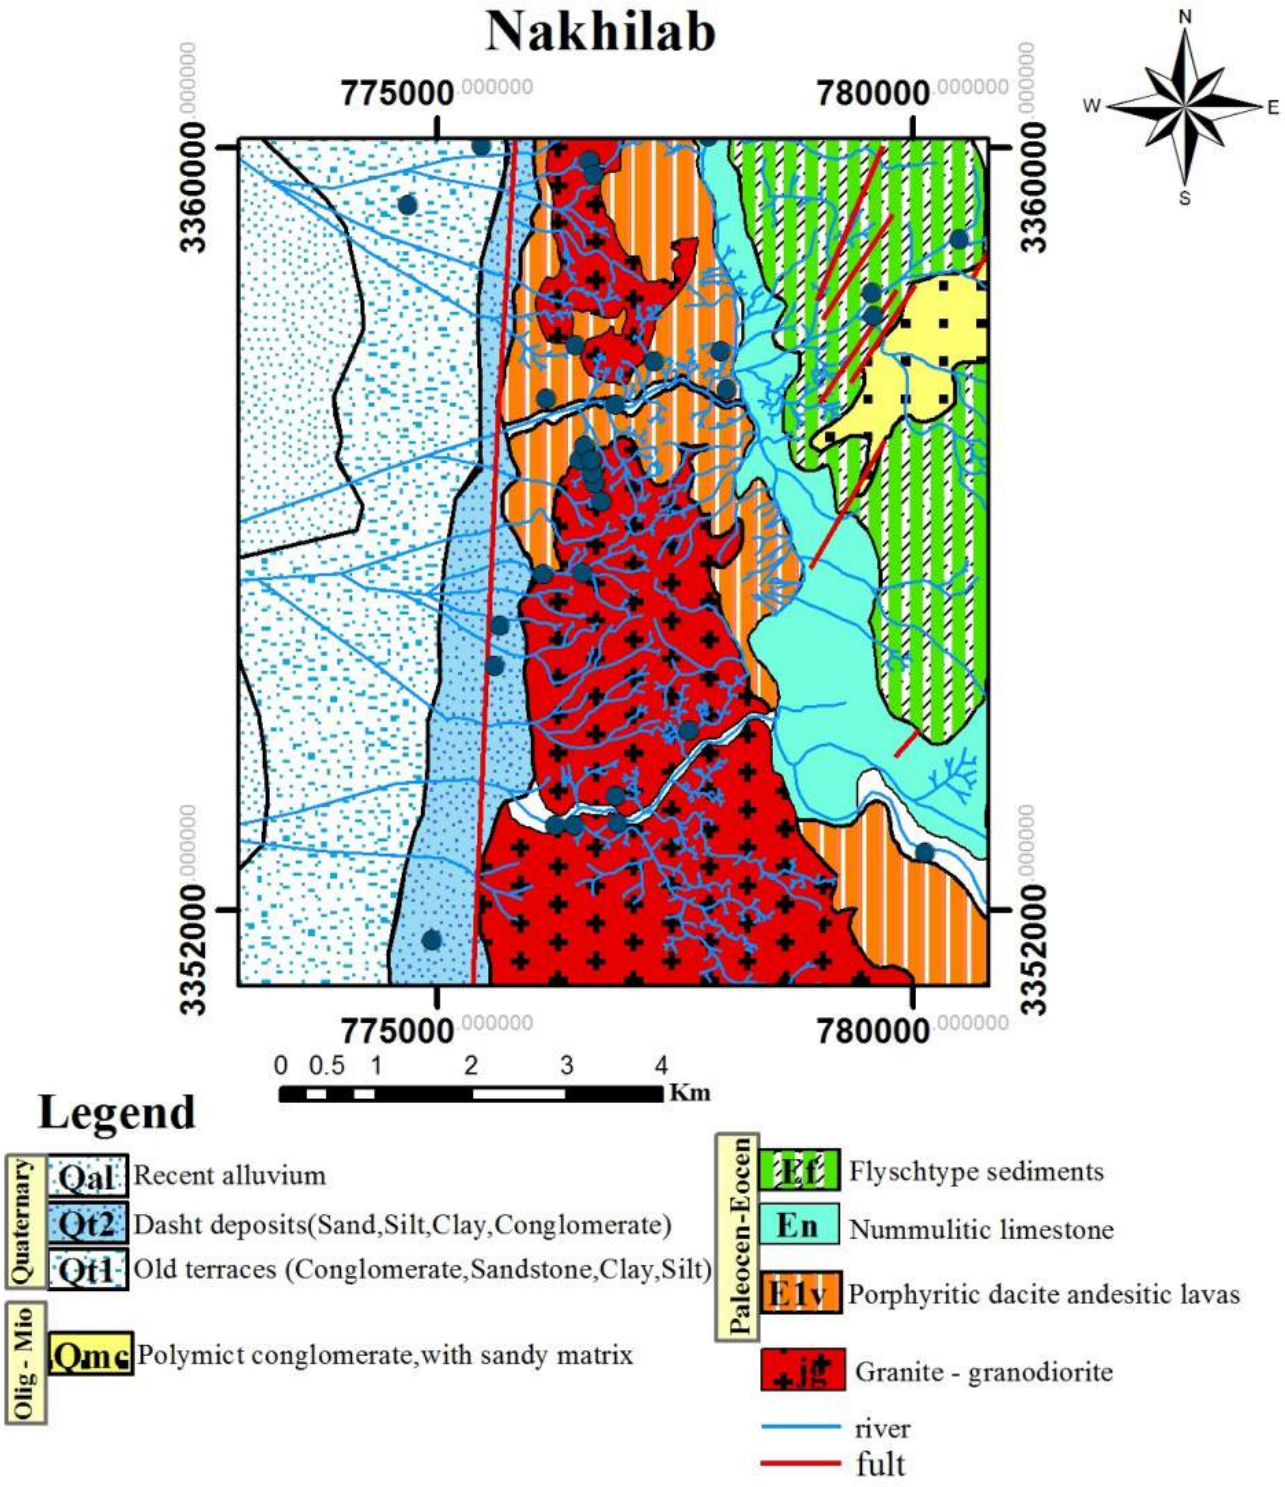

Figure 1. Geological map of Nakhilab region

4 GEOCHEMISTRY AND DATA ANALYSIS

A total of 213 collected stream sediments samples were analyzed by ICP-MS for elements which relate to Au and Cu mineralization and are of interest; As and Ag concentrations were of no significance.

Statistical results show that Cu, As, Ag and Au mean values are 2.8812, 1.1838, 0.1482 ppm and 0.0012 ppb, respectively (Table 1). Their distributions are not normal and variation between maximum and minimum for these data show a wide range (Fig. 2).

Table 1. Statistical parameters of raw data based on stream sediments geochemical samples analysis

Parameters	Au (ppb)	As (ppm)	Cu (ppm)	Ag (ppm)
Mean	0.0012	1.1838	2.8812	0.1482
Median	0.0010	1.1000	2.7600	0.0950
Variance	0.000001	97.788	89.438	0.558
Max	0.017	1.32	1.431	11.00
Min	0.0010	3	2.080	0.0800
Standard Deviation	0.0016	9.8634	9.547	0.7471

The elemental grades were sorted out based on decreasing grades and their cumulative numbers. Finally, elemental log–log plots were generated for Au, Cu, As, and Ag, as illustrated in Fig. 3. Based on this procedure, there are four geochemical populations for Au, and three geochemical populations for Cu, As, and Ag (Fig.3). Cu anomalous threshold is 25 ppm and its high-intensity anomaly is 40 ppm. Also, it is obvious that there are three steps of Cu enrichments based on log–log plot, as shown in Fig. 3. The various events derived by N–S model represent different geological factors, such as lithological differences and geochemical processes. Factors such as mineralizing events, surficial geochemical element concentrations, and surficial weathering are of considerable importance (Cheng et al. 1994).

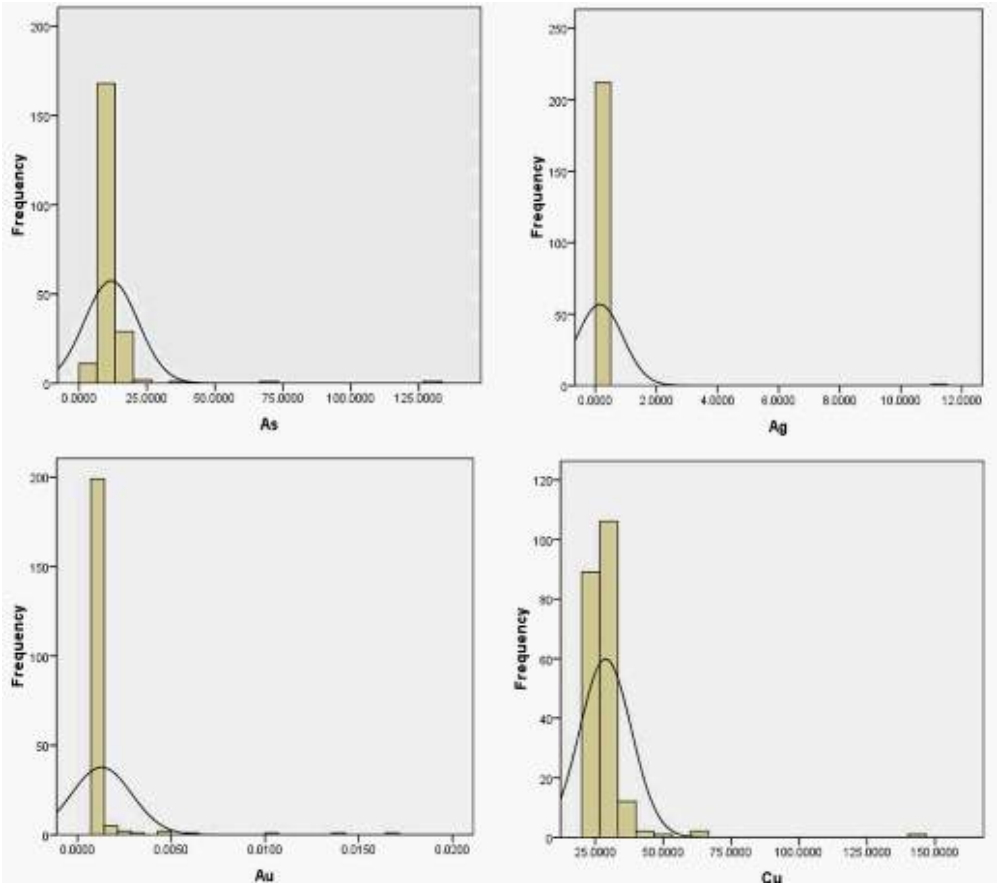

Figure 2. As, Ag, Au and Cu histograms

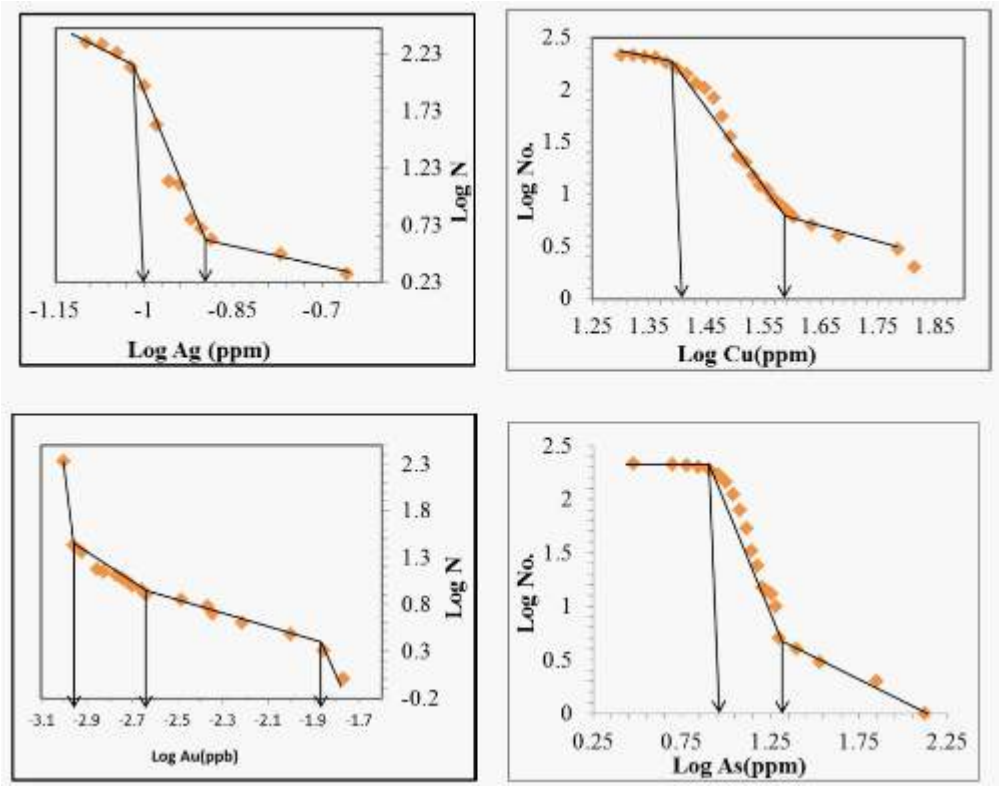

Figure 3. Log–log plots resulted from N–S model for Au, Ag, Cu, and As

Geochemical maps were constructed with inverse distance squared method by Rock Works™ v. 15 software package. The area was gridded by 250m×250m cells. Obviously, situations of Au anomalies are in northern parts of the area and the high-intensity anomalies are situated in NE parts as depicted in Fig. 4. Moreover, Cu anomalies are situated in northern, central parts of the area also high-intensity Cu anomalies were situated in central part of the study area (Fig. 4). Main Ag and Cu anomalies exist in the northern part of the area and correlated with Au anomalies location, as depicted in Fig. 4.

5 COMPARISON WITH GEOLOGICAL PARTICULARS

Threshold values of elements obtained from N–S model are compared and correlated to specific geological particulars of the area including considering nature of lithological units and faults. The anomalous parts visibly show the main identified faults especially in NE, and central parts of the area. Comparison between faults positions and elemental anomalies shows that faults intersect the anomalies situated near those structures. Moreover, faults and elemental anomalies have a proportional relationship. High-grade elemental anomalies occurred inside and within the fault zones or situated on faults intersection areas. This is a positive parameter because silicified and quartz-sulfide veins occurred along these faults and Au particles existed in these veins and veinlets. In the area, based on results of the N–S model, the elemental anomalies correlated with different rock types. High amounts of Cu, over 40 ppm, are highest in sand, silt, clay, and conglomerate. There are sulfide mineralization especially chalcopyrite. The Au high-intensity anomalous parts, higher than 0.

0.002 ppb, are situated in sand, silt, clay, conglomerate, and limestone. Also, there are quartz-sulfide veins and veinlets. An epithermal system is existed in this area and correlated within main Au, Cu, and Ag anomalies. Also, the main step, As mineralization, higher than 20 ppm, is

correlated within granitic and granodioritic units.

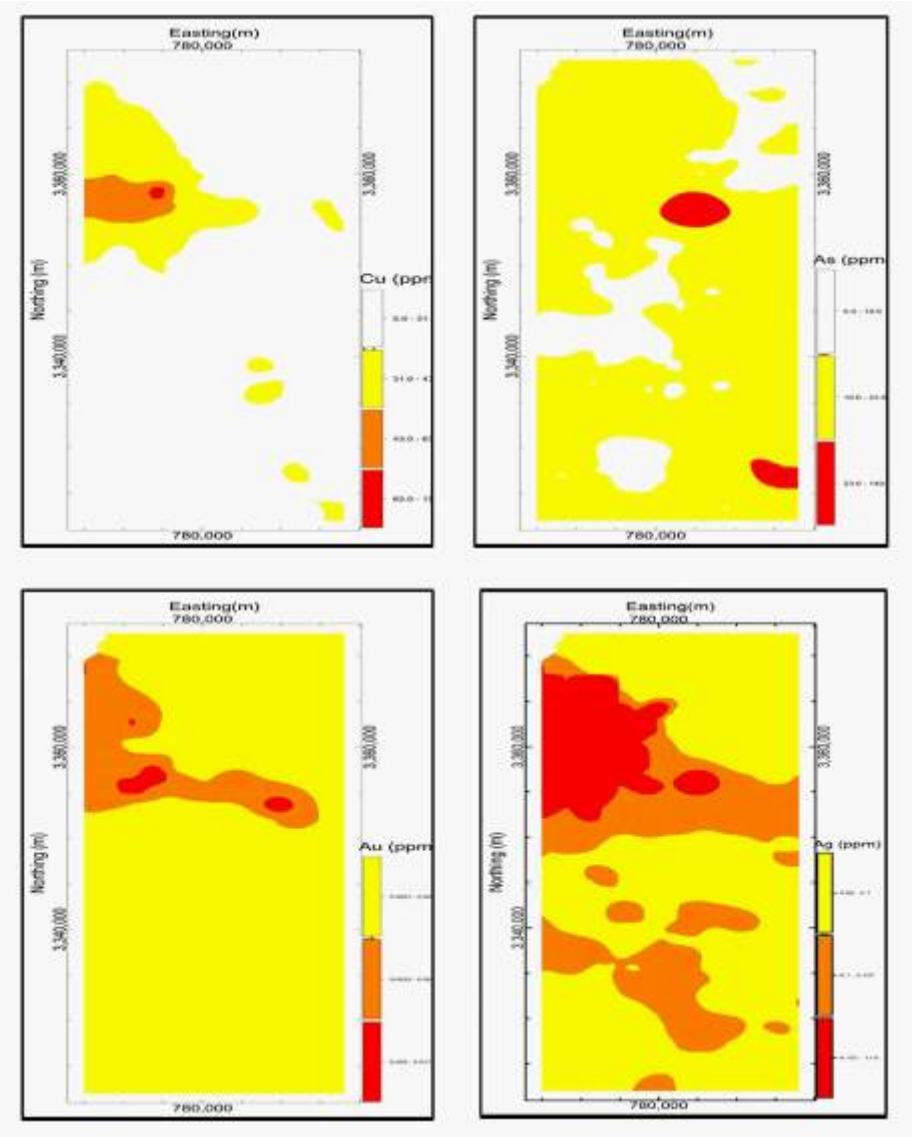

Figure 4 Au, Ag, Cu, and As geochemical population distribution maps based on N–S model

6 CONCLUSIONS

The study on Nakhilab area indicates the potential use of the N–S model for geochemical anomaly separation as a useful tool for geochemical exploration, commonly used in stream sediment geochemistry. The advantages of the model relies fundamentally on its straightforwardness, and easy computational achievement, as well as the possibility to compute the anomalous threshold values for different elements, which is the most useful criteria for cross examination of information with numerical data from different sources. There exists a proper correlation between the calculated anomalous threshold values and the geological specifics in the Nakhilab area. These results may also be interpreted differently according to their multifractal curves in log–log plots. Cu, Au, and Ag concentrations in the area may be a result of the three steps of enrichment, i.e., mineralization and later dispersions. Au and Cu log–log plots were shown that there are three steps for their enrichment and dispersion. Major Au mineralization occurred in sedimentary units in NW parts of the area. Au particles occurred in quartz-sulfide veins and veinlets. Main anomalies

of Ag and Cu are situated in the NW part of the area and correlated with main Au anomalies. It can be interpreted that there is an Au epithermal system. The occurrence of Cu higher than 40 ppm in sedimentary rocks (sandstones and conglomerate) in western parts of the area has been actually realized in the samples collected from the field. The studied elements anomalies have proper and direct relationships with faults in Nakhilab area. High intensity elemental anomalies are mostly located at fault intersections or near fault zones. It is important because quartz-sulfide veins and veinlets occurred along these faults.

ABSTRACT From 1977 to 1981, The National Geological Survey and Mining Company of Algeria (ORGM) tested various geophysical methods at the North Numidian Mercurial Zone. The study included: gravity, magnetic, VES-IP, gradient array IP and a mercury vapour soil gas test. This paper presents the results of a case history from the Mra-Sma site, which is located near the city of Azzaba. The objective of the ground based geophysical survey were the mapping of the lithology and tectonic structure, as well as the study of the extension of the mineralized area. The geology of the study area is very complicated by the presence of several allochthonous units. In the majority of the cases, these allochthonous units and nappes are superimposed and strongly brought closer by tectonic movements.

The results of the present study illustrate that; an integrated geophysical strategy can assist and enhance the exploration for mineralization in a region of complicated geology such as the north Numidian Mercurial zone.

Keywords: North Numidian, gravity, magnetic, VES-IP, mercury

1 INTRODUCTION

The deposits of lead and mercury of the Northern Numidic zone are known since antiquity. The beginnings of the geological investigations go back to the middle of 19th century, when the Baryto-polymetallic deposit of Mra-Sma (1850) and that of Mercury of Ras El Ma (1853) were discovered.

During the later period up to 1966, the geological investigations could not highlight new deposits. Geological investigations were concentrated around the known sites cited above.

In 1967, following work of evaluation on the Grayer Baryto-Polymetallic deposit, a thrust slice of Palaeozoic rocks was discovered in the northern part of the mineral-bearing zone. Further studies of the frontal thrust by trenches according to the dip brought to the discovery of the Mra-Sma deposit.

In 1967-1968, on the basis of the study of the Mra-Sma and Ismail deposits, it was given the principal criteria for exploration of mercury deposits in the North Numidian Zone: The presence of structural highs(domes) covered by thrusting in combination with the feeder faults.

The large volume of exploration data and its high success within a rather short time (1966-1970) made it possible to discover 3 mercury ore deposits and 27 mineral showings of mercury, polymetallic and copper. 19 cinnabar aureoles were the subject of detailed prospection.

The Mra-Sma deposit is located 2 km in the south–east of the city of Azzaba. It is composed of two orebodies: Mra-Sma I and Mra-Sma II. They have a length of 600 m and a width of 150 m. The mineralized zone has a width ranging from 2 to 35 m.

The deposit was discovered in 1971 by Titov and Pikhota (Oblentsev et al, 1985)

The implementation of the geophysical methods (gravity, magnetics, geoelectric prospection) as well as the geochemical survey in the experiment of the studies of the Northern Numidic Zone made it possible to distinguish the positive morphological structures below thrusting and to highlight the geochemical anomalies.

One could manage to say that the deposits of Ismail and Guenicha are characterized by positive gravimetric anomalies.

The purpose of this study was to use a complex of geophysical methods. This includes: gravity, magnetic, gradient array IP and a mercury vapour soil gas test. These geophysical methods seeks to: (1) bring out the structural highs (domes) under the frontal thrust (2) mapping of grinding area and (3) mapping of the hydrothermal alteration zones enriched with sulphide mineralization.

2 GEOLOGY OF THE STUDY AREA

The Maghrebides chain is part of the peri-Mediterranean belt of Tertiary age that delimits the African from European plates and runs from the Betico-Rifan arc to Calabria (Caby, 2001)

The study area (fg.1) belongs to the lesser Kabylia which has a very complex geological structure. Lesser Kabylia belongs to the Alboran–Kabylias–Peloritan–Calabria (AlKaPeCa; Bouillin, 1986). AlKaPeCa domain is of European origin and corresponds to the former northern margin of the Alpine Tethys now included in the so called Tell-Rif, whose it forms the internal domain(Frizon de Lamotte et al, 2009). The geological structure of the area is determined by the presence of some complexes represented by the formation of various structuro-facial zones which in the majority of the cases are tectonically superimposed the ones on the others or strongly brought closer. The lower structural position is occupied by the para-autochtonous complex of the Mount Djebel Safia composed of carbonate rocks of Jurassic and of Neocomian age.

In the higher position, one notes a whole series of allochtonous complexes. Among these complexes, the lower position is occupied by the Kabylie complex consisting of a basement of metamorphic schist and sandstones of Oligocene covering the latter. Higher, one notes the complexes of flysch of Penthièvre and Guerrouch (Tithonic with Oligocene included).

The complex of the so called limestone ridge (la dorsale calcaire), usually thrusted on the complexes of flysch consisting of terrigenous and carbonate rocks of Jurassic, Cretaceous and Paleogene age.

The higher structural position is occupied by the complex of the flysch «with microbreccia» and the Numidian complex, the topmost of the allochtonous complexes.

The formations of Miocene and Quaternary form the post-nappe autochthonous complex.

3 MATERIALS AND METHODS

3.1 Aeromagnetic Survey

The aeromagnetic data used in this study were extracted from a regional-scale aeromagnetic survey of northern Algeria conducted by Aeroservice Corporation for the Société Nationale de Recherches et d'Exploitations Minières (SONAREM) from 1971 to 1974 as a part of the latter's mineral exploration program. The survey was conducted with NNW–SSE profiles perpendicular to the general geologic strike of the study area. . The survey was flown in drape mode using Doppler-assisted navigation at an average ground clearance of 150 m and a line spacing of 2 km for traverses and 10 km for tie lines. The data were collected at a sampling interval of 46 m using a high resolution cesium magnetometer.

Aeroservice Corporation performed standard levelling corrections; however the aeromagnetic map gridded from flight line data suffered from levelling errors appearing as stripes along the flight line direction. To provide the highest quality data possible, most rigorous procedures were performed during the re-processing of the aeromagnetic data. This included the application of a de-spiking filter and microlevelling (Boubaya et al, 2011).

3.2 Ground Geophysical Data

An integrated ground based geophysical study (Oblentsev et al, 1985) comprising gravity, magnetic, VES-IP, gradient array IP and a mercury vapour soil gas test was conducted between 1977 and 1981 to study the possible extension of the mineralization near the known Mra-Sma deposit.

The gravity data were collected on north-south lines with a grid of (100 x 50). The gravity measurements were carried out with a Scintrex CG-1 gravimeter. A reduction density of 2500 kg/m^3 was used for the Bouguer correction. The error on the Bouguer anomaly is estimated to be better than 0.05 mGal.

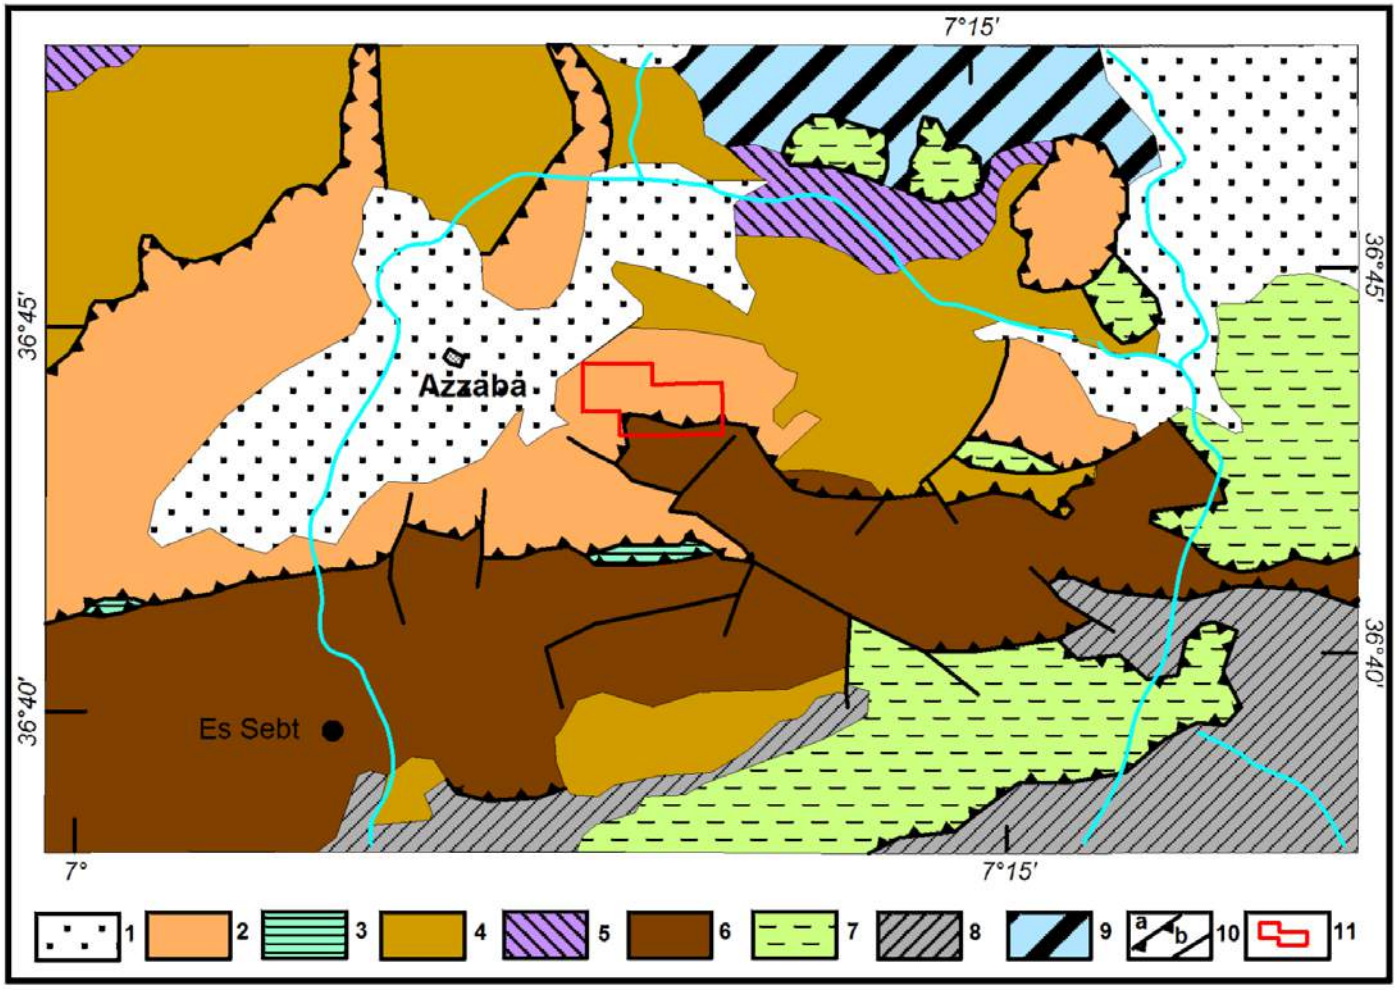

Figure 1. Structural geologic map of the study area (after Tchekhovitch, V. 1971)
Legend: 1- Post nappe complex 2- Numidian nappe 3- Flysch with Microbrecchia unit, 4- neoautochtone Oligocene 5- Kabylie unit 6- The limestone ridge (la dorsale) 7- Guerrouch unit 8- Penthievre unit 9- Parautochtone complex 10- a- thrust, b- fault, 11- study area

Magnetic data were also collected in the same gravity grid with an MF-2 magnetometer measuring the vertical intensity of the earth geomagnetic field. The error on the measured vertical intensity of the geomagnetic field is estimated to be around 10 nT.

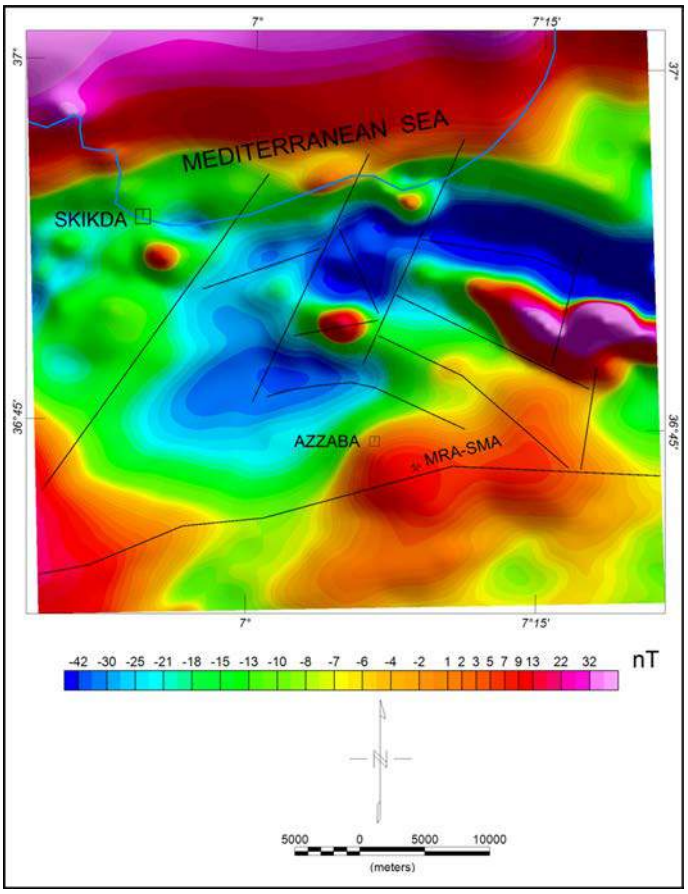

Figure 2. Shaded residual aeromagnetic map of the study area and adjacent regions

Resistivity and Induced polarization (Gradient-IP and VES-IP) data were acquired in the time domain, using a 2S square wave signal with resistivity values calculated during the on times, and IP decay amplitudes were measured in 6 windows during the off times. The resistivity survey was carried out using a Scintrex system operating in the time domain consisting of an IPR-8 receiver and a TSQ-2E transmitter.

4 RESULTS

4.1 Analysis of the Aeromagnetic Data

A shaded residual aeromagnetic map of the Azzaba region and surrounding area is shown in figure. 2. The magnetic field varies between a minimum of -45 nT and a maximum of 40 nT.

The Mra-Sma deposit lies on a broad positive magnetic anomaly.

Short wavelength magnetic anomalies north to the city of Azzaba correlate with the location of small iron ore deposits.

Magnetic basement faults are drawn in the total magnetic intensity (TMI) map. Parts of these basement faults were interpreted by Aeroservice Corporation (AeroService, 1975).

The most prominent geophysical lineament is situated in the south of Azzaba and trends in E-W direction. This linear feature is probably the principal feeder for Mercury mineralization of the North Numidic Mercurial Zone.

4.2 Analysis of the Ground Geophysical Data

In this part, we will deal only with the gravity and VES-IP data.

Figure.3 shows the map of the detailed gravity survey over the Mra-Sma region.

The Bouguer gravity data compiled with a density of 2500 kg/m^3 varies between a minimum of 28 mGal and a maximum of 32 mGal.

The steep gradient in the SW of the map correlate with the Mra-Sma fault which has a total length of 10 km. The Mra-Sma deposit itself lies on a moderate gravity high.

The interpretations of nine (9) VES-IP points conducted in the vicinity of the Mra-Sma deposit along line 08 are presented in figure.4. The section outlines 3 geoelctric layers:

(1) The first layer corresponds to the cover is characterized by low resistivities and low chageabilities

(2) The middle layer corresponds to the mineralized zone and has a moderate high resistivities and high chargeabilities. The rise of chargeability is probably caused by the presence of sulfides

(3) The last layer corresponds to the basement. This layer is characterized by low resistivities and low chargeabilities.

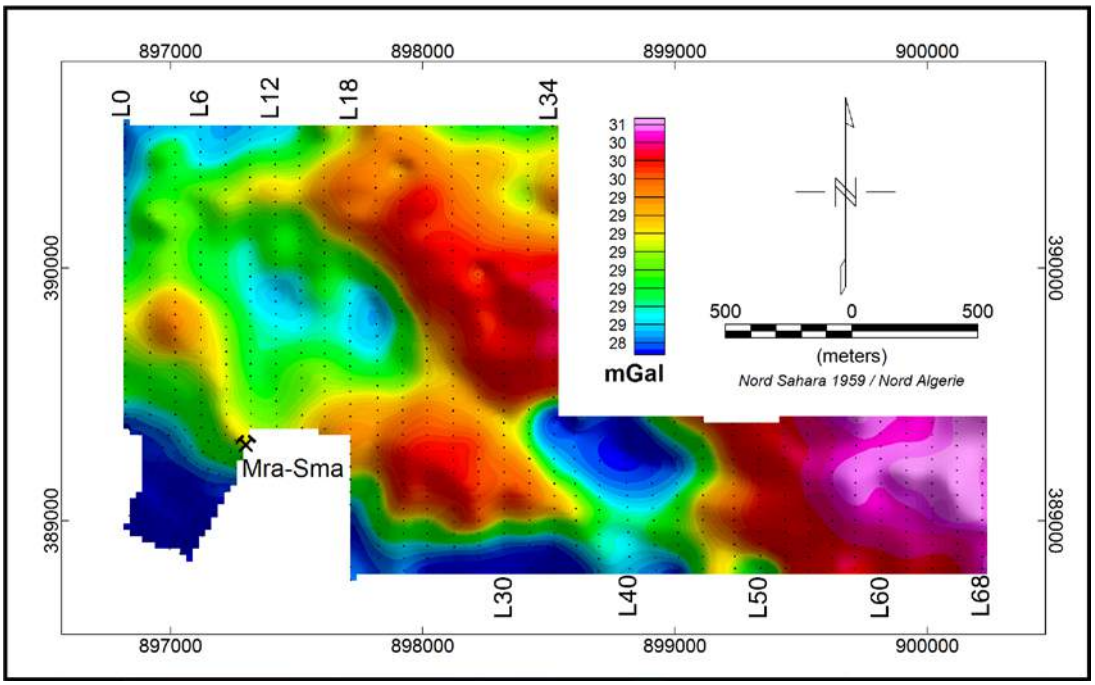

Figure 3. The Bouguer gravity map of Mra-Sma

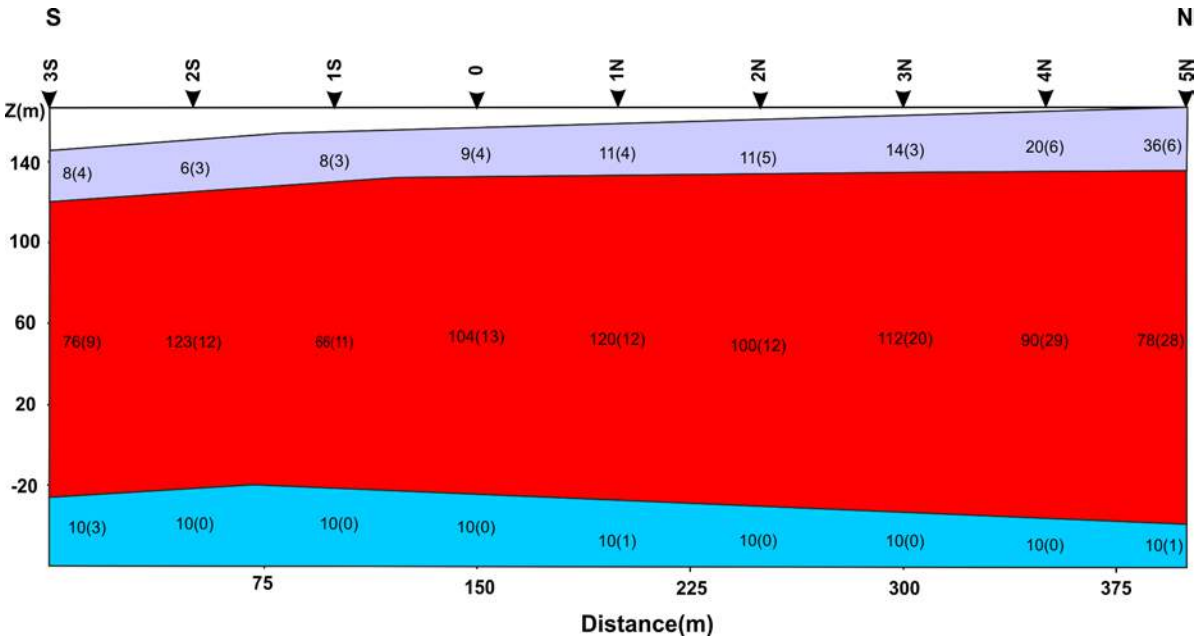

Figure 4. VES Geoelectric section along line 08 of Mra-Sma
10(0): values of resistivity and chargeabity

5 CONCLUSION

The integrated geophysical study conducted in the vicinity of the Mra-Sma deposit of Mercury helps us to study the extension of the mineralized area further to the east and to the north of the known deposit.

The mineralized area has a moderate resistivity and a high chargeability.

The VES-IP data provide important information about the deeper parts of the survey area.

Geostatistics As a Tool to Estimate Undiscovered Deposits of Coal

F. Atalay, A. E. Tercan, G. Ertunç
Hacettepe University, Mining Engineering Department, Ankara

ABSTRACT The key of sustainable electricity production is directly related to coal. In order to satisfy sustainability, coal presence and undiscovered coal potential have to be studied carefully. The aim of this study is to examine potential coalfields in Turkey by using geostatistical tools such estimation and simulation. For this purpose, kriged and simulated maps for lower calorific value are produced using the coal data collected in the Tertiary fields of Turkey. Then locations for which the kriged values do not fall in symmetric 95% probability intervals of simulated values are determined and these locations are considered as highly uncertain and target areas for potential coal resources. This study experimentally shows that geostatistical tools such as kriging and simulations have a great potential to predict and analyze coal resources.

Keywords: Geostatistic, coal, kriging, simulation

1 INTRODUCTION

In Turkey, 73 % of the electricity is produced by the thermal power stations (T.E.T.C, 2013) where coal is the feeding source. Coals in Turkey mostly occurred in the Tertiary period with some exceptions. Therefore, sustainability of the electric production is directly related to the presence and discovery of the Tertiary coal resources.

Tertiary fields are studied by the Paşamehmetoğlu et al. (1983), Görür et al. (1996), Temur et al. (2008) from the view point of coal potential and discovery. Paşamehmetoğlu et al. carried out coal prospecting studies in various sites and determined target locations for coal. Görür et al. made an attempt to classify tertiary basins into seven categories according to their tectonic characteristics and discussed the geological evolution and coal potential of each basin. Tuncalı et al. (2002) studied the chemical and technological properties of the tertiary coals. In these studies, main method for the discovery of coal was surveying. Neither mathematical models nor sophisticated estimation methods were used in these studies to predict the location of the undiscovered coal resources.

In this study, geostatistical methods are used to predict the locations of the undiscovered coal resources. Using the data collected from Tertiary coal fields, lower calorific value (LCV) distribution over the Tertiary fields is estimated by using ordinary kriging . To asses the uncertainty of the LCV distribution multiple realizations of LCV are generated using sequential gaussian simulation. Then locations for which the kriged values do not fall in symmetric 95% probability intervals of simulated values are determined and these locations are considered as highly uncertain and target areas for potential coal resources. This experimental study shows that geostatistical tools such as kriging and simulations have a great potential to predict the location of the undiscovered coal resources.

2 MATERIALS and METHODS

Data used in this study is based on Tuncalı et al. (2002) who collected data primarily from both government and private owned coal fields. Descriptive statistics of LCV is given in Table 1.

Table 1. Descriptive statistics of LCV

	LCV (kCal/kg)
Number of data	187
Minimum	1185
Maximum	5574
Average	3186
Median	3103
Standard Deviation(σ)	921
Skewness	0.30
Kurtosis	-0.21

For the purpose of estimation and simulation a block model of the Tertiary fields is created with individual block dimensions of 4000 X 4000 m. LCV is estimated by using ordinary kriging and then simulated using Sequential Gaussian Simulation.

Experimental variogram for LCV is calculated and modelled. The parameters of the model variogram are shown in in Table 2.

Table 2. Variogram model parameters of LCV

	LCV (kCal/kg)
C0 (Nugget)	187
C (Sill)	1185
Range (m)	5574
Model	Spherical

In order to assess the validity of the variogram model cross validation is performed. Table 3 presents the cross validation results. For a reasonable variogram model, the average of errors should be near to zero, error variance and kriging variance should be close to each other and percentage of error within two standard deviation should be around 95. Table 3 shows that model parameters are acceptable in terms of these criteria.

Table 3 Cross validation results

	LCV
Number of Data	187
Average Error	39
Error variance	811
Kriging error variance	770
Error % in ±1.96 σ	93.5

Using the variogram model given in Table 2. lower calorific value of the Tertiary fields is estimated. In estimation a maximum of 16 samples and a minimum of 3 samples are used. The distance of one and half times of the range is considered as a size of search neighborhood. Estimation only gives a single estimate in an un-sampled location. In order to characterize the uncertainty of the estimates simulation is widely used.

To characterize the uncertainty of the estimation results, direct sequential simulation is used. This simulation method is first introduced by Soares (1998) based on the principle introduced by Journel (1994). The LCV distribution of the tertiary fields is simulated fifty times in order to capture the uncertainty associated with the tertiary fields

3 RESULTS and DISCUSSION

Figure 1 shows the kriged map of LCV over Tertiary fields while Figures 2, 3 and 4 present 1st, 25th and 50th realizations of the simulations respectively.

To determine the high uncertainty areas kriging and simulation results are compared. The areas where the kriging result falls beyond the 95% confidence interval are considered as the high uncertainty areas. These areas are shown in the Figure 5.

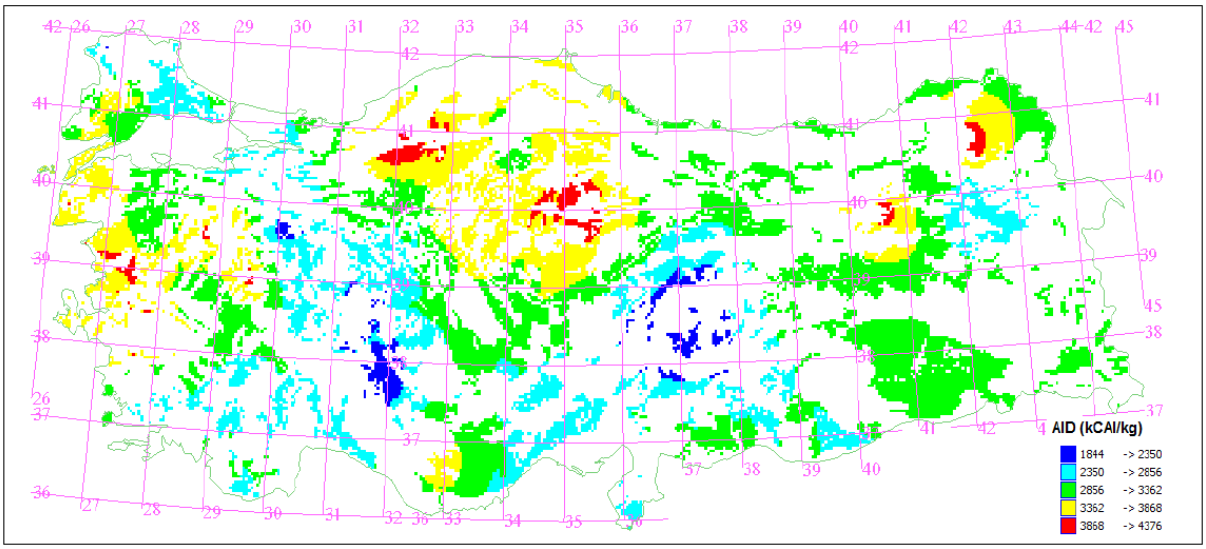

Figure 1 Spatial distribution of LCV over Tertiary fields

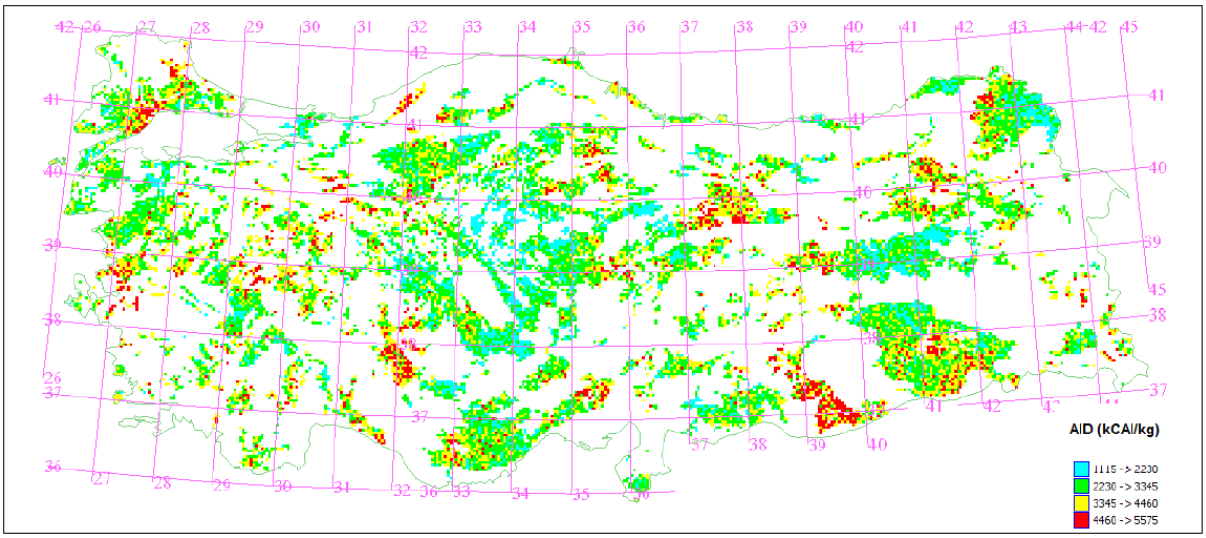

Figure 2. 1st realization of the LCV distribution of the Tertiary Fields

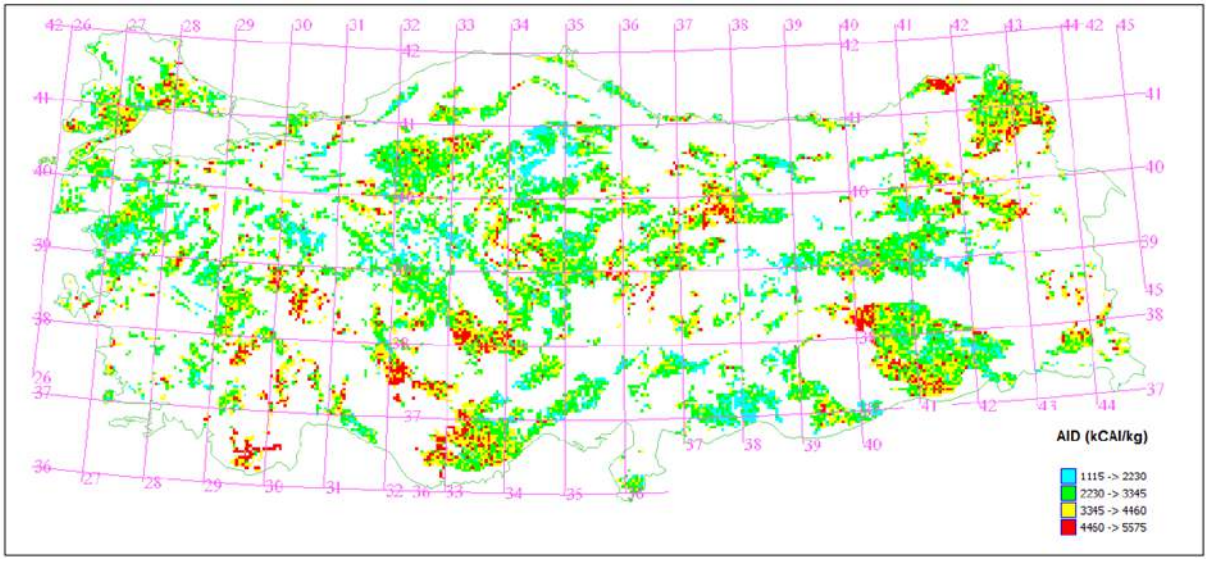

Figure 3. 25th realization of the LCV distribution of the Tertiary Fields

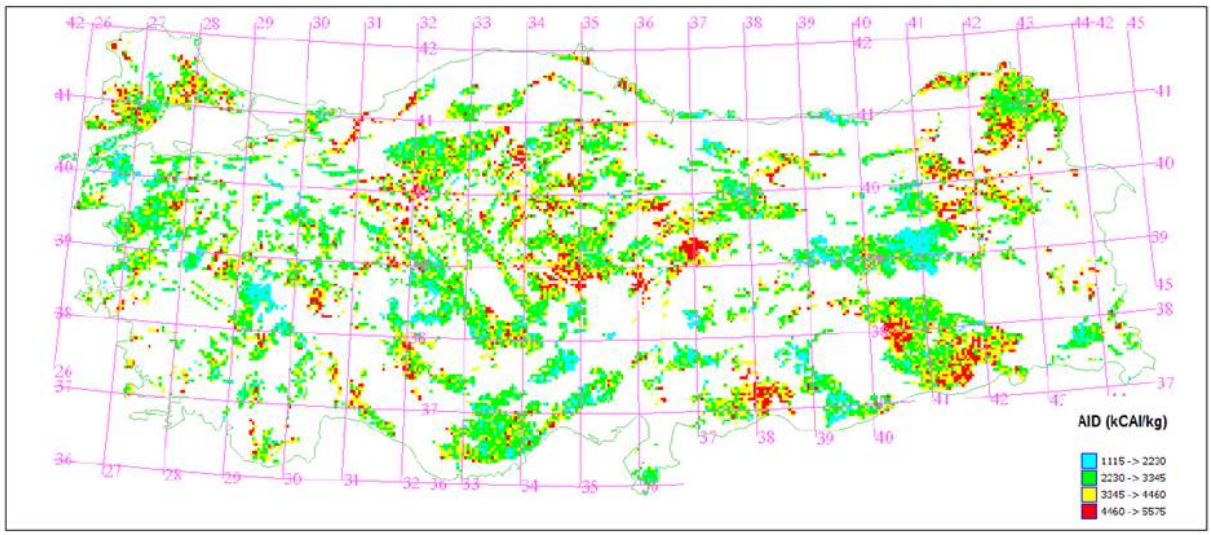

Figure 4. Figure 3. 50th realization of the LCV distribution of the Tertiary fields

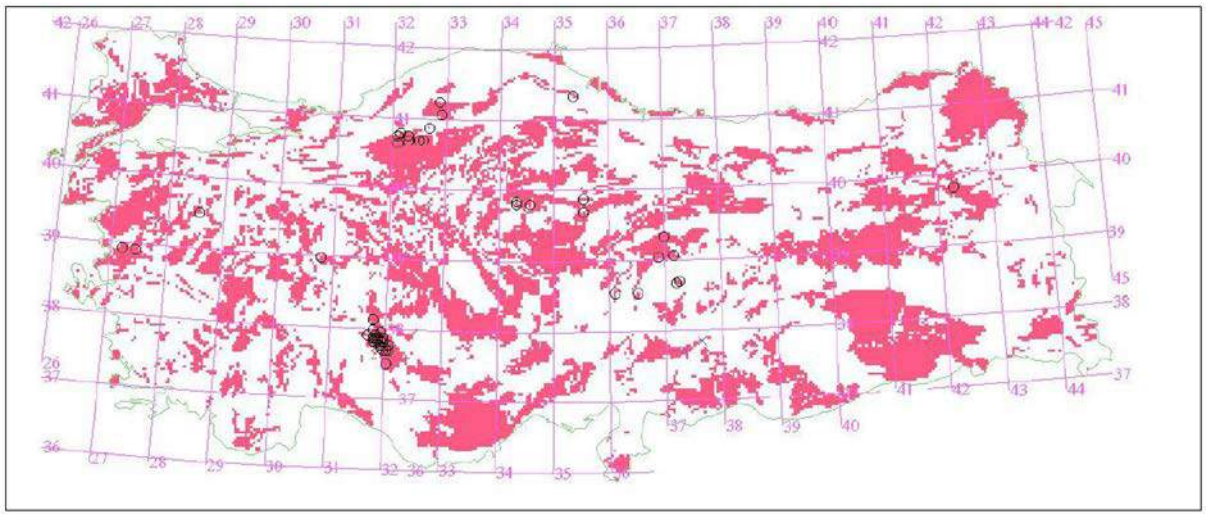

Figure 5. Locations of the high uncertainty areas in black circles

High uncertainty areas are located at Ağrı, Bolu – Gerede, Sivas Gürün and Kangal districts,Sinop-Nezir Köprü, İzmir-Kırkağaç, and especially at Konya regions. At the time of this study is made no data was available from the Konya region. Recently a big coal resource discovered by the General Directorate of Mineral Research and Exploration (MTA) which is close to the uncertainty areas found by this research. This shows that high uncertainty areas has great potential to discover the yet undiscovered coal resources.

4 CONCLUSIONS

From global perspective to assess the coal fields geostatistical estimation and simulation can be used. Using simulation high uncertainty areas can be determined and additional sampling should be carried out at this areas in order to better understanding of the field. This high uncertainty areas can reveal the coal occurrence which is not discovered yet. So geostatistics potentially can be used to estimate the undiscovered coal resources.

ABSTRACT Delineating the geochemical anomalies from background is a fundamental task in geochemical exploration. Fractal methods are very useful methods for such purposes. This paper is devoted to separate geochemical anomalies from background based on stream sediments data by utilizing the Concentration-Area (C-A) fractal model in Nakhilab region, southeast of Iran. Stream sediments data were used in this study which was conducted for the primary regional exploration for 4 elements (Au, As, Ag, Cu) in Nakhilab region. Log-log plots for the mentioned elements were drawn. Threshold values for the region were computed based on these log-log plots. The thresholds were identified for elements. Based on the thresholds of the C–A model, the anomaly maps of elements were drawn. Results showed that C-A method was capable for separation anomaly from background.

Keywords: Anomaly identification, Concentration-area (C-A) fractal model, Nakhilab

1 INTRODUCTION

Separation anomaly from background is a fundamental issue in mineral exploration (Daya 2014a, b). The methods and techniques for separation of anomalies from background have been the subject of research for many years (Cheng et al., 1994). For the past two decades, the traditional statistical methods assumed that the concentration of chemical elements follows a normal or log-normal distribution. A geochemical anomaly is defined as a region where the concentration of the element of interest is greater than a certain threshold value.

Various quantitative methods have been developed in this field, and among them, statistical methods have played an important role. Conventional statistical methods used for geochemical anomaly separation such as moving-averages, Kriging, probability graphs, univariate and multivariate analysis methods are primarily concerned with the frequency distributions of element concentration values and correlation coefficients among multiple variables. Spatial statistical methods such as moving average techniques, Kriging and spatial factor analysis can take into account spatial correlation and variability within neighboring samples in addition to concentration value frequency distributions and correlation coefficients.

Fractals is a natural consequence for geological phenomena that display self-similarity resulting from scale-independence properties, such as the frequency-size distributions of sediments and porosity, faults, earthquakes, volcanic eruptions, mineral deposits and oil fields. Fractal is more or less important in nearly all geoscientic disciplines. Scientists interested in fractal applications come from widely deferent backgrounds both inside and

outside the earth sciences. Fractal geometry established by Mandelbrot (1983) is a non-linear geometry based on the Latin word ‘‘fractus’’ and has been widely applied in geosciences (e.g., Turcotte, 1986; Sim et al., 1999; Ali et al., 2007; Zuo et al., 2009a,b,c; Afzal et al., 2010). Cheng et al. (1994) proposed the Concentration–Area (C–A) fractal method for separating different geochemical populations. This method has been an evolution in geochemical studies for recognition of different grade anomalies and related mineralization from background. Fractal dimensions in geological and geochemical processes correspond to variations in physical attributes such as rock type, vein density or orientation, fluid phase, alteration phenomena, structural feature or dominant mineralogy, and so on (Sim et al., 1999). The concentration–area model (C–A model) proposed by Cheng et al. (1994) has been developed and applied by many geoscientists (e.g., Sim et al., 1999; Ali et al., 2007; Wang et al., 2012).

The aim of current study is to separate geochemical anomalies from background based on stream sediments data by utilizing the concentration–area (C–A) fractal model in Nakhilab region, northwest of Iran. Stream sediments data were used in this study which was conducted for the primary regional exploration for eight elements (Au, Ag, Cu, As) in Nakhilab region.

2 CONCENTRATION-AREA (C–A) MODEL

Cheng et al. (1994) proposed the concentration–area (C–A) method, which can be used for separating geochemical anomalies from background. Concentration-area (C–A) method has the general form of:

$$A(\rho \leq v) \propto \rho^{-a1};\ A(\rho \geq v) \propto \rho^{-a2} \quad (1)$$

where A(ρ) denotes the area with the concentration values greater than contour value ρ, v represents the threshold, and $-a1$ and $-a2$ are fractal dimensions. Two approaches that were used by Cheng et al. (1994) to calculate A(ρ) include: (1) A(ρ) is the area enclosed by contour value ρ on a geochemical contour map resulting from the interpolation of the original data by weighted moving average method, and (2) A(ρ) is the value obtained by the box-counting of original elemental concentration values. By box-counting, one superimposes the grid with cells on the studied region. The area A(ρ) for a given ρ is equal to the number of cells multiplied by the cell area with the values of greater than ρ (Cheng et al., 1994). Area–concentration [A(ρ)] with the elemental concentrations greater than ρ usually shows a power–law relation (Cheng et al., 1994). The breaks between straight-line segments on this log–log plot and the corresponding values of ρ have been used as thresholds to separate geochemical values into different components (Afzal et al., 2010).

3 GEOLOGICAL SETTING OF THE NAKHILAB REGION

The study area is located in northwestern of Zahedan city, SE of Iran. The study area is located in boundary of Loot Block and eastern flitch zone In Iran. It is probably a part of Iran’s eastern flitch zone. Loot Block in contact with Iran’s eastern flitch zone occurred in a very metamorphosed, faulted, sheared, and brecciated zone. From the upper cretaceous to quaternary the study area experienced different mountainous phases including Laramide and Alpine. These mountainous phases have an effective impact in developing the geological setting of the study area. Another important feature of the study area is that it is near the active Nehbandan fault system. Loot Block is more dynamic in its eastern part where the study area is located. The study area is highly brecciated and has faults with general trend of NS and NE-SW. The folding systems in the study area are normal anticline and normal syncline. Their trend is NW-SE to NS.

In the study area lithological units comes from upper cretaceous to quaternary ages. The study area occurred in a tectonic regime that Ophiolites complex was present. The lithological units according to 1:250,000

geological map of Nakhilab sheet divide into three parts which are metamorphic, sedimentary and igneous rocks (Fig 1). Metamorphic unit itself divides into three parts. The first consists of serpentine and harzburgite. Their trend is NS and generally occurred in a folded, fractured, and transformed units. The second group consists of marble, phyllite, serisite, and schist. Theses metamorphic rocks are widespread and its strike in the study area is NS. The last (third) group of metamorphic rocks consists of chlorite, epidote, schist, and mica schist. Their strike in the region is NS. This unit is affected by tectonic activity and as a result is highly fractured. Sedimentary rocks are very widespread in the study area. The most abundant of them are shale, sandstone, limestone, marl, and conglomerate (Fig 1). There are many igneous rocks in the study area. The most important of them comes from Oligocene. It consists of granite, granodiorite, and monzonite. Alteration phenomena are obvious in the igneous rocks and these rocks are much altered (Fig 1).

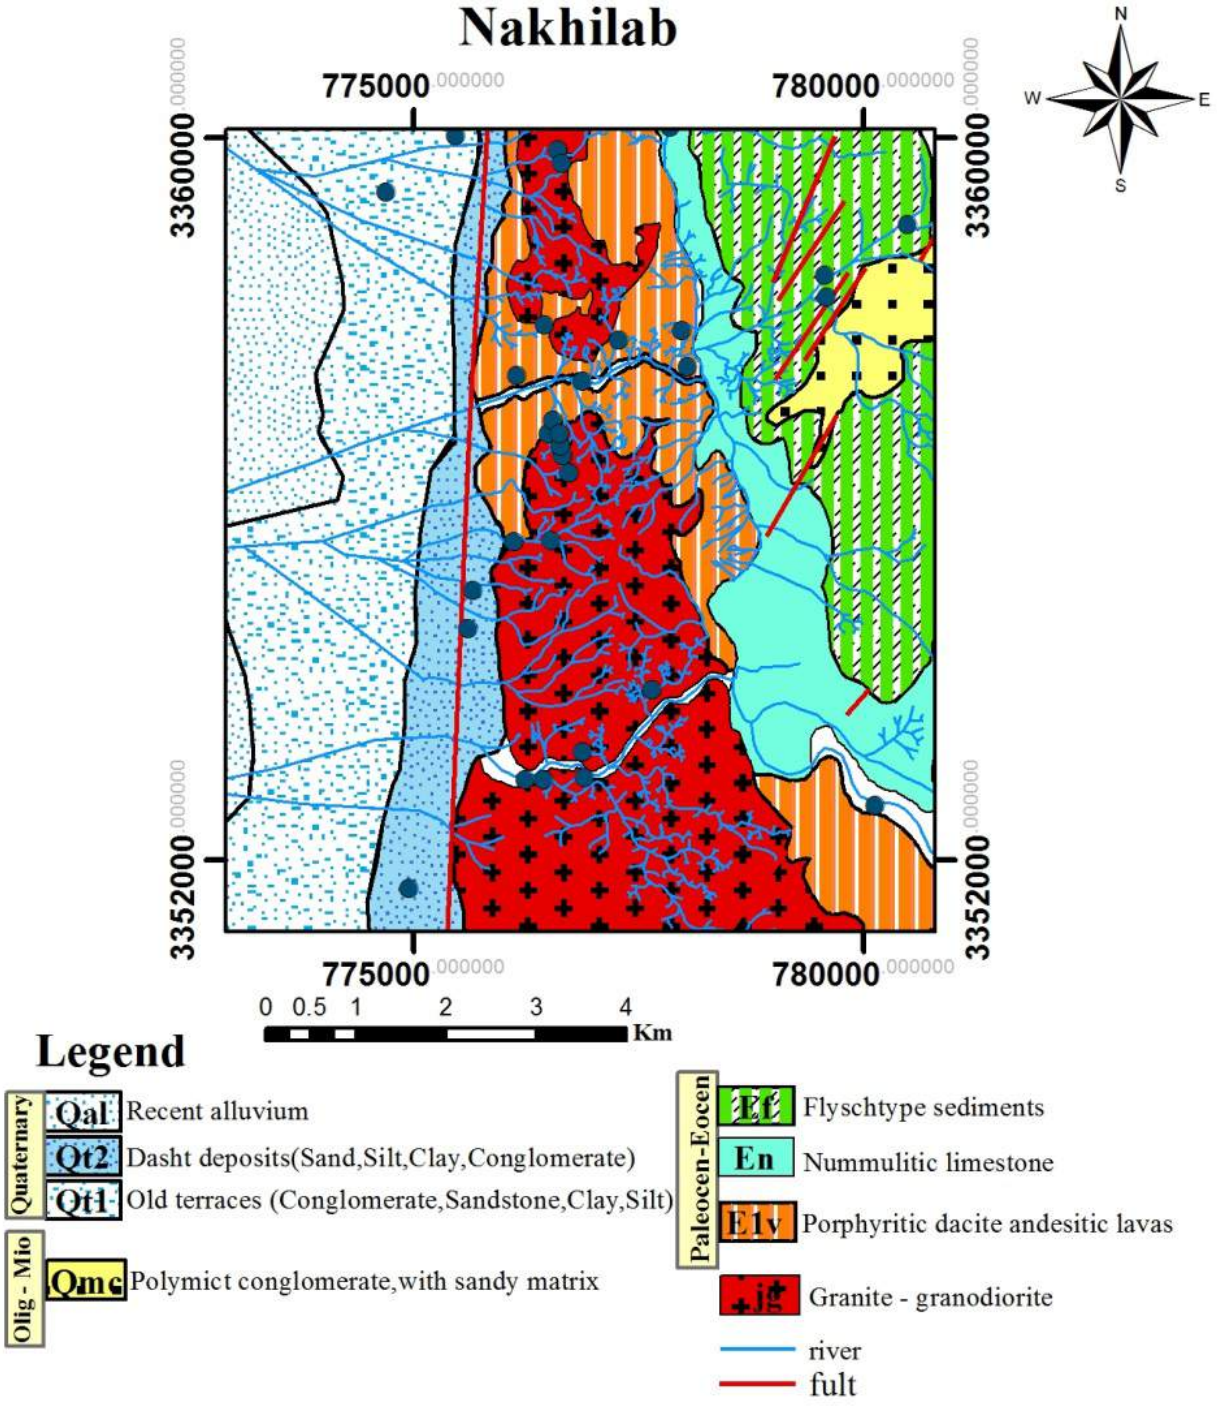

Figure 1. Geological map of Nakhilab region

4 STREAM SEDIMENTS GEOCHEMISTRY

A total of 213 collected stream sediments geochemical samples were analyzed by ICP-MS for elements which relate to Au mineralization and are of interest. Statistical results show that Cu, As, Ag and Au mean values are 2.8812, 1.1838, 0.1482 ppm and 0.0012 ppb, respectively presented in Table 1. Their distributions are as shown in Fig. 2 and are not normal. Variation between maximum and minimum for these data shows a wide range. If median is assumed to be equal to threshold values. The obtained statistical results are 2.76 ppm for Cu, 1.100 ppm for As, 0.095 ppm for Ag and 0.001 ppb for Au.

Table 1: Statistical parameters of raw data based on stream sediments geochemical samples analysis

Parameters	Au (ppb)	As (ppm)	Cu (ppm)	Ag (ppm)
Mean	0.0012	1.1838	2.8812	0.1482
Median	0.0010	1.1000	2.7600	0.0950
Variance	0.000001	97.788	89.438	0.558
Max	0.017	1.32	1.431	11.00
Min	0.0010	3	2.080	0.0800
Standard Deviation	0.0016	9.8634	9.547	0.7471

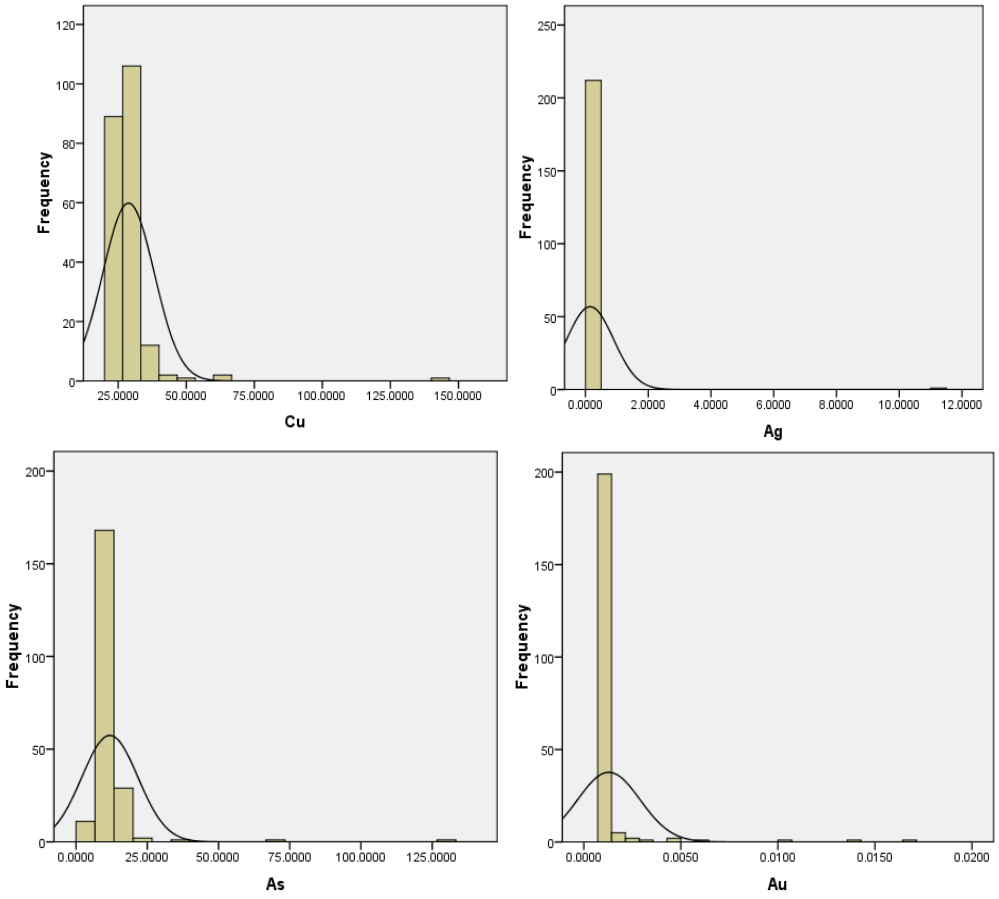

Figure 2. As, Ag, Au and Cu histograms

Geochemical maps were generated with IDS (Inverse Distance Squared) method by RockWorks™ v. 2006 software package. This procedure is suggested because it eliminates the undesired smoothing effects caused by the usage of Kriging method. Since the IDS method clarifies the ore grade boundaries and ore concentration values, it is more desirable to use IDS method instead of Kriging which inherently has rather high amounts of truncation errors for the upper and lower boundaries of ore grades. The area was gridded by 250 m×250 m cells.

The proposed gridding pattern is put to use because the fundamentals of C–A fractal method is based on the existence of partition function, and the sampled data cannot be utilized effectively; also, since one cannot sample the entire study area, and for evaluation and estimation of any parameter, i.e., ore grade, gridding of the area is inevitably a desired mandate and one cannot do otherwise. The necessary and the needed partition function to be used in fractal methods are based upon assumption of having a cell characterization in the area in order to find and calculate the area which has a certain ore grade. By this method the problem of over sampling will not enter into picture because the C–A fractal method will automatically eliminate any probable grid related problem in division of the area into smaller elements and the original fractal character is preserved (Cheng et al., 1994).

Concentration–area relations were computed by assigning an area of influence to each sampled point and summing all elemental areas whose concentration lies below a given value. This procedure was repeated for different elemental concentrations. Carrying on this procedure is not cumbersome because there is a regular gridding of 250 m×250 m cells. The evaluated grades in cells were sorted out based on decreasing grades and cumulative areas were calculated for grades.

Finally, log–log plots were constructed for Cu, Ag, As and Au (Fig. 3). Geochemical populations are delineated in these plots of Cu, Ag, As and Au. On the basis of this procedure, there are 3, 3, 4 and 3 populations for Cu, Ag, As and Au, respectively as shown in Fig. 3. Cu anomalous threshold is 49 ppm and its high intensity anomaly is 101 ppm. Also, it is clear that there are three stages of Cu enrichments based on log–log plot as depicted in Fig. 3. The first event for Cu C–A variations occurred at grades below 49 ppm. The second event shows up between grades 49 ppm and 101 ppm. The final event included major Cu mineralization which occurred and interpreted in grades higher than 101 ppm. Ag threshold and high intensity anomalies are 2.28 ppm, and 7.28 ppm (Fig. 4). As log–log plot shows that major As enrichment occurred at 24 ppm and higher. Au anomalous threshold is about 0.0024 ppb. There are three enrichment steps interpreted as seen in C–A log–log plot of Au in Fig. 3. Major Au enrichment started from 0.0024 ppb, and, 0.013 ppb concentration is beginning of high intensity Au anomaly. Each geochemical population in this study was assumed to have various kinds of distributions, and its various components, such as individual chemical elements and their concentrations could be fitted into a straight line on log–log plot.

Obviously due to non-uniform behavior of the elements, if plotted on log–log co-ordinates, the plot will have different slopes and various straight-line segments which connects them at them an angle or with breaks on the plot. Breaks between the straight-line segments and the corresponding values of As, Ag, Au and Cu have been used as cut-offs to reclassify cell values in the IDS interpolated maps and are presented in Fig. 4. Based on these results, elemental grade distribution maps were drawn as Fig. 4. Clearly most of Cu anomalies are located in central parts of the area, especially high intensity Cu anomalies. As anomalies were situated in central and southeastern parts and they are small.

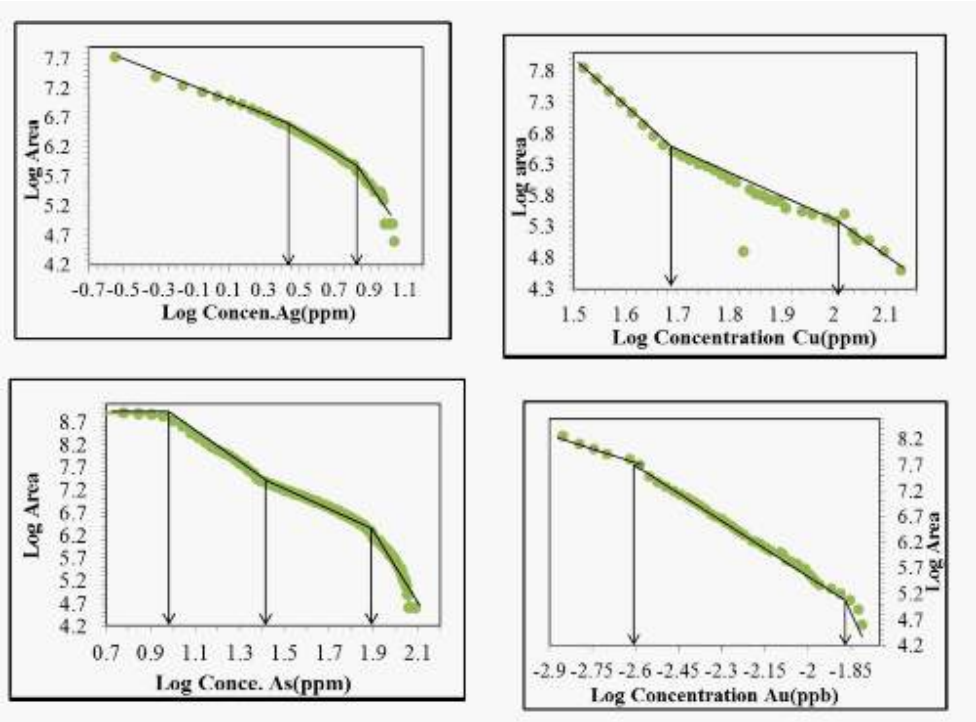

Figure 3. Log–log plots (C–A method) for As, Ag, Au and Cu. The vertical axis represents cumulative cell areas A(ρ), with elemental concentration values greater than ρ, and the horizontal axis is the actual value (ρ).

Locations of Au anomalies are in central parts of the area and the high intensive anomalies are very small located in western and central parts. Based on these maps, potential presence of these elements are located in central and western parts as shown in Fig. 4. Also, several small Ag anomalies are interpreted in northwestern part of the area as delineated in Fig. 4.

5 COMPARISON WITH GEOLOGICAL PARTICULARS

Thresholds and cut-off results from C–A method are compared and correlated to specific geological particulars of the region including considering nature of lithological units and faults.

Lithological unit's positions were correlated with elemental distribution maps. There exists astrong relationship between Cu concentration values higher than 101 ppm and Au higher than 0.013 ppb in high intensive anomalous parts with sand, silt, and conglomerate based on this correlation. It shows that sand, silt, and conglomerate host high intensive Cu enrichment and Au anomalies. In other words, major Cu and Au mineralization occurred concurrent with sand, silt, and conglomerate in final stage of Cu and Au enrichments. But, As high intensive anomalous parts (higher than 71 ppm) in central parts of the area are hosted by granite and graniodiorite units. In western parts of the area sedimentary rocks hosts high intensive Ag and Au and high intensity Cu anomalous parts as illustrated in Fig. 4. Also, faults have caused the increase in porosity or void volume in sedimentary rocks. Granite and granodiorite units contain low amounts of Cu, having the maximum values of 49 ppm and Ag and Au values are about the same as background values, lower than 8 ppm and 0.0024 ppb, respectively. Granite units have low amounts of Cu, Ag and Au that they host low intensity Cu anomalous amounts in western part of the study area, lower than 49 ppm concentration. Granitic unit present in central part of the area is barren and does not host these elements. Its elemental contents are equal to background, but in western part, sedimentary units show low values of As, between 8 ppm and 24 ppm. Results from C–A method are correlated with elements' median values in rock types. These concentrations show a good relationship with intrusions.

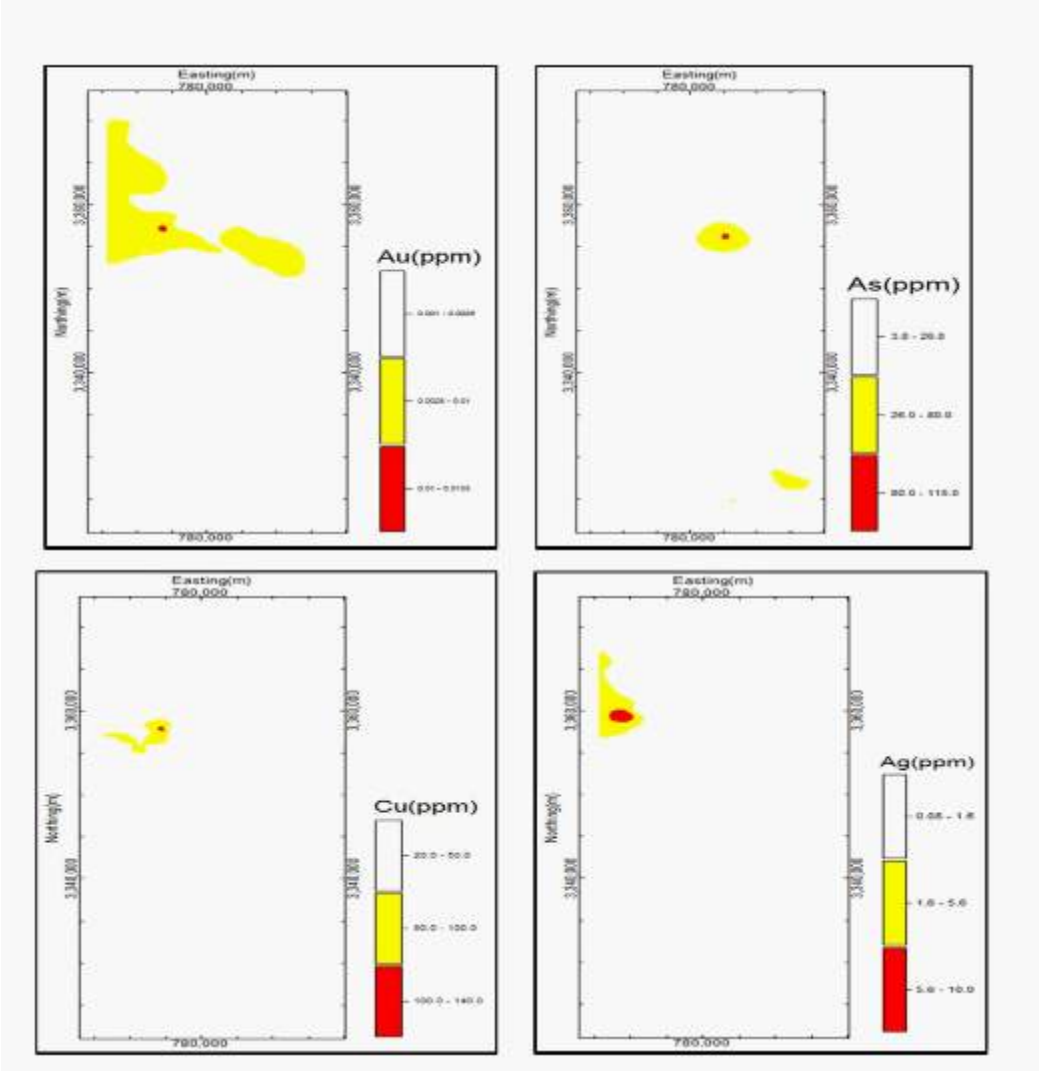

Figure 4. As, Ag, Au and Cu geochemical population distribution maps based on C–A method

6 CONCLUSIONS

Study on Nakhilab region reveals the potential use of the C–A method for geochemical anomaly separation as a useful tool for geochemical and mineral exploration. The advantages of this method rely essentially on its simplicity, and easy computational implementation, as well as the possibility to compute a numerical value of concentrations, i.e., the anomalous threshold, which is the most useful criteria for cross examination of information with numerical data from different sources, commonly used in stream sediment geochemistry. There exists a very good correlation between the calculated anomalous threshold values and the range of concentrations obtained in the rocks, especially for Cu in the Nakhilab area. Such correlation is also valid for other elements, but, the range of values is clearly different. These results may also be interpreted differently according to their nature, especially multifractal curves in log–log plots. Cu concentration in the area may be a result of the three steps of enrichment. Major Cu and Au mineralization occurred by the sedimentation of sand, silt and conglomerate in this area. But, for Ag and Au in Nakhilab area this may be explained by three enrichment steps that the major step occurred in sand, silt, and conglomerate units.

The occurrence of Cu and Au high enrichments in sand, silt, and conglomerate in western parts of the area has been actually realized in the samples collected from the field. As high intensive anomalies was found within granitic units. Statistical analysis also confirms these results. Elemental anomalies in western parts of the area are associated

with sand, silt and conglomerate. Granitic units in central parts host As in high intensive anomalies. It can be concluded that lower grade enrichment of Cu has occurred in granitic and granodioritic units. Also, data analysis shows that major Cu and Au enrichment steps are concurrent with that of sand, silt and conglomerate. The process for As enrichment is synchronized with granitic rocks and their subsequent changes. Cu, Ag and Au enrichment processes are correlated with lithological units and their time table emplacement. Granitic and granodioritic units were last emplacements in this area and these units host high grade As anomalies. Ag anomalies in western part of the area are located in sedimentary units that show Ag enrichment may have occurred in primary and secondary emplaced sedimentary rocks. Low Ag grade is proper evidence in this area. Although it may be easier to study geochemical anomalies with the C–A method, multifractal nature of C–A log–log curves could be of essential help to geoscientists for interpreting the stages which an element is enriched. The developments in multifractal theory and their usage could provide a favorable ground for the stochastic simulation of geochemical distributions, and their understanding and interpretations.

Improving Mineral Resource Estimation Using Domaining: A Case Study

S. Al-Hassan
University of Mines and Technology, Tarkwa, Ghana

W. A. Anandorah
AngloGold Ashanti, Obuasi, Ghana

ABSTRACT The Obuasi Mine gold orebody is structurally controlled exhibiting dextral strike-slip duplex structures with numerous faulting and fissures. Various geologically homogeneous lithological and structural zones are identifiable on the mine. Structurally, straight faults, points of inflection, metavolcanic-caps and fissure junctions do occur. The mineralization is either free milling gold in quartz veins or gold in sulphide ore. Historically, Obuasi resource evaluation was done across heterogeneous zones (domains): free milling gold in quartz veins and gold bearing sulphide zones. This practice did not recognize the different styles of the mineralization in these domains; thereby resulting in unsatisfactory reconciliation between estimated grades and mined grades.

This paper presents the study that reviewed the resource estimation methodology taking into account the two important domains (free milling gold in quartz veins and gold bearing sulphide zones). The new model improved reconciliation between estimated and mined grades.

Keywords: Reconciliation, variography, wireframe, grades, domaining

1 INTRODUCTION

Obuasi Gold Mine is situated within the Obuasi mining district approximately 320km north-west of Accra, the capital of Ghana in West Africa (Figure 1). The Obuasi concession is located on a north-easterly striking Ashanti belt, the most prominent of the five Birimian Supergroup gold belts found in Ghana (c.f. Figure 1). Two broad styles of gold mineralization are present at the Obuasi mine. The free milling quartz vein gold in shear zones and sulphide-rich (arsenopyrite) disseminated refractory gold lodes which form alteration haloes around the quartz vein lodes (Anon, 2011; Kesse, 1985). The study area covers Blocks 9 and 10 in the southern part of the mine.

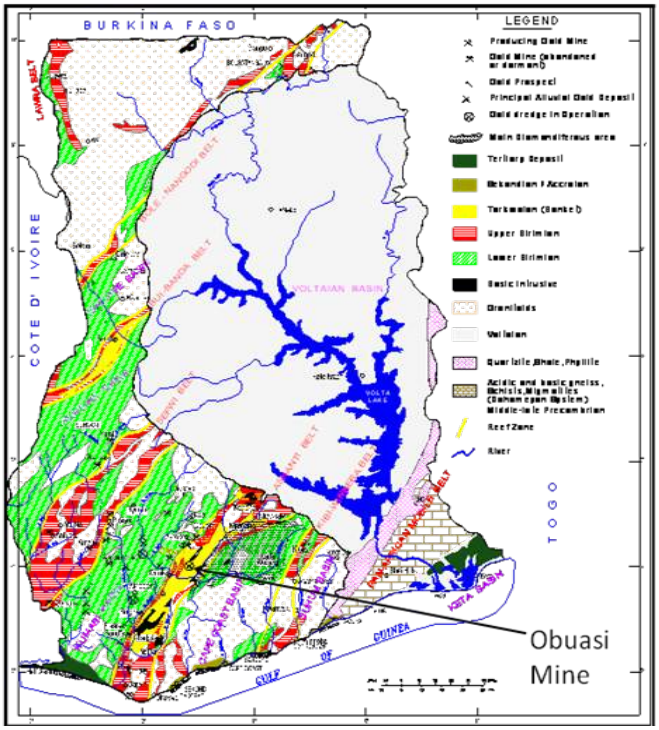

Figure 1. Location of Obuasi in Ghana (Modified after Kesse, 1985)

Historically, Obuasi Resource evaluation was done across heterogeneous zones

(domains): free milling gold in quartz veins and gold bearing sulphide zones. This did not recognize the different styles of the mineralization in these domains and this resulted in significant smearing effects resulting in poor reconciliation between resource grades and milled grades. This study takes into account these domaining and estimates the quartz and sulphides differently. It improves reconciliation considerably from 71% to 103%.

2 LOCAL GEOLOGY

Obuasi concession is located on a north easterly striking Ashanti volcanic belt which predominantly comprises sedimentary and mafic volcanic rocks, and is the most prominent of the five Birimian Supergroup gold belts found in Ghana (Kesse, 1985).

The Obuasi deposit is also characterised by the development of strong pinch and swell structures, as shown in Figure 2. It is often associated with mineralized lodes. In some areas, this is spectacularly demonstrated with abrupt termination of massive quartz material at an inter-nodal or necking point. Periodicity of these structures is variable, ranging from a few tens of meters to less than a meter.

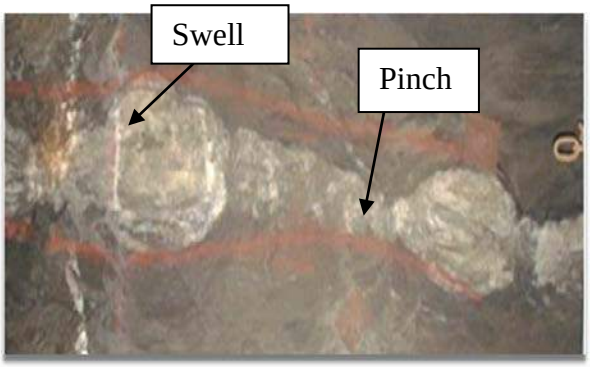

Figure 2. Underground Exposure of Pitch and Swell Structures

There are two basic ore types at the mine (Anon, 2011):

i. Free milling gold in quartz veins (QVs) which are found in the shear zones. These zones are responsible for the highest grades recorded at Obuasi Mine. It is characterised by free gold sometimes visible to the naked eye and as nuggets. The quartz veins may range from a few centimetres to over 2 m wide and from a meter to over 300 m long in strike and along dip.

ii. Sulphide-rich (arsenopyrite) disseminated refractory gold lodes which form alteration haloes around the quartz vein lodes that may be much wider and longer than the quartz veins.

These can be modelled as separate domains since they have different styles of mineralisation. The grades in the quartz veins, averaging over 12 g/t, are normally much higher than those of the sulphides which average about 7g/t. These are very common in the project area and in many ore blocks in the Obuasi Mine.

3 DATA COLLECTION AND VALIDATION

The project area covers Blocks 9 & 10. The data collected in the project area consisted of 4212 sulphide samples and 1077 quartz samples. Core sample lengths varied between 0.3 and 1.5 m. These were validated to correct for duplicates, missing data, inconsistent coordinates, etc. Various parameters of drill holes that were collected included Borehole identification (BHID), Collar coordinates, Surveys, Lithological units, Assays and Recoveries. These were entered into a Century Database and then imported into Datamine and *desurveyed*.

The orebody geology was modelled by digitizing around quartz ore (red line) and the sulphide ore (green line) at various elevations as exemplified in Figure 3.

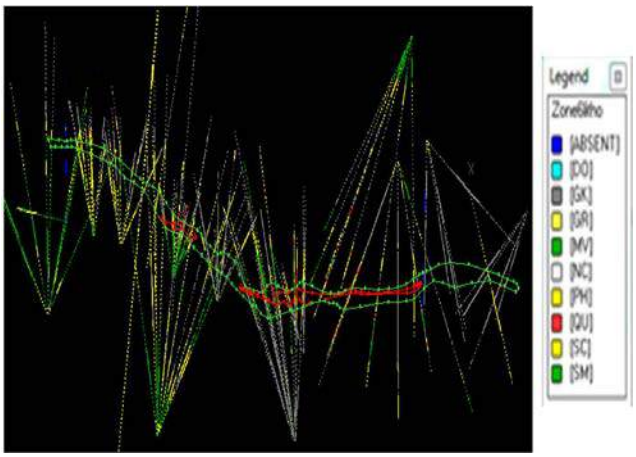

Figure 3. Digitized plan- view at -930 m elevation.

The digitized strings were linked into 3-D wireframe volumes with the quartz volumes occurring in the sulphide volumes as quartz veins, though some portions of the quartz veins do protrude to the outside of the sulphides. Figure 4 shows the quartz and sulphide domains.

4 DATA ANALYSIS

Samples within each wireframe were retrieved. There were 4212 sulphide samples and 1077 quartz samples. The two sample types were subjected to further validation processes which included:

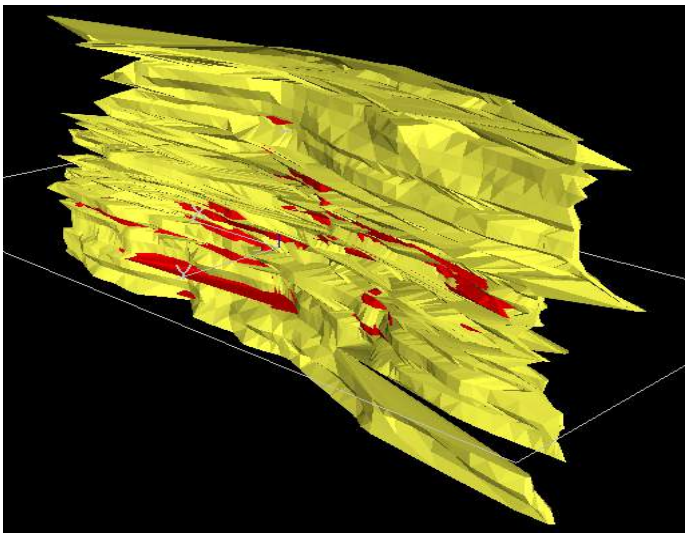

Figure 4. Wireframe showing quartz (red) sandwiched in Sulphides (yellow).

- Compositing over 0.9m so as to make their statistics meaningful with equal support (Dowd & Milton, 1987; Reedman, 1979).
- Removing unrealistic sample lengths.

Classical statistical analysis on the composite was done. Table 1 shows the summary statistics for each ore type. Both F- and t-tests at 5% level of significance failed, indicating that the quartz and sulphide samples did not come from identical populations (Davis, 1986) and this further justified their being modelled separately.

Table1. Statistics of the composited samples

Sample statistic	**Sulphide samples**	**Quartz samples**
Number of samples	3981	961
Maximum (g/t)	29.75	59.09
Minimum(g/t)	0.01	0.01
Mean(g/t)	4.41	9.22
Variance	24.18	55.54
Skewness	1.70	0.73
Kurtosis	2.93	0.37

Various methods are available for identifying and handling outliers (Anderson et al., 2003; Bluman, 2004; Bowerman, B. L. & O'Connell, R. T., 2003). Top cutting was used to minimise the impact of outliers. Cumulative frequency graphs of the composites shown in Figures 5 and 6 for quartz and sulphide respectively, using the 95% (Annels, 1991) were used. Thresholds of 35 g/t and 13 g/t for quartz and sulphide respectively were obtained.

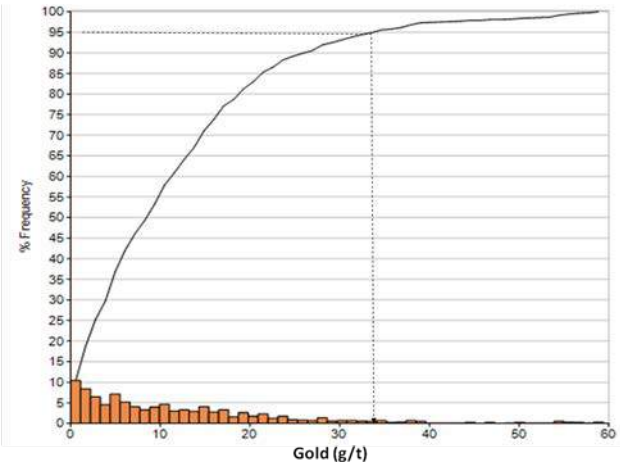

Figure 5. Cumulative frequency plot of quartz samples

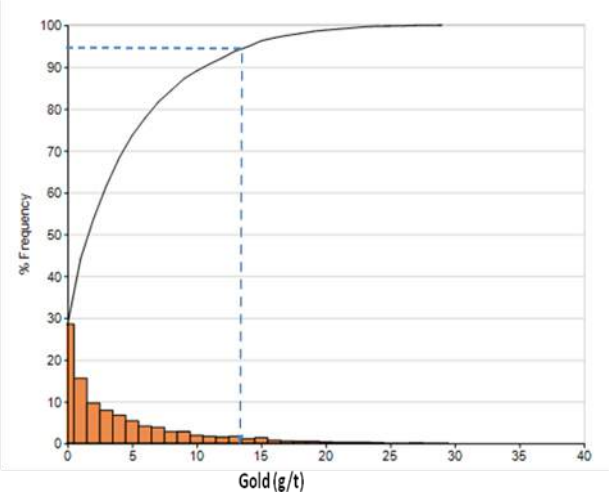

Figure 6. Cumulative frequency plot of Sulphide samples

5 VARIOGRAPHY

Semi-variograms were calculated for both quartz and sulphide samples vertically and along 0°, 45°, 90° and 135°. The directional experimental semi-variograms for the sulphide samples had discernible simple isotropic structures and were modelled with a simple spherical model. Figures 7 and 8 show examples of semi-variograms in 045° and 135° respectively.

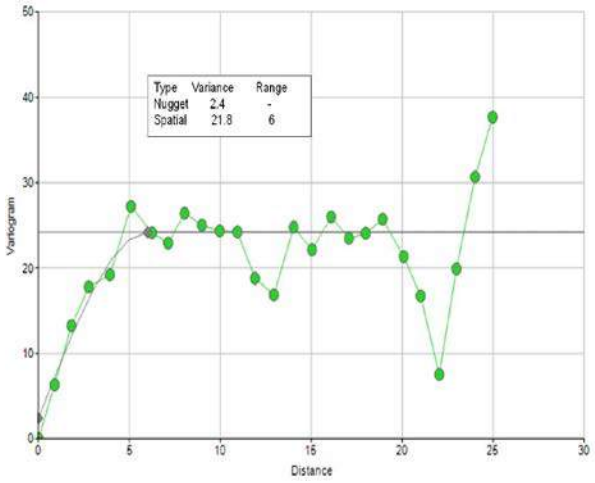

Figure7. Experimental and model semi-variograms for Sulphide samples (045º)

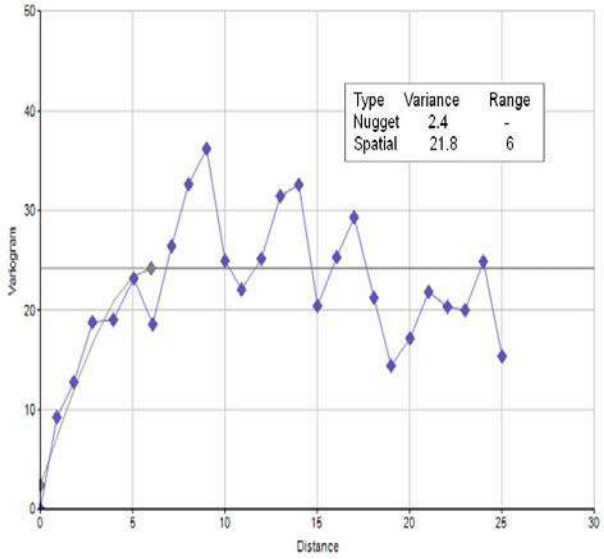

Figure 8. Experimental and model semi-variograms for Sulphide samples (135º).

However, the experimental semi-variograms for the quartz samples were so erratic that there were no discernible structures. Hence they could not be modelled. Inverse distance weighting was used instead as there have been instances when IDW has given acceptable results (Royle, 1978).

6 RESOURCE BLOCK MODEL

Block modelling was done with block dimensions of 5x5x5m that corresponds with the typical mine stope size. Other stopes are multiples of this parental cell size. Details of the model are shown in Table 2.

Table 2. Details of the block Model

	Coordinate Limits		Cell Sizes	
	Min.	Max.	Min.	Max. (Parent)
X	13350	14600	2.5	5
Y	10775	11025	2.5	5
Z	-1125	-575	2.5	5

7 RESOURCE ESTIMATION

Grades of the Sulphide orebody (zone 1) were estimated using ordinary kriging whilst those of the quartz orebody (zone 2) were estimated using Inverse Distance Weighting (IDW) method (established through cross

validation). In both cases a minimum of 3 and maximum of 20 samples were used.

The resource model was validated by visual inspections. For a good and well optimized model, all model cells within the quartz wireframe should have Zone 2. The Sulphide should have Zone 1 while the Waste Zone should have Zone 0. Grade estimates into the geology block model cells at -830m elevation are shown in Figure. 9. The quartz zone (Zone 2) wireframe is shown as red outline and that of the sulphide as green.

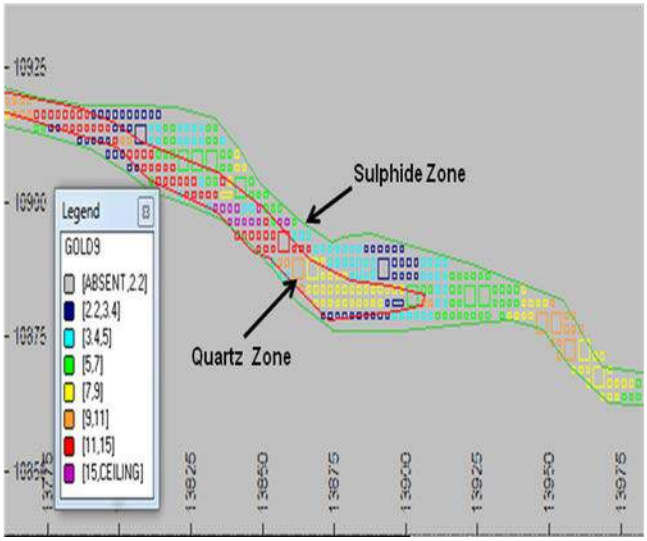

Figure. 9. Grade estimates into the geology block model at -830m RL

8 COMPARISON OF THE NEW MODEL WITH THE OLD MODEL

A portion of the new model has been mined out and a cavity monitoring survey (CMS) was carried out to measure the void created. The CMS wireframe generated was used to evaluate the new model and old models. The new model, together with the CMS wireframe, is shown in Figure. 10. Since the zonal constraining process was applied, there was no significant smearing of grades.

Figure 11 also shows the old model with the same CMS wireframe. There was no quartz and sulphide domaining for the old model, but just one wireframe which lumped together the quartz and sulphides; thereby, resulting in severe smearing of grades.

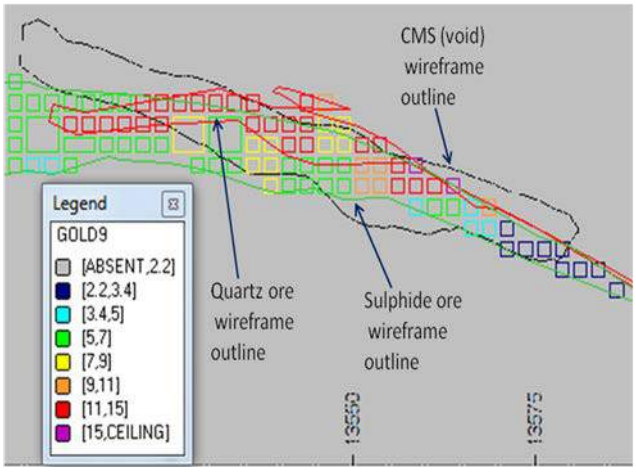

Figure 10. New model with quartz, sulphide and CMS wireframe

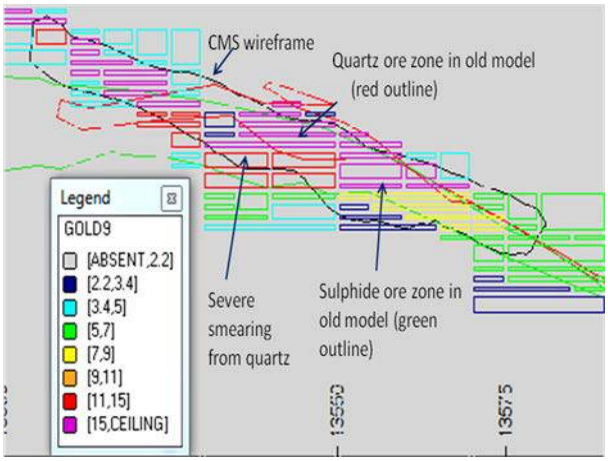

Figure 11. Old model with the CMS and Ore Wireframe

Tonnage and grade calculations within the CMS wireframe for both models were done. Table 3 shows a comparison of the volumes of the new and old models that were contained in this CMS void. Also, Table 3 shows the calculated tonnes and grades of the two models within the void.

There is smearing of high grades from the quartz into the sulphides such that grades in some of the sulphides are bloated up to the level of grades usually found in the quartz and makes them appear as quartz zones. Also the same density (2.89) was used for both quartz and sulphides in the old model.

9 RECONCILIATION OF THE NEW AND OLD MODEL GRADES WITH ACTUAL PRODUCTION GRADES

Table 4 shows the reconciliation of the estimated grade from both models and the actual mined grade from within the CSM.

Table 3. A summary of the calculation results and comments

	New model				Old model			
Category	Tonnes	Grade	Oz	Zone	Tonnes	Grade	Oz	**Comments**
[< 2.2]	50653	1.64	2671	0	35631	0.87	997	Smearing of grade from quartz improved some waste and low grades material
[2.2 ,3.4]	7143	2.84	652	1	4620	2.62	389	
[3.4, 5]	9222	4.08	1210	1.	3210	4.06	419	Sulphide tonnes constrained in their zones in the new model
[5, 7]	12130	5.87	2289	1	2209	5.93	421	
[7, 9]	4665	7.94	1191	1.6	8113	8.12	2118	High grades in quartz smeared the sulphides in the old model
[9, 11]	9071	10.19	2972	2	9213	9.80	2903	Similar
[11, 15]	13132	12.39	5231	2	11690	13.23	4972	Similar
[≥ 15]	4003	16.48	2121	2	41386	22.76	30284	Grades in some sulphides bloated up by smearing in old model, such amount of tonnes (41385.9) of quartz as in the old model do not really exist in the block
Total	110018	7.87	27837		116072	11.39	42505	

Table 4. Reconciliation of the new and old model mined grades to actual mined grades

	New Model	**Old Model**
Actual (g/t): (a)	8.11	8.11
Estimate (g/t): (b)	7.87	11.39
Reconciliation (%): (a/b)x100%	103	71

It can be observed that the new model has better reconciliation. The old model causes more smearing effects.

10 DISCUSSION

It is well known that in the Block 9 & 10 when the quartz pinches off the sulphides grades become very low (experience of the second author). This can be observed in the drill holes and channels in the mine. There is therefore smearing of high grades from the quartz into the sulphide zones in the old estimation model.

The comparison of the results in Table 3 indicates that the smearing effect of high grades from the quartz causes two significant adverse consequences:

- Low grade materials, that could have been considered waste, may be brought up to ore category.
- The low grades in the sulphides can be bloated up to very high grade levels found in the quartz.

This poses a problem of poor reconciliation between estimated grades and mined grades.

With the new model, it is possible to know the amounts of quartz and sulphide ores, with their respective grades and

ounces, in any piece of block planned to be mined. A prediction of what ounces will be contained when the quartz should pinch off unexpectedly can also be made.

11 CONCLUSIONS

The following conclusions may be made:

- The old model did not recognize the different styles of the mineralization in the deposit; thereby resulting in significant smearing effects of the high grades from the quartz. This causes two significant adverse results: sub-grade material can be brought up to economic values, and the grades in the sulphides can be bloated up to very high grade levels. Hence the problem of poor reconciliation between estimated grades and mined grades.
- From the variography, there appears to be a structure in the sulphides but not in the quartz; a simple isotropic spherical model semi-variogram of a range of 6 m in the x, y and z-directions respectively was established for the sulphides.
- A prediction of what ounces may be produced in case quartz pinches off unexpectedly can be made.
- Ordinary Kriging and Inverse Distance Weighting may be used to estimate the quartz and sulphides resources respectively. The resource estimates using domaining are shown in Table 5, which is a summary of Table 3.

  Thus, the resources in the block are estimated as 10,760 000t @ 5.4g/t for the sulphide ore, 592 000 t @ 12.75g/t for the quartz ore and 783 000t @ 9.95g/t of sulphide and quartz mix.

Table 5. Resource Estimates using the new model

Grade Category (g/t)	Tonnes (t)	Ore Type	Grade (g/t)	Totals
[3.4 - 5]	5, 375442	Sulphides	4.19	
[5 - 7]	3,543,210	Sulphides	5.85	
[7 - 9]	1,841,741	Sulphides	7.92	10760393t @ 5.38g/t
[9 - 11]	783738	Sulp/Quartz	9.95	783738t @ 9.95g/t
[11-15]	547251	Quartz	12.49	
[>15]	44795	Quartz	15.91	592046t @ 12.75g/t

12 RECOMMENDATIONS

It may be recommended from the study that:

- Ore shoots in the Obuasi Mine that have considerable quartz veins in strike and width must be domianed into quartz and sulphide zones and the estimates constrained within each zone in order to improve upon reconciliation.
- A major research work on the structural controls of gold localisation in the major ore shoots of the Obuasi Mine is highly recommended, since geological structures like straight faults zones, points of inflection in the fault planes, the shear morphologies, metavolcanic-caps in the shear zones and fissure junctions occur and play significant roles in the gold.

ABSTRACT Geochemical prospecting/ mineral exploration and environmental geochemistry are typically not carried out in tandem despite the fact that some survey data and data requirements are common to both tasks. This paper examines the potential for using groundwater and surface water geochemistry data collected for environmental purposes in combination with knowledge of geology, mineralogy and basic hydrogeology to enhance understanding of processes that may be exploited by the exploration geochemist.

The novel approach in this paper can be used for maximising the value of environmental data by combining mineralogy, aqueous geochemistry and kinetic test data to design ground and surface water exploration programs to detect buried mineralization. The approach is tested on environmental data, available in the public domain, collected by Adanac Molybdenum Corporation at the Ruby Creek Molybdenum project, Atlin, BC, Canada. Implications of this approach for geochemical detection of buried mineral deposits in the Menderes Massif, Turkey are discussed.

Keywords: Molybdenum, geochemical exploration

ÖZET Jeokimyasal maden arama ve çevresel jeokimya çalışmalarının ortak etüt ve veri gereksinimleri olmasına rağmen, genelde bu iki süreç birlikte ele alınmaz. Bu makale, çevresel çalışmalar sırasında toplanmış yeraltı ve yerüstü sularından elde edilen jeokimyasal verilerin, saha hakkındaki jeoloji, mineraloji ve temel hidrojeolojik bilgiler ile birleştirilerek jeokimyasal etütlerde kullanılma potansiyelini incelemektedir.

Bu makalede ele alınan yeni teknik, çevresel verilerden elde edilen yararın, mineraloji, su jeokimyası ve kinetik test verileri yardımıyla artırılması ve gömülü mineralizasyonların bulunmasına yönelik yeraltı ve yerüstü suyu etütlerinin tasarlanmasında kullanılabilir. Bu yeni teknik, Adanac Molybdenum Şirketi tarafından Atlin, BC, Kanada'da bulunan Ruby Creek Molibden projesinde toplanmış erişime açık çevresel veriler üzerinde denenmiş ve uygulanabilirliği gösterilmiştir. Ayrıca, bu yöntemin Türkiye Menderes Masifi'nde yer alan gömülü mineral yataklarının tespitinde kullanılması konusu da tartışılmıştır.

Anahtar Kelimeler: Molibden, jeokimyasal arama

1 CONCEPTUAL MODEL

This paper describes the results of research carried out to investigate the potential of multi-parameter ground and surface water data, typically collected during environmental studies, for the detection of partially or completely buried mineralization. An initial conceptual model was proposed (Figure 1) in which precipitation percolates through surface rocks, gradually equilibrating with the minerals present in the rocks dependent on their relative solubility. It was theorized that if such percolating water were to pass through mineralized rocks it would perhaps alter the groundwater, especially if sulphidic minerals were slowly oxidizing with oxygen supplied by advective flow. Groundwater passing through fissures or cracks in the mineral deposit would at some point migrate beyond the mineral deposit and gradually slowly re-equilibrate as it encountered additional lithologies depending on reaction kinetics. Eventually the partially re-equilibrated groundwater may reach the surface at a spring or seep and contribute to surface water flow, becoming increasingly diluted in the process. It was considered that if the increasing dilution of groundwater could somehow be detected it may provide a very useful guide to buried mineralization.

The Ruby Creek Molybdenum Project was selected for study for a number of reasons: multi-parameter ground and surface water environmental data was available in the public domain; one of the authors was familiar with the project; except for a small exposure in the stream bed the deposit was buried beneath barren basalts and quartz monzonites; pyrite was known to be present above the mineralization giving rise to ‘natural Acid Rock Drainage /Metal Leach (ARD/ML)’ (Lett and Jackaman, 1995); and a zone of groundwater flow into surface water from beneath the basalts was known to exist.

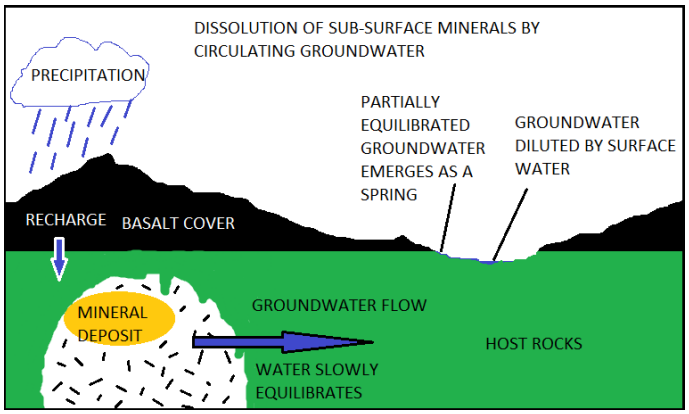

Figure 1. Conceptual model of Groundwater equilibration.

2 RUBY CREEK MOLYBDENUM PROJECT

The Ruby Creek Molybdenum project is located east of Atlin, British Columbia (BC), Canada; Figure 2. Molybdenum mineralization underlies the valley floor near the headwaters of Ruby Creek, (MacLeod, 2007). The host plutonic rocks are generally classified as quartz monzonites although sufficient variation exists to distinguish three phases of magma intrusion (Figure 3). The host intrusion, which includes the contact phase between the Cretaceous Fourth of July and Surprise Lake batholiths consists of a highly variably textured unit that grades from “coarse-grained quartz monzonite” (CGQM) south of the Adera fault through a number of texturally transitional phases. North of the molybdenum deposit’s bounding fault (Adera fault) is a quartz monzonite with fewer quartz and feldspar pheoncrysts (SQFP or “sparse quartz feldspar porphyry”), containing a higher proportion of pyrite leading to local gossan development at surface. The Mo mineralization is generally confined to fractures in quartz monzonite south of the Adera fault and except for a small exposure in the valley floor is almost completely buried under barren rocks. The quartz monzonites are overlain by a sequence of basalts and the surficial deposits include extensive scree on valley slopes as well as

alluvium in the valley bottoms and small ponds.

Figure 2. Location of study areas.

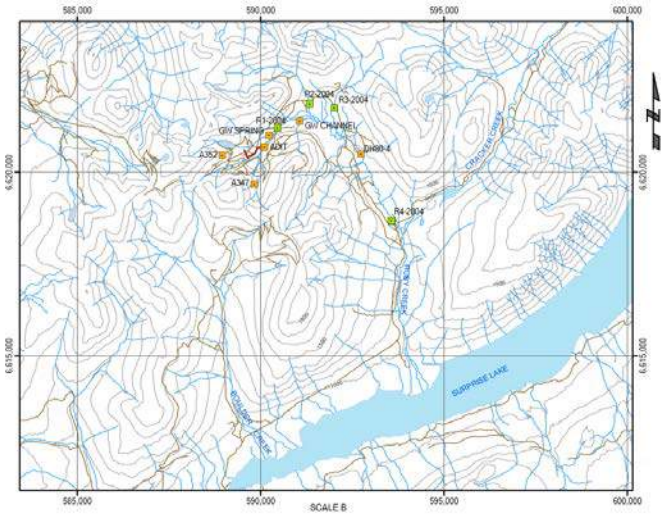

Figure 2. Ruby Creek Project study area location, also showing ground (orange) and surface water (green) sample sites.

2.1 Mineralogy / Petrography

The mineral assemblages were determined using standard X Ray Diffraction (XRD) (with Reitveld refinement) and petrographic procedures (MacLeod, 2007). SQFP was found to contain quartz (35%), orthoclase (50%), anorthitic plagioclase (12%), muscovite/sericite (1.5%), kaolinite (0.3%) and pyrophyllite (0.9%) together with trace quantities of pyrite, chalcopyrite, marcasite and minor kaolinite and limonite. CGQM was found to contain quartz (45%), orthoclase (33%), anorthitic plagioclase (15%), muscovite/sericite (6.6%) with trace magnetite. Petrographic and XRD studies did not find any molybdenite in CGQM although three repeat analyses yielded 180, 7.3 and 7.9 mg/kg Mo, illustrating a typical nugget effect. Carbonate minerals were found by acid digestion and ICP-MS analysis to typically be very low or absent in these lithologies. Gladwell and Ziten (2009) report that alkalinity and Mo are the only parameters which are statistically higher in leachate from molybdenite bearing samples.

2.2 Hydrogeology and Hydrology at Ruby Creek

Surface drainage at Ruby Creek consists primarily of a single (though in places braided) channel with a number of tributaries entering it (Figure 4). An adit was driven into the mineralized quartz monzonite in the early 1970's by Kerr Addison along which there is a low flow of groundwater into Ruby Creek. In addition, groundwater was observed flowing into Ruby Creek between the most southerly drill hole (DH-80-4) and the most southerly water sample site (R4). The hypothesized distribution of surface and groundwater, based on these observations is presented as Figure 5. It was considered that the hypothesized zone of groundwater inflow into the stream channel could contribute water into the stream that had at some point equilibrated with the mineral deposit.

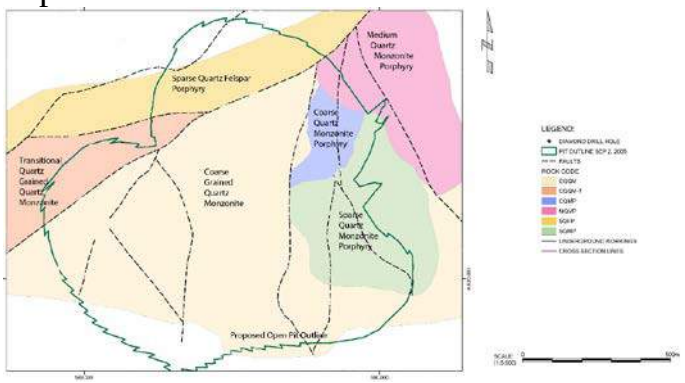

Figure 3. Ruby Creek Project study area showing simplified igneous geology.

MacLeod (2007) reports that five groundwater samples were collected at a series of groundwater springs and artesian wells in the project area through 2004 and 2005 together with five surface water samples (Figure 4). Water sampling was carried out at several dates; the earliest (2004) data was used for this study. The

water samples were analysed for a suite of cations and anions as well as general parameters such as pH, conductivity etc. PHREEQC aqueous modelling software was used to assist interpretation of the ground and surface water data (Apelo and Postma, 2007). PHREEQC, among numerous other features, facilitates charge balancing of aqueous solutions as well as calculation of the saturation index (SI). SI is defined by PHREEQC as the log of the ion activity product less the thermodynamic constant, Kt for a given mineral phase. A negative value of SI for a mineral phase implies the aqueous solution in question is thermodynamically capable of dissolving more of that phase, a SI value of zero implies the aqueous solution would be in equilibrium with that phase and a positive SI value implies the aqueous solution is thermodynamically capable of precipitating that phase. It is important to note that PHREEQC does not take account of kinetic constraints. This means, for example, that a mineral such as silica may be predicted to precipitate from the aqueous solution, based on its SI, however silica is kinetically very slow to precipitate from solution (Apelo and Postma, 2007) and these authors note that water saturated with respect to silica is quite common in the surface environment. This fact allows the silica SI to be used under certain circumstances as a 'geothermometer' (Tarcan et al., 2000).

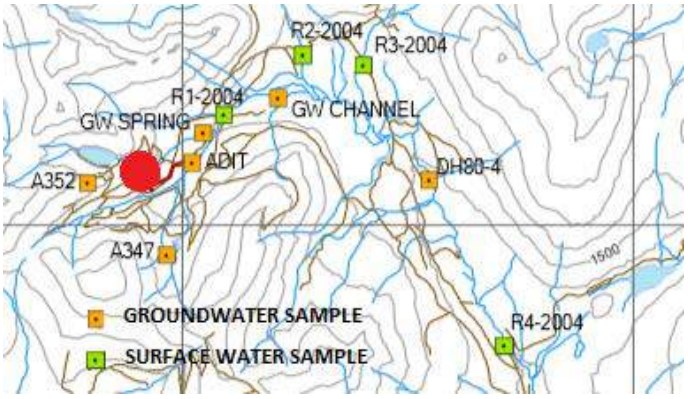

Figure 4. Ruby Creek study area showing location of surface and ground water environmental sample sites.

The authors considered, based on the conceptual model advanced above, that water samples showing high (but not necessarily positive) SI values for a number of mineral phases would tend to have a higher groundwater component than water samples dominantly comprised of surface runoff. A conceptual map of the study area showing groundwater versus surface water inflows is shown in Figure 6. Water sample site R3 is located on a tributary that drains a watershed northeast of the mineralization and therefore the water is not expected to come into contact with mineralization; it was selected as a background sample site for the purposes of this study.

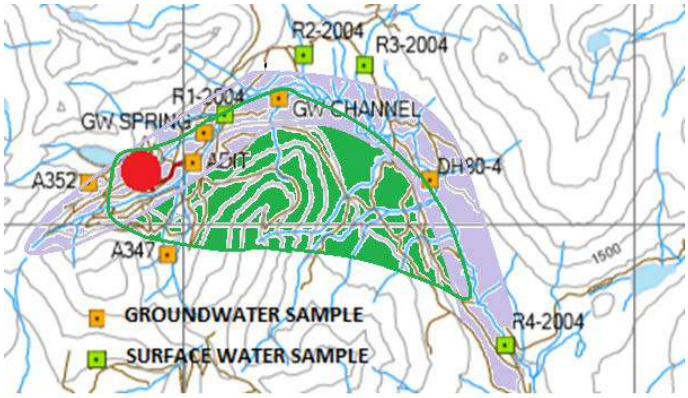

Figure 5. Ruby Creek Project study area showing hypothesized inflow of groundwater (green shading) compared to surface water (blue shading).

2.3 Geochemical PHREEQC Interpretation of Ground and Surface Water Data at Ruby Creek

The only raw geochemical parameter that clearly delineates the mineralization is Mo (Figure 7) although the only clearly anomalous value is at the mouth of the adit at 4.1 times background (R3) at 0.079 mg/L (red circles in Figure 7). Seven other water samples (orange circles on Figure 7) exceeded 0.00034 mg/L Mo. F shows lower concentrations over the mineralization. Cd also shows slight enrichment but appears to be generally associated with the monzonite (i.e. high values are observed upstream of the mineralization).

It might be expected (as noted above) that the SI for silica would be higher in groundwater samples than in surface water samples. Figure 8 shows that this is indeed the case.

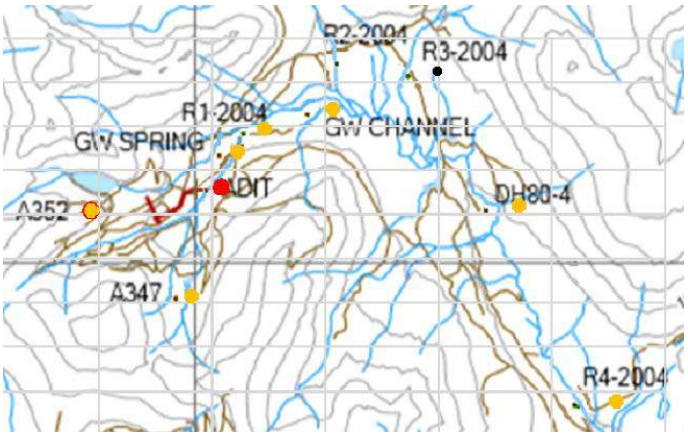

Figure 6. Ruby Creek Project study, distribution of Mo concentrations (Values as red circles exceed 0.079 mg/L and values as orange circles exceed 0.00034 mg/L).

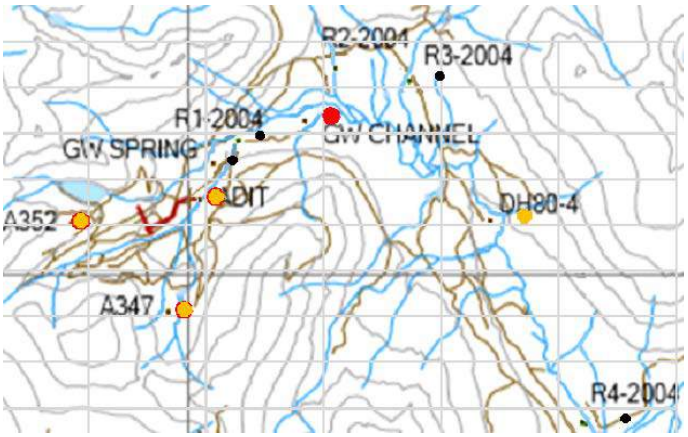

Figure 7. Ruby Creek Project study, distribution of silica SI values in ground and surface water samples (Red circles show SI values exceeding 0 and orange circles show SI values exceeding -0.47).

All of the drill hole water samples show high silica SI, as does the GW (groundwater) channel sample. R4 also shows a higher than expected silica SI sample confirming the observed groundwater input emanating from exposed basalts into the stream upstream of this site. The silica SI appears to indicate the presence of groundwater at Ruby Creek satisfactorily, as was expected from its slow reaction kinetics.

When precipitation kinetics for a particular mineral phase are slow then the SI value for that mineral may show a gradual decrease in value as the groundwater in increasingly diluted with surface runoff and as precipitation gradually occurs (if SI values are above zero). Such is the case for the fluorite SI (Figure 9), which exceeds the background (R3) SI value for over 3 km downstream. The PbMoO4 SI shows similar downstream dilution (Figure 10). Interestingly, the SI for Halloysite also shows downstream dilution (Figure 11), although the background value is reached at between 1000 and 2000 m downstream. Halloysite is most probably produced by plagioclase buffering of acidic groundwater produced by natural ARD produced by accessory pyrite in the quartz monzonite north of the Adera Fault (Gladwell and Ziten, 2009).

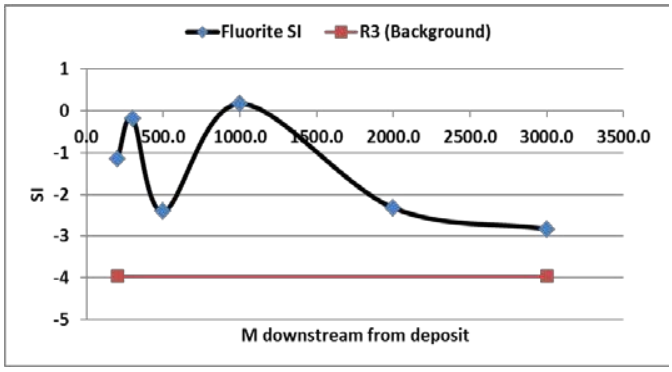

Figure 8. Ruby Creek Project, downstream dilution of the fluorite SI.

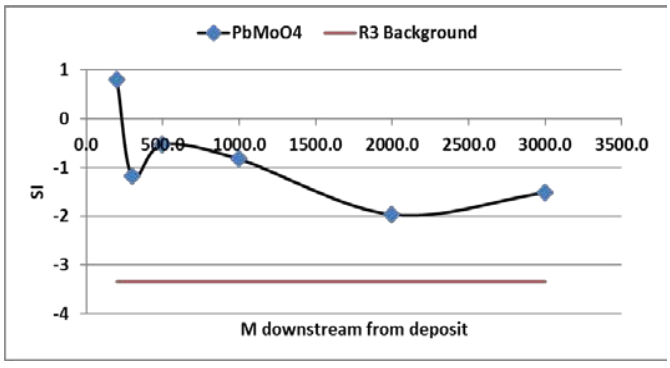

Figure 9. Ruby Creek Project, downstream dilution of the $PbMoO_4$ SI.

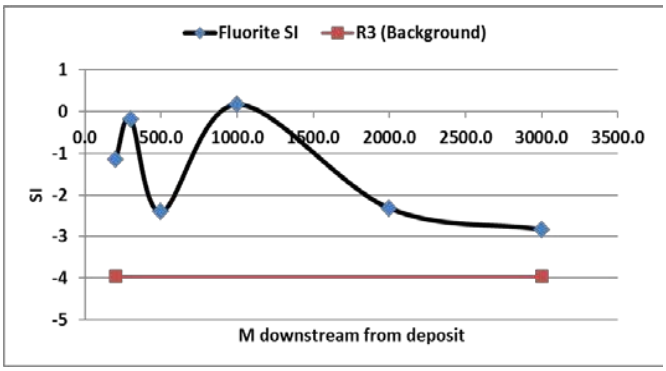

Figure 10. Ruby Creek Project, downstream dilution of the fluorite SI.

The results of the Ruby Creek Project study show that: the silica SI may be used to identify influx of groundwater into surficial drainage; dilution of SI values for mineral phases with slow precipitation kinetics may clearly indicate mineralization, and; the conceptual model for groundwater equilibration with mineral phases present in buried mineralization is corroborated. The conceptual model was subsequently applied to a reconnaissance exploration survey in the Menderes Massif, Turkey.

3 MENDERES MASSIF STUDY AREA

The Menderes study area is located near Alasehir, Western Turkey (Figure 2). The study area is on the Menders massif and close to Alasehir detachment, which is one of several detachment faults and/or related shear zones of exhumation Menderes massif (Seyioglu et al., 2014). The geology of the area comprises basement rocks of high to low grade metamorphics (gneiss, mica schists, marbles) and granodiorite of Early Triassic to Upper Cretaceous age. The basement is unconformably overlain by Neogene sedimentary rocks and basaltic lavas (Holocene Kula volcanics). Permeability is highly variable and is mainly controlled by fractures and fissures (Tarcan et al., 2000). The study area is located on the Salihli-Alaşehir part of Gediz Basin, which is the second biggest basin in Aegean Region. The important tributaries of Gediz River around the study area are Alaşehir and Nif creeks. There are two main aquifer systems namely Quaternary and Neogene in the study area (Ağartan, 2010). Natural springs are confined to fault and fracture zones.

3.1 Menderes Study Area – Water Quality Results

Twenty six groundwater samples were taken from drinking water wells along a trend of over 30 km and their multi-element cation chemistry was determined by ICP-MS and ion chromatography for anions. Sample sites are shown on Figure 12, which also shows the MTA metallogeny base map for the area. A known gold occurrence is present in the northwest of the sampled area. The multi-element chemistry was processed using PHREEQC and the SI values for minerals likely to be present were calculated.

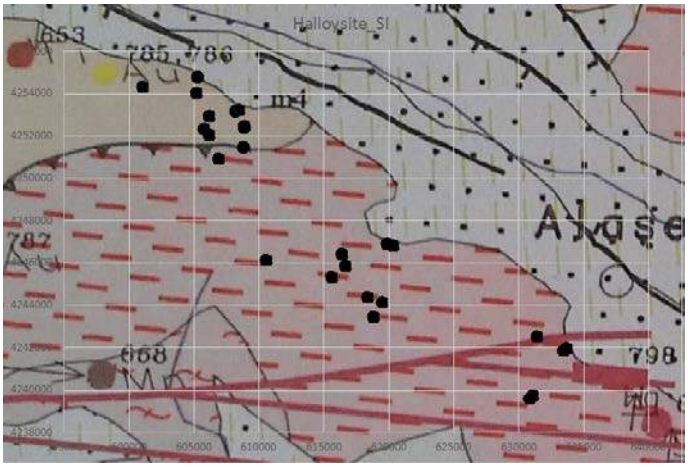

Figure 11. Menderes study area, distribution of groundwater samples superimposed on the MTA metallogeny basemap.

The distribution of positive SI values for halloysite is shown as Figure 13. The anomalous halloysite SI values form a cluster along strike from the known gold occurrence. The cluster of anomalous SI values for Halloysite is also associated with a very low level Cu anomaly (Figure 14 shows Cu concentrations above 0.0006 mg/L as red circles), which is reflected in high SI values in these samples for copper bearing minerals.

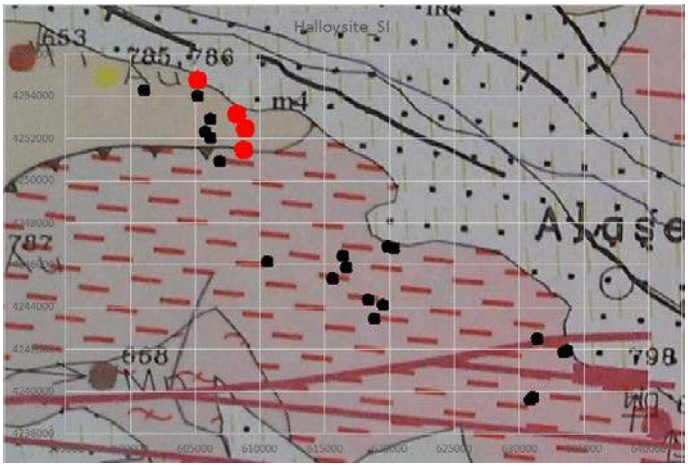

Figure 12. Menderes study area, distribution of halloysite SI values, red circles indicate SI values above zero.

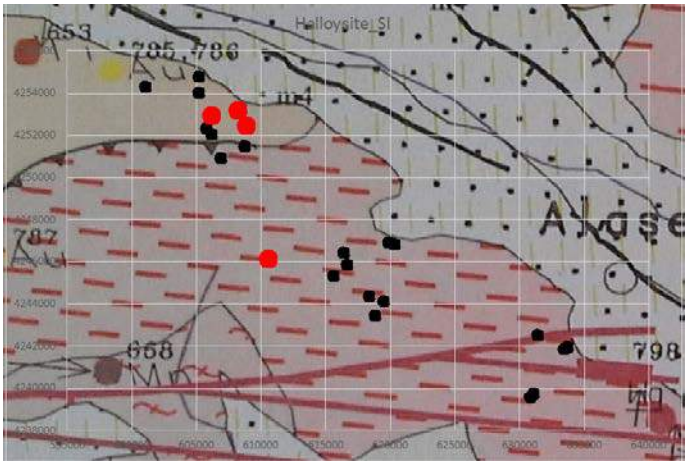

Figure 13. Menderes study area, distribution of Cu concentrations in groundwater (red circles indicate Cu concentrations above 0.0006 mg/L).

The study area is geothermally active and this is corroborated by the positive SI values for silica, which are clustered in three groups, probably reflecting movement of silica laden warm water travelling through faults and fractures (Figure 15). The observed distribution of high silica SI values suggests that the observed halloysite/Cu anomaly is of geothermal origin and may reflect mineralization along strike from the known gold occurrence.

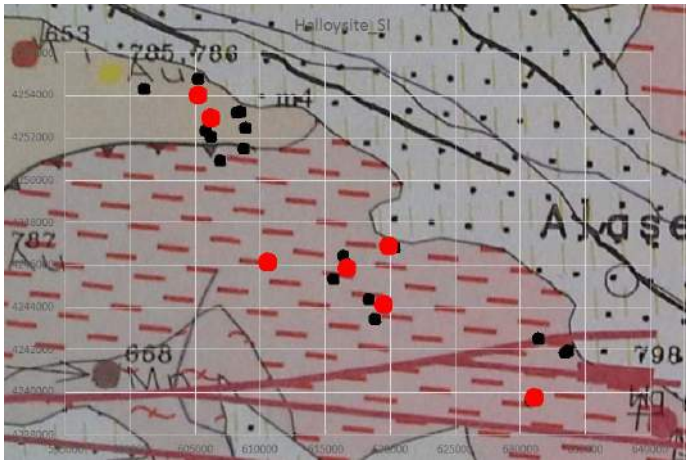

Figure 14. Menderes study area, distribution of silica SI values (red circles indicate SI values above 0.17).

4 CONCLUSION

The detailed interpretation of ground and surface water data collected for environmental purposes has allowed corroboration of a groundwater equilibration model that enhances geochemical exploration for buried mineral deposits, both on a local and reconnaissance scale. High silica saturation index values were shown to indicate groundwater entering surface drainage. In addition, dilution of ore and gangue mineral phases with slow reaction kinetics was observed and shown at the Ruby Creek (BC, Canada) and Menderes Massif (Turkey) study areas to delineate molybdenum and copper/gold mineralization respectively. The conceptual model appears to be applicable to both local (< 3 km) surveys as well as reconnaissance (> 30 km) surveys. Collection and analysis of environmental data is very expensive and careful use of the acquired data in geochemical exploration adds considerable value to the investment.

ACKNOWLEDGEMENTS

The authors are indebted to Jeoband A.S. for supporting their research and to Asia Minor Mining A.S. for permitting publication of the Menderes Study Area water quality data.

ABSTRACT The main objective of this work is to map the Curie depth of the West African Craton (WAC) using satellite magnetic data with the aim to provide first order evaluation, within this vast territory, for the spatial association between Curie-depth surface and known kimberlite locations. Taking into account Clifford's rule, the first and foremost exploration guideline for diamond exploration is the existence of a sufficiently thick lithosphere that expected to have a low surface heat flow. The Curie depth is closely related to the surface heat-flow conditions and lithosphere thickness. In actual fact, the only few regions that have sufficient density of surface heat flow measurements corroborate the association of these conditions with the diamond resources. To better explore in an efficient way the spatial relationship between the Curie depth and known diamondiferous primary sources within the WAC, we used GIS-based weights of evidence method to provide a quantitative analysis.

Keywords: Mapping, Clifford's rule, WAC, GIS, diamond exploration

1 INTRODUCTION

The diamonds form from carbon within the high-pressure environment present in nature at depths of over 150 km. In most parts of the Earth, at such depths we are right in the asthenosphere and the temperatures at this depth are too high to allow the crystallization of diamonds. However ancient cratonic blocks have a sufficiently thick (150-250 km) and relatively cool lithosphere (less than about 1200° C) in which diamonds can form and be preserved. The diamondiferous kimberlites are confined to these Precambrian cratons, particularly on those of Archean age. This empirical association is known as Clifford's rule (Clifford, 1966).

Thick and cool lithosphere potentially has a regional signature in almost all geophysical techniques. Teleseismic and magnetotelluric methods are the only methods able to directly ''look" into the mantle. However, magnetic method may predict the presence of lithospheric root (thick lithosphere) rather than direct detection. Surface heat flow measurements may be the first predictive approach for identifying conditions favorable for primary diamond deposits, as temperature at depth is the primary controlling parameter in diamond genesis. Exploration targets for diamond genesis are expected to have a low heat flow of 40–45 mW m^{-2} (Morgan, 1995). Several studies have shown a strong correlation between heat flow measured at the surface and the thickness of the magnetized crust. As is known, crustal rocks lose their magnetization at the Curie point temperature (about 525 ± 25° C). At this temperature, ferromagnetic rocks become paramagnetic, and their ability to generate

detectable magnetic anomalies disappears. The depth to the Curie isotherm surface may be at mid-crustal levels in regions of high heat flow, and at or close to the Moho in stable, low heat-flow regions. Therefore, the maximum magnetic source-depth is closely related to the surface heat-flow conditions.

The objective of this study is to assess the spatial relationship between the mapped Curie depth, and the known kimberlites locations, to answer the question whether the spatial distribution of these kimberlites is controlled by Curie-depth in the WAC assumed to be closely related to Heat-flow conditions. A geospatial quantitative assessment based on Bayesian statistical approach, in a log-linear form know as Weights of Evidence modeling technique (Bonham-Carter, 1994), was used to quantitatively analyze the spatial association between the Curie-depth surface and kimberlites locations. This method has been applied previously by Paganilli et al (2002) to determine the spatial relationship of various direction lineaments to known kimberlite locations in the Canadian Buffalo Head Hills.

2 STUDY AREA AND DATA SETS

The vast extent (4.5 million km^2) Western African Craton (WAC) considered in this study covers many countries. It lies at the North-Western part of Africa, between 17°30' W - 3°30'E longitudes and 4°10'N - 30°40'N latitudes. The geological map of west Africa (Fig. 1) shows two shields of Precambrian rocks exposed in the Reguibat and Man uplifts, separated by the Taoudeni Basin. The southern Precambrian core covers most of Sierra Leone, Liberia and southeast Guinea. In this core are located the diamond-bearing kimberlites of Sierra Leone, Liberia and Guinea. The Reguibat shield is the northern core, almost the mirror image of the southern core. Kimberlite eruptions have been rare through geological ages with an important episode during Cretaceous times. The basement of the WAC, stable since 2000 MA, is dominated by the occurrence of Archean nuclei surrounded by low-grade volcanoclastic Birrimian formations, which were affected by the Eburnean orogeny (at about 2 billion years) and intruded by numerous lower Proterozoic granitoids.

The data used in this study are extracted from satellite magnetic field model MF7 developed from CHAMP mission using measurements collected from May 2007 to April 2010. The original data set was compiled at 1.5 arc minute ascii grid of the anomaly of total intensity at 2.5 km altitude above the WGS84 ellipsoid. It is intended for use in the World Digital Magnetic Anomaly Map project for the 2011 revision. These data provide the most effective means of mapping the long wavelengths of the magnetic field caused by the magnetization of the Earth's crust. The CHAMP satellite, active until 2010, was launched in July 2000 into a lower orbit, initially at 450 km altitude. It has been providing excellent quality data at solar minimum conditions and at steadily decreasing altitudes. Using a field model instead of raw satellite magnetic field observations is highly productive as the magnetic field measured by a satellite contains contributions from several different sources: the core, the crust, the ionosphere, and the magnetosphere. Field modeling allows separation of various sources, thus allowing the crustal field to be isolated.

The crustal magnetic field of the WAC derived from world digital magnetic anomaly map was resample at a 4-km grid spacing resolution using Minimum Curvature interpolation method (Fig. 1). The main characteristics observable in the magnetic field are the NE-SW trends apparent in the central portion of the study area which seem affected by NW to WNW direction particularly in the northern part of the region. The most intense anomaly appears to be localized in the NE of Mauritania on the border with the Western Sahara. This large sub-latitudinal bipolar anomaly present an amplitude of more than 500 nT, and most of the known kimberlite occurrences discovered in Mauritania are within this zone. To the southwestward termination, a magnetic low characterizes a E-W trend within a region on horseback between Guinea, Liberia and

Sierra Leone, where all of the known diamond-bearing lithologies lie within this area.

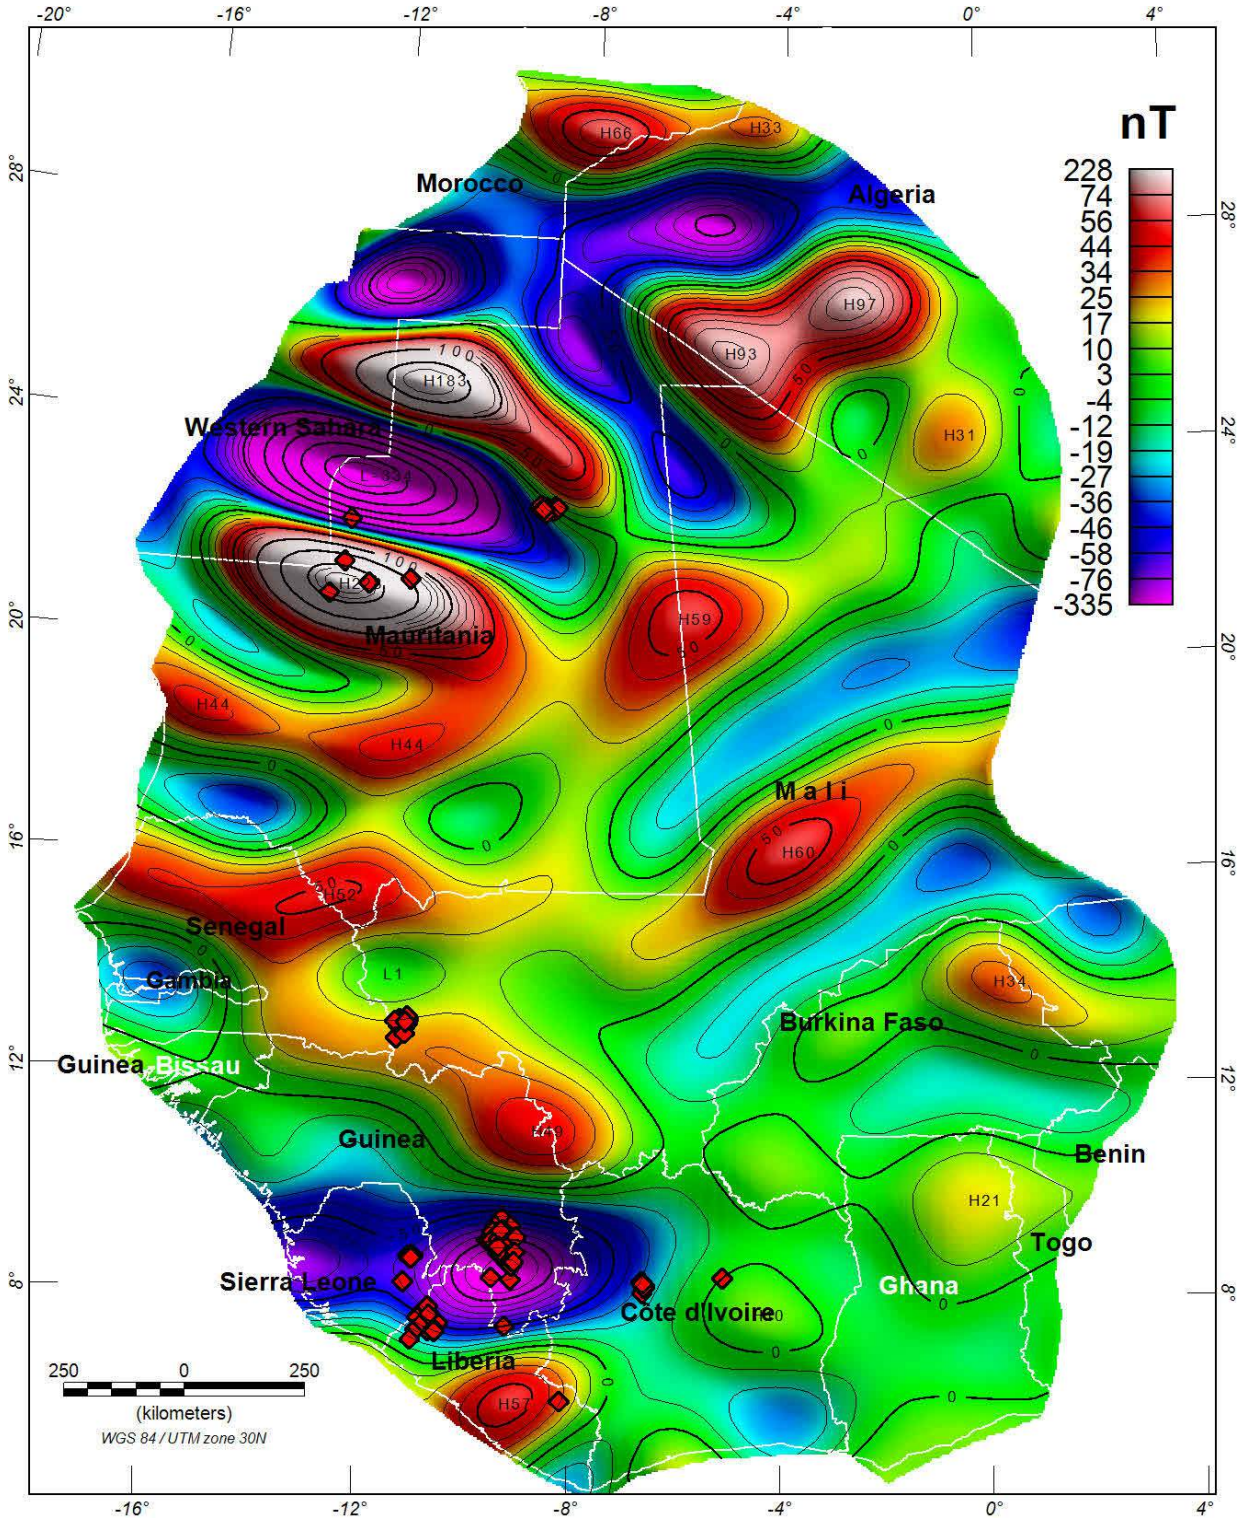

Figure 1. West African Craton crustal magnetic field and kimberlites locations

3 METHODOLOGY

3.1 Curie point depth estimation

The basic physical phenomenon that governs the investigation's of magnetic depth method is the Curie temperature by which the detection of magnetic bodies is limited by the depth of the Curie isotherm. Using magnetic data to infer heat flow is possible because the magnetic properties of rocks are temperature dependent, and at the Curie temperature rocks lose their magnetism. Negi *et al.* (1987) have elaborated empirical relationships which may

be readily used in converting Curie depth into the corresponding surface heat flow density values and lithosphere thickness.

The geothermal heat flow is an important factor in the area selection for diamond exploration. The estimation of the depth to magnetic bottom, assumed to be at the Curie temperature, can be realized using spectral analysis. However, this approach depends upon many assumptions and therefore has limitations. It requires that the depth to the bottom of magnetic sources be large relative to the depth of the top, essential to spectral separation.

Magnetic data have been used in various parts of the world in order to estimate Curie Point Depths (CPDs). Two approaches have been usually used for the computation of the CPDs; the spectral peak and the centroid depths. The spectral peak approach originally is given by Spector and Grant (1970), and the centroid approach originally presented by Bhattacharyya and Leu (1977) and was developed by Okubo et al. (1985). As part of the work presented here, we used the first one.

Spector and Grant (1970) derived an expression for the power spectrum of the total magnetic field intensity by assuming that the anomalies are due to an ensemble of vertical prisms. The method treats the observed magnetic field anomalies as a statistical population. They demonstrated that contributions from the depth, width and thickness of a magnetic source ensemble could affect the shape of the energy spectrum.

The dominant term, which controls this shape, is depth factor. The depth estimates could be made using the equation,

$$E(r) = e^{-2hr} \qquad (1)\ ;$$

where E(r), h and r are the spectral energy, depth and frequency respectively. The thickness factor $(1 - e^{-tr})^2$ plays an interesting role in shaping the power spectrum. When combined with the depth factor (e^{-2hr}) (for not too large values of r), its effect is to produce a peak in the spectrum whose position shifts towards smaller wavenumbers with increasing values of '*t*' (thickness). When this peak occurs (significant maximum), it indicates that the source bottoms are detectable. The frequency f_{max} of the spectral peak, the mean depth '*h*' to the source tops (depth to deep-seated causative bodies) and the mean depth '*d*' to the source bottom (Curie depth) are related by the equation (Boler 1978).

$$f_{max} = \frac{1}{2\pi(d-h)} ln\left(\frac{d}{h}\right) \qquad (2)$$

where d = h + t. Whether the sources appear to be depth limited or not depends very much on the size of the map. If there were no restrictions upon either the size of the map, then presumably the Curie-point depth isotherm could be observed. Therefore, large-scale magnetic maps are useful for understanding and characterization of crustal temperatures.

The WAC was subdivided in 209 square subregions (windows). The dimensions of these windows were initially set at 100 x 100 km²; in numerous cases this size was insufficient to allow the observation of spectral peak presumably related to the CPD because it occurs at frequency lower than the fundamental frequency for the subregion. This led us to increase the size of the windows gradually by steps of 10 km until reaching a size of 150 x 150 km^2 which seems suitable for CPD determination.

The radially averaged power spectra were computed for each subregion. the Curie depth estimate is derived using equation (2). Graphs of the logarithms of the spectral energies against frequencies for the various blocks were obtained. Linear segment from the low frequency portion of the spectra, representing contributions from the deep-seated causative bodies could be drawn from each graph. The slope of the linear segment can be used to calculate the depth to the ensemble of causative bodies from the equation (1). An example of spectra for one subregion is given in Figure 2.

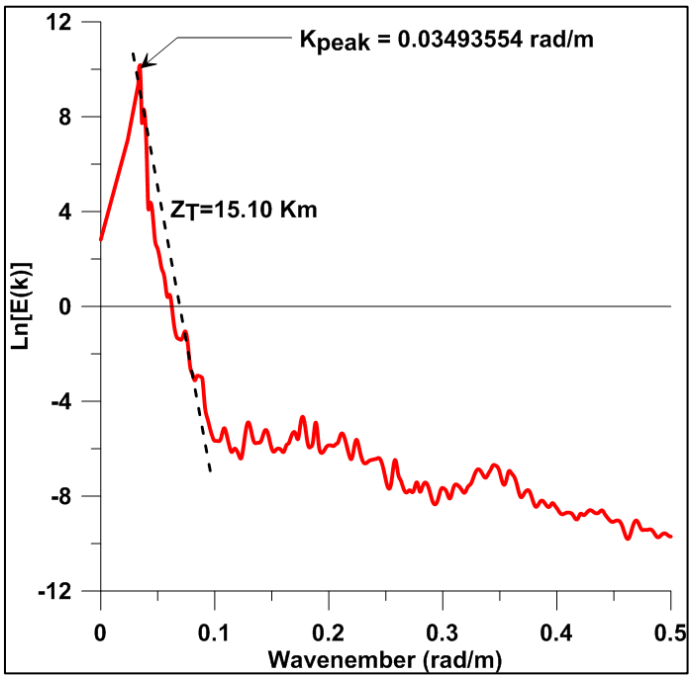

Figure 2. Example of spectrum for the estimation of the depth to Curie point using spectral peak approach.

The calculated Curie point depths were interpolated onto a regularly spaced grid using a minimum curvature technique (Briggs 1974). A grid with a cell size of 41 km was designed according to the known Rule applicable to data evenly distributed where the nominal cell size is = ¼ (sqrt (grid area / number of data points)). The data set was resampled to a 4-km grid spacing resolution in order to have more precision in the location of favorable or unfavorable evidential zones (Fig. 3). Curie point depths (CPDs) of WAC vary between 18.5 and 51.5 km.

3.2 Weights of Evidence Approach

Weights of evidence (*WofE*) is a Bayesian statistical method for assessing the degree of spatial association and for combining evidence to test a hypothesis. It determines the probability of an event to occur under certain conditions. The method was originally developed for a non-spatial application in medical diagnosis, later it was extensively used for mineral potential mapping in a GIS environment (Bonham-Carter, 1994), and soon after adapted for landslide susceptibility analysis, hazard modeling, fires and so on. The WofE method is applied here to investigate the spatial associations between Curie point depths and known kimberlite occurences within the WAC. The importance of the weights depends on the measured association and permits to provide an insight into the thermal flow condition of the WAC. This method could be used as spatial evidence in diamond prospectivity mapping.

A detailed explanation of the mathematical formulation of the WofE modeling method is available in Bonham-Carter (1994). The method uses a log-linear of the Bayesian probability model to estimate the importance of evidences by a pair of weights, one (positive weight W^+) for presence of the evidence H, and negative weight (W^-) for absence of the evidence H.

$$W^+ = ln\left(\frac{P(C|K)}{P(C|\bar{K})}\right) \quad (3)$$

$$W^- = ln\left(\frac{P(\bar{C}|K)}{P(\bar{C}|\bar{K})}\right) \quad (4)$$

where P() denotes probability, C is the presence of predictive pattern (it corresponds to area occupied by class of CPDs), $\bar{C}$ is the absence of predictive pattern, K is the presence of training points of interest corresponds to kimberlite occurrences), $\bar{K}$ is the absence of kimberlite occurrence.

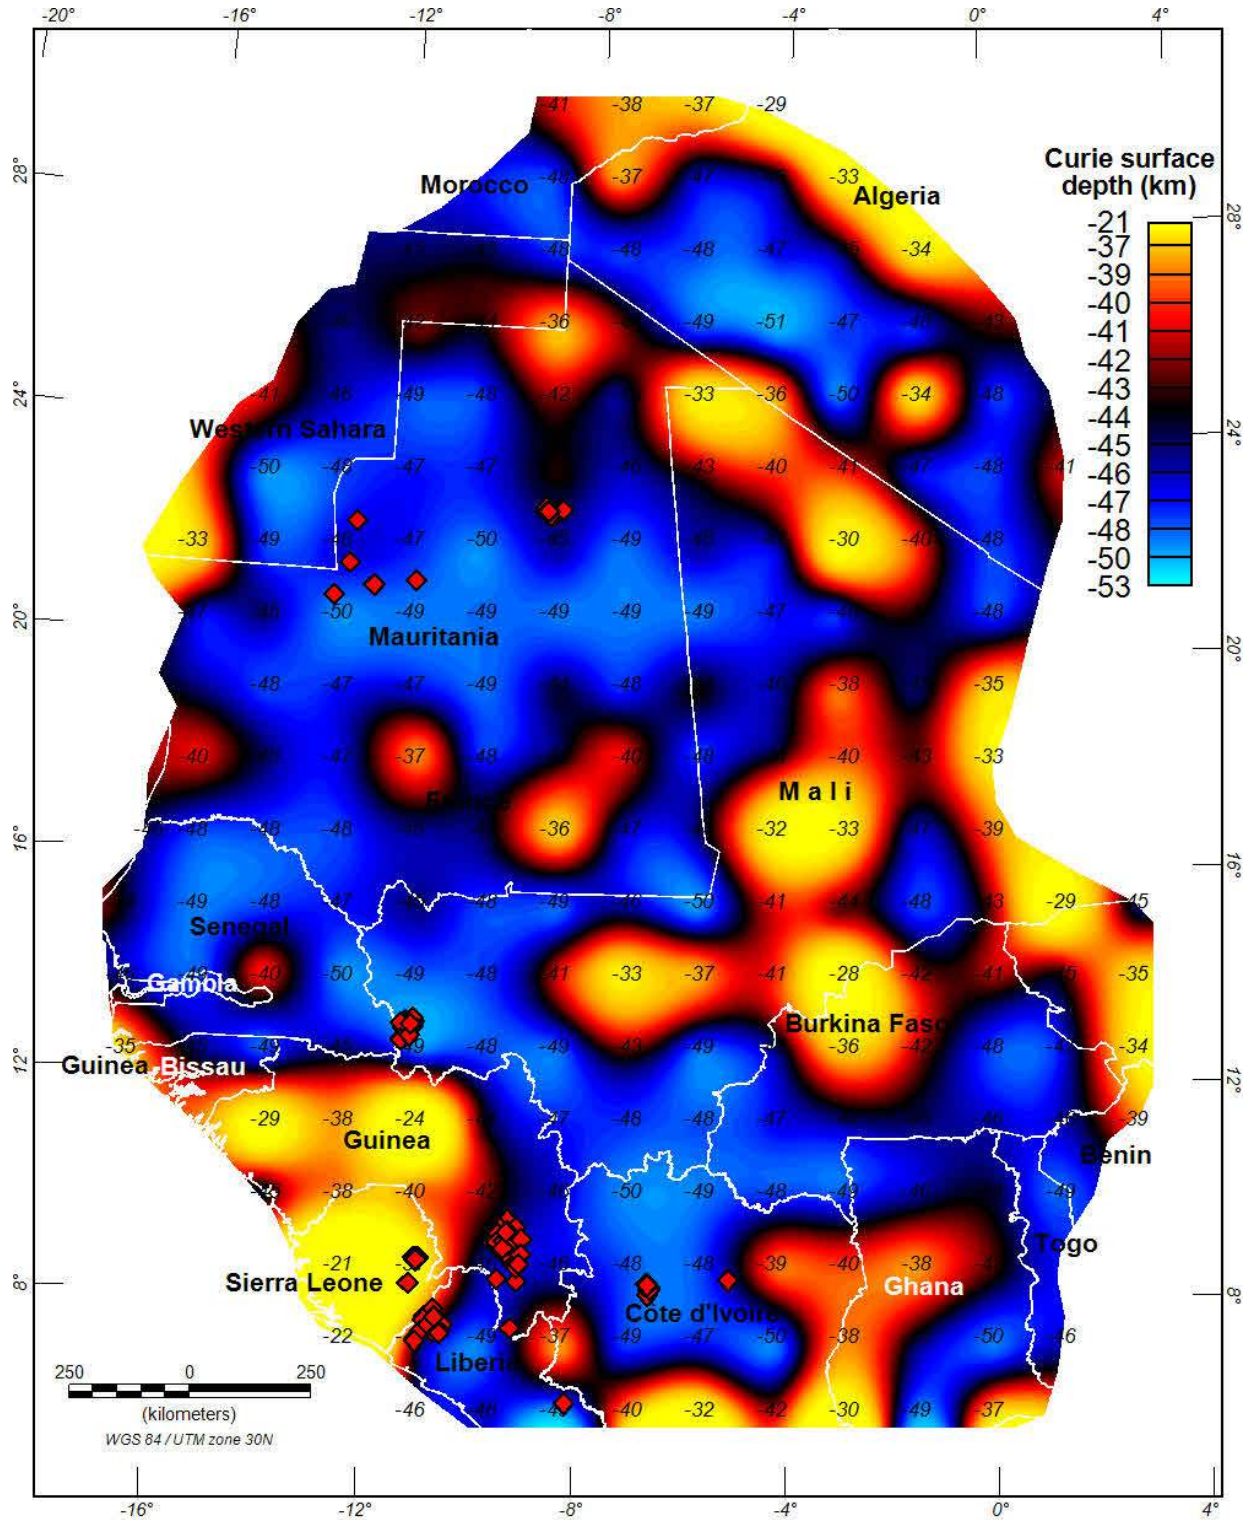

Figure 3. Curie-point isotherm map of the study area and kimberlite locations. CPDs of each subregion are reported on the map

The weights (W^+ *and* W^-) provide a measure of spatial association between the training points K and the binary theme C. The value of the weight W^+ is positive, whereas W^- is negative, indicates that there are more kimberlite occurrences on theme class C than would occur due to chance. Conversely W^+ would be negative and W^- positive for the case where fewer points occur than expected. If the kimberlite occurrences K are distributed randomly with respect to the binary theme C, then both of weights will have a value of zero, or very close to zero. The difference between the weights is known as the contrast, C. Thus:

$$C = W^+ - W^- \qquad (5)$$

The contrast is an overall measure of spatial association between the set of points K and

the theme C, combining the effects of the two weights. It is the best estimator in a large area and when a large number of points occurrences are considered (Bonham-Carter, 1994). Hence, for a positive correlation, C is positive; C is negative in the case of negative spatial correlation.

The studentized confidence value *s(C)*, defined as the contrast *C* divided by its standard deviation, corresponds approximately to the statistical level of significance defined by standard z-tests, and provides a useful measure of the significance of the contrast (Raines, 1999). The standard deviation of C is calculated as:

$$s(C) = \sqrt{s^2(W^+) + s^2(W^-)} \quad (6)$$

In the spatial analysis, as applied in this work, a simplified and intuitive approach similar to that suggested by Turner (1997), was adopted. The surface of the study area and the predictive pattern C are expressed in number of unit cells, and each training point is assumed to occupy a single unit cell. That way, the weights W^+ and W^- can be calculated by means of map crossing functions as follows:

$$W^+ = ln\left(\frac{\frac{Number\ of\ training\ points\ K\ (kimberlites)\ \boldsymbol{inside}\ the\ pattern\ C}{Total\ number\ of\ \ points\ K}}{\frac{Number\ of\ unit\ cells\ \boldsymbol{inside}\ pattern\ C\ not\ occupied\ by\ points\ K}{Total\ number\ of\ unit\ cells\ of\ the\ study\ area\ not\ occupied\ by\ points\ K}}\right) \quad (7)$$

$$W^- = ln\left(\frac{\frac{Number\ of\ training\ points\ K\ \boldsymbol{outside}\ the\ pattern\ C}{Total\ number\ of\ points\ K}}{\frac{Number\ of\ unit\ cells\ \boldsymbol{outside}\ pattern\ C\ not\ occupied\ by\ points\ K}{Total\ number\ of\ unit\ cells\ of\ the\ study\ area\ not\ occupied\ by\ points\ K}}\right) \quad (8)$$

A unit cell of 4 km x 4 km was used. The total number of unit cells area (16 km²) in the study area map is 289 181 cells. The training points used for the spatial association analysis are all diamond-bearing lithologies, namely: mafic lamprophyres, lamproites, and kimberlites from Côte d'Ivoire, Guinea, Mali, Sierra Leone, Liberia, and Mauritania publically available from World kimberlites CONSOREM database (Faure 2010).

4 SPATIAL ASSOCIATION ANALYSIS

The locations of 141 known diamondiferous primary sources (mainly kimberlites) have been used as training points to quantitatively analyze the spatial association with Curie point depths. Each training point/kimberlite is assumed to occupy a small unit area, defining the 'unit cell area'. Given that some kimberlite occurrences are very close to each other, we used a systematic reduction in the number of training points by geographic *weeding* - removing training points that are too close together. The minimum spacing is taken as the unit cell size specified when defining the study area, i.e. 4 km. After removing the undesirable items, we lead to 109 training points.

A multiclass Curie Point Depths (CPDs) map was produced from the reclassification of the original continuous grid into ten classes to create the Curie surface depth theme as shown in Figure 4. This multiclass predictor theme provides a representation of heat flow conditions in relation to kimberlite occurrences. For the weights calculations, we have initially calculated the weights for each class (table 1). Because some of the classes may have a very small number of kimberlite occurring in them and this is particularly critical for the weights calculated in this case, we experiment the computation of weights for cumulative Curie point depths, and to examine the variation of the weights and contrast at successive cumulative CPDs intervals (Table 2). The relative weights and contrasts values of the CPDs theme are shown in Table 1 and 2. As indicated by contrasts C, they clearly outline a strong spatial correlation with CPDs class interval (53 to 49 km) in which 19 kimberlite occurrences are present. A less important

spatial correlation seems to be present with the CPDs class (46 to 43 km), despite the occurrence of 49 kimberlite occurrences, resulting from the large area units proportion covered by this Curie depth class, with respect to the number of kimberlite occurrences. This spatial association between kimberlite occurrences and deepest Curie-points is due to the role of low heat flow as the primary controlling parameter in diamond genesis. This result is supported by some studies have shown a strong correlation between heat flow measured at the surface and the thickness of the magnetized crust. which reveals favourable lithospheric conditions

In general the surface heat flow reflects the tectonic stabilization of the crust, i.e. the stable old structures are characterized by low heat flow, and the young geologically active areas presumably have to display relatively high Moho heat flow. It can be concluded, from Figs. 12 and 13, that the heat flow decreases with an increase in Curie depth, as suggested by Negi et al. (1987).

-24 to -20	4531120	283195	109				

5 CONCLUSION

Although the formulation of a kimberlite prospectivity mapping is not the objective of this study, the spatial association between kimberlite occurrences and deepest Curie-points is of potential importance for diamond exploration, as it may enable us to predict the diamond potential of target areas within craton on the basis of the mapped Curie point isotherm.

After these quantifications of spatial analysis, it could be implied that zones of deepest Curie-points can be fertile for diamond-bearing lithologies emplacements. This condition is most commonly found in regions of thick and cold lithosphere, and are consistent with Clifford's Rule, an empirical diamond exploration strategy.

ABSTRACT Duzduzan area is located at 45 km of Tabriz in the NW of Iran. The main objective of the study is to recognize the distribution patterns of elements in the area in order to establish an optimized pattern in regional and semi-regional exploration programs and ultimately to detect the promising potentials in the area. In this regard 384 stream sediments samples were collected at non-regular pattern. The samples were preprocessed to (-200) meshes and analyzed for 19 elements by ICP method.

The data processing by different methods with the aim of estimating the distribution parameters were carried out. During data analysis, detecting censored and probable outliers data and data normal testing were carried out. Then to demonstrate the correlation between elements concentrations and to extract the paragenetic sequence of elements, hierarchical clustering analysis (CA) method was used. Subsequently to reduce the variant and determine relative contributions of each component in elemental distribution, the Principal Components Analysis was employed.

CA based results indicated that only elements such as Cu, Pb, Zn, Mo, and Au are major elements some extend paragenetically and geochemically are important in the ore bearing solution. Also, PCA results revealed that only 7 components are important and have maximum variations in the area. Interpreting the components showed that PC_1, PC_2, PC_3 and PC_4 indicated the major elements and syngeneic effect variations. Whereas components7, and 5 indicate epygenetic effect of mineralization and show anomalous localization of oxides and sulphides in the region. The overall results also depict that probably the area have subjected to multi-phase mineralization.

Keywords: Geochemical pattern,anomalous region,PCA and CA method and Duzduzan area

1 INTRODUCTION

Understanding the pattern of distribution of elements in the various zone in order to intensify for the anomalies and detection the false anomalies of special importance. So in every exploration, the application of the ideal method is important for mineralization zone identifying accurately detection of the mineralization zone (Sandjivy, L., 1984. Sousa, A.J., 1989. JimeÂnez-Espinosa, R., et al, 1993. Bellehumeur, C., et al, 1994).

The application of the ideal method for processing geochemical data and providing more accurate distribution maps, requires appropriate methods for optimization the geochemical anomalies and recording the real anomalies , has finally by introduced an optimize method is possible to the separation zone and more accurate detection of them.

The present study is part of a systematic geochemical exploration, which is performed Garachaman area in 1:100000 scale. In order to obtain mineral index, the results and maps

from geochemical data, were compared with the original data (Javid, F., 2014).

Necessity if existence of ways to optimize the geochemical projects and record the original anomalies is important (Govett, G.J.S., et al., 1975). Of the methods that are frequently used in the field of science, discovery studies and detection of potential minerals, are included multivariate methods (Howarth, R.J., et al., 1983). As can be used for detection of geochemical anomalies (Loska, K. et al., 2003), remote sensing (Fresman, A.E., 1939., Loughlin, W.P.G., 1991), environmental (Loska, K., et al., 2003), geophysical researches to oil and gas (Pasadakis, N., et al., 2004., Prinzhofer, A., 2000., Sabeti, H., et al., 2007). Because of the importance of the Multivariaty method for identification the anomalies and area requirement for more accurate detection and reconnaissance geochemical halos, using a two Cluster Analysis way and Principal Component Analysis way, the detection and identification of anomalies was done.

A multivariate method, for identifying of parageners and simultaneous of materials using clustering (CA). Cluster Analysis aims to achieve a more appropriate criterion for the classification of the variables or samples based on the more similarity of in-group and every greater difference between-groups. This feature helps to data and samples to classification as clusters which had maximum possible similarity betweem themselves and maximum difference between their own. Hierarchical clustering, which its very similar continuous and repeated observations that are linked together, is the most common method. So the data simply inserted in groups, on the basis of similarity that they have with each other. Hierarchical Cluster Analysis can be very helpful when the data are available and when they are following of a completely clear model. For this, in recent years, the CA method is applied to detect the region anomalies in, isolation anomalies from the geochemical field (Ji Hongjin, et al., 1995., Collyer, P.L., et al., 1973., Julian., K., 1976). So according to application ability and resolution of simultaneous and parageners separation, the elements clustering and identification of parageners for different types of raw and normalized data in the area was done.

To identify the direction and type of minerals, there is another method called Principle Component Analysis. This method is based on that in Scree Plot the variables that are correlated with each other, considered a line with the highest variability and also plot a vertical line to it, and considering the dispersion in the new coordinate system. should always be considered a direction which has explained the most diffraction. Thus, this procedure was repeated for each series, so the best direction which express the greatest variability was considered as the main direction and mineralization, and other factors to anomalous behavior. Principal Component Analysis method is briefly called (PCA). The main problem in this way, was the expression principle of correlations between the concentration of elements values in order to display their simultaneously change pattern in the region. In recent decades, towards the geochemical regional researchs in the area of stream sediment, to identify potential areas, and the prone areas to minerals (Govett, G.J.S., et al., 1975. Jun deng., et al., 2010. Xiang Sun., et al., 2010), separation anomaly distribution (Jun deng., et al., 2010. Xiang Sun., et al., 2010), identify the source of pollution of soil (Facchinelli, A., et al, 2001. Boruvka, L., et al., 2005), and identify the results based on detection of regional anomalies and identify some results based on hydrothermal activities and leads to regional mineralogy in the area (Al Hakimi, A., et al., 2009), identify the geochemical patterns (Sulistijo. B., 2012) and identify the relationship between the type of deposit and integrate them with the alterations (Grunsky E.C., et al., 2003. Groves, D.I., et al., 1998), all were done by PCA.

2 GEOLOGY

Duzduzan area is located in East Azerbaijan province of North West of Iran and on the Metallogenic Belt of Alps – Himalaya. That

due to the having the reserves of Copper and possibly "in some parts points of parageneric polimetal, it is important. The study area is located between 47° 46° 30' east longitude and 38° 37° 30' north latitude (Figure 1).

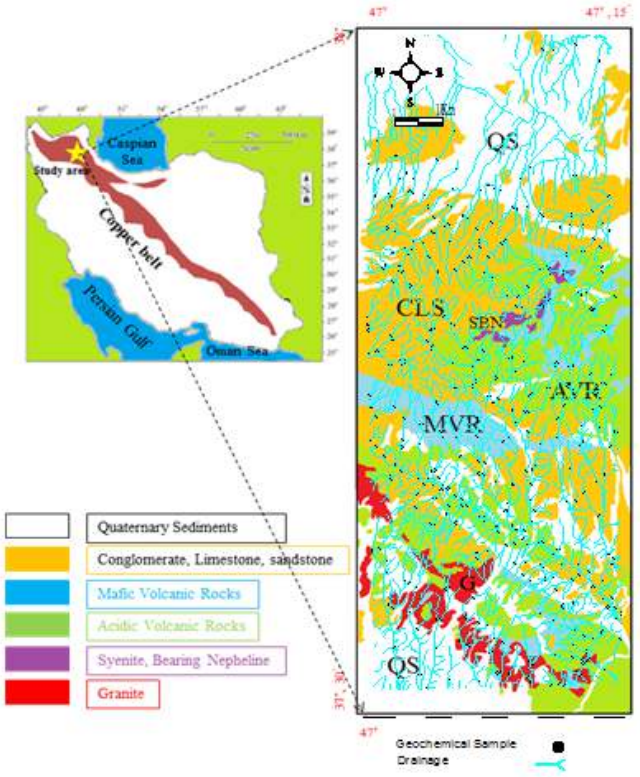

Figure 1. Geological and stream sediment sample location map of the Duzduzan area, E.Azerbaijan, Iran.

The study area is divided into two zones (Bozgush zone and zone of Shaharchayi-Gharachaman). Bozgush Eocene zone, is located in the northern region, And is mostly included of volcanic and sedimentary series.

Oligocene related rocks in this zone, are widespread both in intrusive - semi-intrusive, volcanic and sedimentary rocks. Shaharchayi-Gharachaman unit, is located in the southern region. It's Eocene and Oligocene units are mostly of volcanic rocks, intrusive masses and in small quantities of Sedimentary series. Oligo-Miocene unit of this zone, mostly composed of Sedimentary Rocks. Sediments of the present age cover a large area of that area. Area in the point view of geological structures classification, according to the Eocene Volcano Sediment sediments, is related to Urumie-Dokhtar zone. Area is from the Volcanic Rocks exhausting and existence of intrusive masses is important, which have a key role in the mineralization (Javid, F., 2014).

Metallogenic zone of the area suggest that older units of the Eocene, has not been observed the region. Geochemical analysis of the Oligocene Volcanic Rocks of this area, shows their Alkaline Magmatic origin. In the Paleogene Tectonic phase, a large Magmatic activity (Pyrenees phase) led to intrusive Igneous Rock reach the earth's surface with a wide volume, which many of these intrusive masses of Iran have been created in this phase and most Metallic minerals, especially Copper, Lead and Zinc are related of this phase. This subject have been detected in the area of Duzduzan mostly in the form of large intrusive masses of Granite and Syenite. Duzduzan area is of high mineral potential because the Magmatic origin exhausting Volcanic Rocks And the impact of intrusive Igneous masses and reactivity of Hydrothermal solutions. the Pyrite and Chalcopyrite traces in Volcanic Rocks, are sulfidized under the influence of hydrothermal solutions from the locally granite and syenite masses. Influence of acidity hydrothermal solution lead to alteration of related rocks and mineral, So then the hydrolysis of iron and magnesium silicates in the early stages and then later in the Feldspath alteration have been occurred. which lead to the kaolinite and then sericitic products in the study zone.

3 MATERIALS AND METHODS:

Regional geochemical exploration with the aims to prospecting the Duzduzan base-metals and gold were done with providing 384 stream sediments (Figure 1), which has the maximum compatibility with the center of gravity method and send to the Australia AMDEL company for analysis the 19 elements by the ICP-MS and gold element by the Fire Assay method.

For data analysis, the pre-processing stage of the data analysis was conducted Censored data and Outlier data. So outlier data with the Q method were identified and replaced.

$$Q = (x_i - x_{i+1}) / (x_{Max} - x_{Min}) \quad (1)$$

$$\overline{Q} - 2\delta_Q < Q < \overline{Q} + 2\delta_Q \quad (2)$$

The results of this study were presented in the below table (Table1).

Table 1. Determination of outlier data by Q method in Duzduzan area

	Sample.No	Natural (ppm)	Replacemant (ppm)
Mg	63	2630	2880
K	105	2950	4920
Ag	231	0.04	0.05

Table 2. Descriptive statistics of original and normal stream sediment geochemical data.

Pb	Mo	Cu	As	S	Au	Normal / Raw	Au	S	As	Cu	Mo	Pb
384	384	384	384	384	384	N	384	384	384	384	384	384
2.99	.76	3.87	3.1	5.95	.84	Mean	3.31	572.3	27.33	51.1	2.4	23.3
2.96	.74	3.85	3.1	5.85	.69	Median	2	350	22.55	47.4	2.1	19.4
2.7	.53	3.69	3	5.34	.69	Mode	2	210	20.6	40.2	1.7	16
.583	.44	.343	.57	.825	.78	Std. D	4.01	728.1	19.16	19.51	1.1	15.8
-1.2	.03	.413	.09	.509	.3	Skewness	4.52	4.317	3.092	1.573	1.3	3.35
11.3	.37	.432	1	.563	.81	Kurtosis	24.4	22.6	13.8	3.01	1.8	15.4

The statistical parameters were calculated(Table 2). Because of skewness and existence of abnormalities in elements such as Au, Cd, Pb, S, Cu, Mo, As, Hg, Bi attempts to normalization, which Figure.2 is illustrated an example of a histogram of the geochemical data for Au, Pb, Cu, S, Mo, As.

Multivariate statistical methods, provide simultaneously statistical analysis of many variables. Sometimes, in the explorational problems we are faced with N dimensional space, which makes it difficult to evaluate the relationship between them.

In such cases it is necessary, using multivariate statistical methods, reduce the number of dimensions in the study space, where, the results of this new dimension, with the number far less than previous state can explain much of the variability of the data. Thus, it was attemped to apply comparative study based on PCA and along with CA. In order to discriminate anomaly from background in the area.

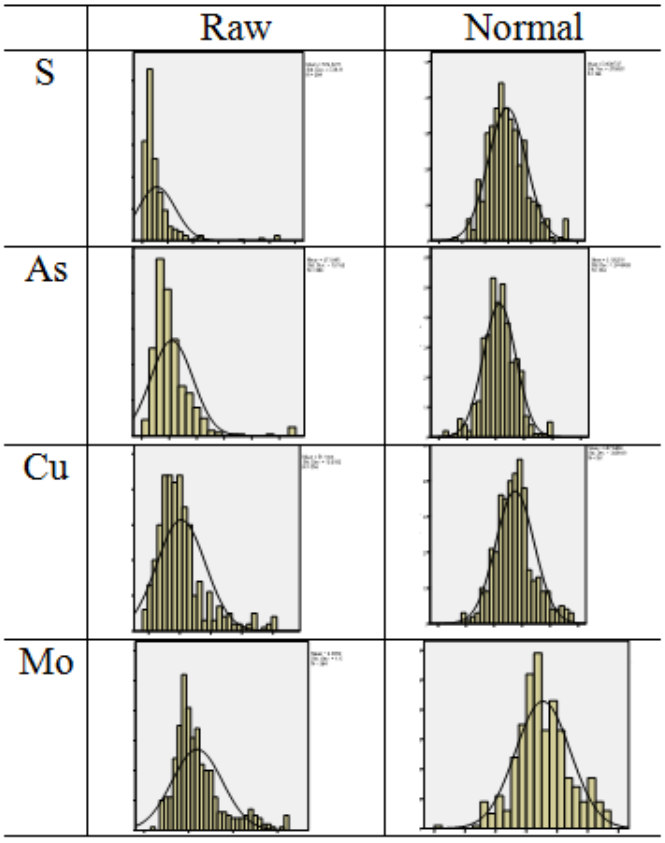

Figure 2. Histograms of As, Cu, Mo, S concentrations.

3.1 CA

Clustering is the classification of objects into different groups, or more precisely, the partitioning of a data set into subjects or clusters, so that the data in each subject share some common trait often proximity according to some defined distance measures. Data clustering is a common technique for statistical data analysis and used in many fields (MacQueen, 1967). The computational tasks of classifying the data set into different clusters include the k-clustering method, tree-clustering and two-way joining. With agglomerative algorithms on the basis of weighted pair-group average rule and Manhattan distances.

3.2 PCA

Principal Component Analysis method has has been widely used in geochemical applications to identify mineral sources and to apportion natural anthropic contribution. Application of this method to sediments (Tuncer et al., 1993; Fernandez et al., 1996), soils (Ratha and Sahu, 1993; Garcia et al., 1996), and waters (Cave and Reeder, 1995) have been carried out.

4 RESULTS

4.1 CA

Clustering states the treatment of relationship between the elements under the correlation maximum expression. The goal of this way is achievement to a criterion for the more appropriate classification of the variables or classification of the samples based on how more similarity within groups, the differences between the parties and offer paragenesis of elements (Hassani Pak, A.A. et al., 2002). With regard to functionality, resolution power in the simultaneous and paragenesis separation, attempt to the clustering of the area. the drawn dendrogram to the area elements, was significant and interpretable (Figure 3).

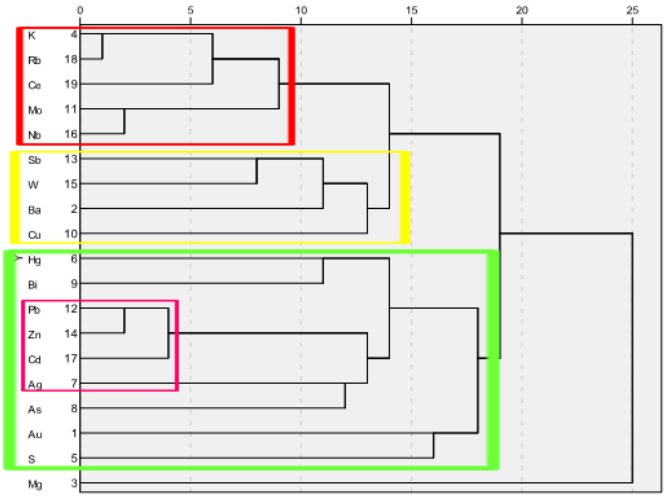

Figure 3. The horizontal cluster dendrogram of elements concentrations.

1) Mo-Rb-K-Nb-Ce
2) Bi-Cd-Zn-Pb
3) S-Hg-Ag-As-Bi-Zn-Au-Pb-Cd
4) Sb-W-Ba-Cu

Bi-Cd association with Zn-Pb elements is suggests of the detector nature of these elements for Pb-Zn sulphide deposits. Since the evidence shows that the deposits of Zn-Pb elements are volcanic, So these elements were can be used as detectors for these deposits. Due to the Simultaneous No.3, the association of these elements with gold

represents that these elements are detectors for Au, And this could be said that Au anomalies derived from Subvolcanic-hydrothermal processes in region.

4.2 PCA

This method is a technique for finding linear combinations of the original variables. The PCA method is indeed reduced the dimension of problem, which can, in fact, determine the separation of anomaly communities of context and epigenetic and syngenetic effects more precisely. With this method some directions are identified with the maximum of variability, then with define the new variables which are the linear combinations of the original variables, the number of dimensions (variables) declined and the role of each variable in the linear combination has been determined.

The main step in describing the PCA analysis results, is the describing the total variance. The proper interpretation of this table, has an important role in PCA. As one of the main criteria for the selection of components number, is the variability of the data. The new data must have a minimum number of dimension and could explain the maximum variability of all of data. The number of new dimensions, determined about 7 component (Table 3).

Table 3. Total variance explained (Seven factors selected).

Component	Initial Eigenvalues			Rotation Sums of Squared Loadings		
	Total	% of Variance	Cumulative %	Total	% of Variance	Cumulative %
1	4.44	23.37	23.37	2.93	**15.406**	**15.406**

19	.12	.65	100			

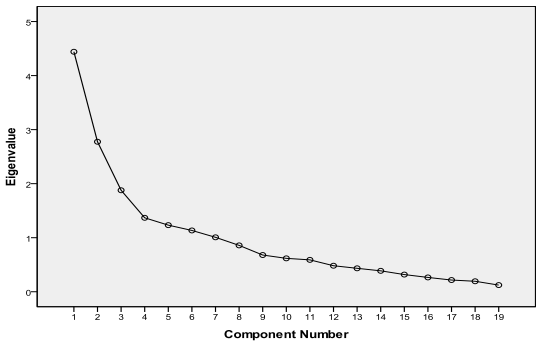

Figure 4. Scree plot of Duzduzan area

In this table the values of the statistical parameters include of spatial values, variance and the comulative variance of each component with the participation values of each component was calculated.

Based on table.3 about 7 component with 73% of the variability factor could be explain the significant changes in the region ,these results are shown graphically (Figure 4).

According to Table 3, the first component in the 19 component, explained the 15.406% of the total variability, after it, the second component has a greater role. Given the importance of the separation of paragenesis, using PCA method, obtained results are presented (Table 4). Table 4 shows existence simultaneous in the region based on the above technique.

Whereas, an application of principal component analysis in the exploration, is drawing maps of the main components, In the studied region, these maps are communicating between the focus of its deposit with its controller component (lithology, structural, climate, geomorphology). According to the drawn plans, you can separate the elements of each main component (Table 5).
Thus The elements in each component, which have a high score gain, could be considered as an indicator element.

Table 5. Pathfinder elements.

Component	Indicator Element
PC1	K-Nb-Rb-Ce
PC2	Mg-Mo-Nb
PC3	S-Cu-Sb-W
PC4	S-Ag-As
PC5	Pb-Zn
PC6	Hg-Cd
PC7	Au-Bi

Corresponding map to the first component, shows the syngenetic mineralization (Figure 5). The second component, shows the REE (Rare Earth Elements) anomaly map (Figure 5). Fifth, sixth and seventh component shows the oxides and sulfides implied in the area and states the effects of the fluid, these three factors may be implicated on several phases of mineralization in the region which is acted in the various sequences and lead to assembly of these three components in the region (Figure 5). Second, third and fourth components derived from the properties of the rock building of the study area and has no significant relationship to the mineralizing fluids.

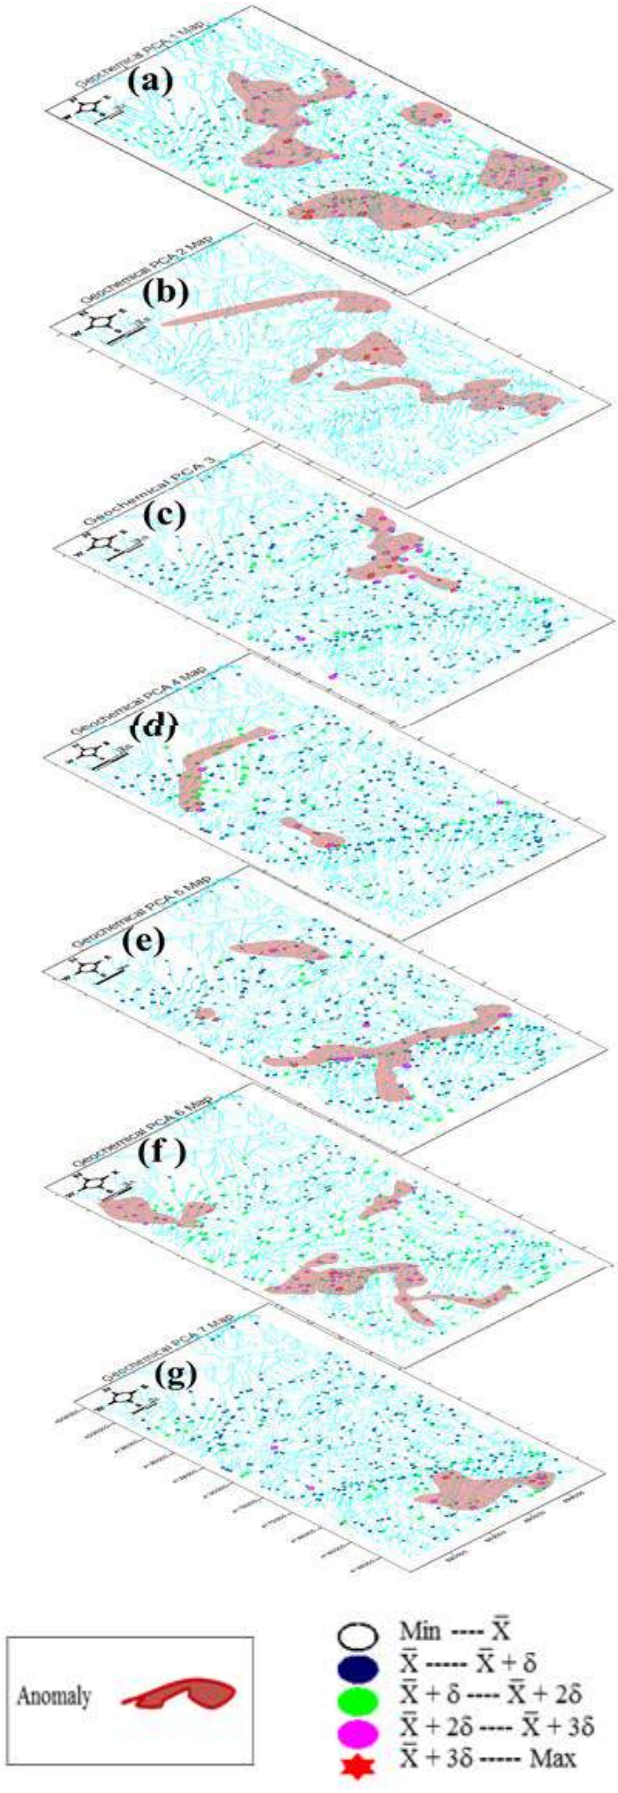

Figure 5. The results of the distributions of the PCA maps: (a): PC1 map, (b): PC2 map, (c): PC3 map, (d): PC4 map, (e): PC5 map, (f): PC6 map, (g): PC7 map.

The results show the pathfinder and potential elements of Ba, Cu, Sb, As, Au, Zn, Pb in the area. Sulphidation outcrops and the whole area was fully observed of S element distribution, correlation Mo, Cu up to more than 50 percent has been associated with causing mineral solutions, but the nature of these elements and porphyrite or other formats of these deposits including closer alteration study in this area is needed.

Association of Pb, Cu, Mo, Zn was more evident based on various studies. Study and review was conducted in the area of maximum variability of the PCA, and The results show the seven most important related component, in this study the 1, 2, 3, 4 components denote to the stone formation components (Syngenetic), and 5, 6, 7 component indicate concentration the significant anomalies associated with mineralization (Epigenetic). In principle, the more important aim of this study was to identify behavior patterns of Au, Cu, Zn, Pb elements in the Duzduzan region, and detect their pathfinders in the region. Small distance between Cu, Au was exist in the region. This area is more likely to involve several mineralization phases, because The deposition of Au, Cu probably not in the same phase.

Finally, with considering our need to very detailed record of the anomalies and separation of communities and achieving to the optimal geochemical network, multivariable methods are used, and the results indicate the severity of the anomaly intensity and revealed some anomalies which are masked in the region.

The comparison of these maps shows with the main component, shows that these two methods have an overlap with each other. The component maps can communicate between the deposit concentration with its controler factors, e.g. the lithology of building, climate, geomorphology, etc.

5 CONCLUSION

According to recent studies, the results of this study can be summarized as follows: to

be used as a key, in other parts of this region and continue of this study the detectors and concluded indicators.

In this paper, the PCA and CA model are used to identify geochemical anomalies associated with Cu and Au mineralization. The following conclusions are obtained:

(1) The multivariate statistical method PCA and CA modeling is

a useful tool to identify geochemical anomalies. The former is used to integrate multi-element concentration values, and the later is used to decompose mixed geochemical paragenesis in a complex geological setting

(2) The anomalies of Ba, Cu, Sb, As, Au, Zn, Pb occurring in the area should be further investigated in the next phase of mineral exploration.

ACKNOWLEDGEMENTS

The authors to place their thanks to Mr. Hosein Hematiyan and Geological Survey of Iran for their attentions in this respect. We would like to acknowledge our sincere thanks to reviewers for their constructive comments.

Providing Zinc and Lead Anomaly Maps Using U Statistic, Khooni District (Esfahan Province)

N. Mahvash Mohammadi
PhD student, Department of Mining & Metallurgical Engineering, Amirkabir University of Technology,Tehran, Iran.

A.Hezarkhani
Professor, Department of Mining & Metallurgical Engineering, Amirkabir University of Technology, Tehran, Iran.

ABSTRACT Khooni area is located in 60 kilometers of North East of Anarak and 270 kilometers of Esfahan, and belongs to Central Iran geological zone. According to existence of Zinc and Lead mineralization evidences in this area, identification of favorable area and preparation of Pb and Zn mineralization potential maps is necessary, in order to separate the anomaly from geochemical background in the data which are obtained from surface sampling, initially, corrections on the data includes the estimation and replacement of censored data and adjustment of row sets were done. Then, some statistical parameters were calculated and histograms were plotted and the data were normalized. Therefore, structural method for separation of anomaly from background on the results was used. U statistic method as a highly effective method for separation the anomaly from background of the data was used. Finally, with separated anomaly values from background, the anomaly map of the promising area for elements such as lead and zinc was plotted. By studying geochemical maps, we saw that there is Lead and Zinc anomaly area in southwest and northwest of khooni mountain.

Keywords: Zinc, lead, anomaly map, U statistic

1 INTRODUCTION

Data frequency in the exploratory samples are often Lognormal due to high skewness (Graybill, et al 1965). large amounts in the samples are constitute of anomalies distribution function. The values are inseparable from other data (background) to appearance promising areas for economic mineralization. Different statistical methods are presented to distinguish anomaly areas from background. These methods are changing from simple kinds (based on distribution statistical parameters) to complicated ones (based on data spatial distribution). Second kind includes methods which consider sampling point coordination and their spatial relation in estimation of anomaly areas. The anomaly separation methods of background can be divided into two groups which includes structural and non-structural methods (Hassani pak et al 2005).

One purpose of using statistical methods in exploration geochemistry is to assist exploration geologists in separating anomalies from background. This always involves two types of negatively associated errors of misclassification: type I errors occur when samples with background levels are rejected as background; and type II errors occur when samples with anomalous values are accepted as background. U spatial statistics method is proposed to minimize errors of total misclassification using a moving average technique with variable window radius. The idea of this method was applied for the first time in 1331 by Cheng et al. In fact, this method as a strong method is proposed in the separation anomaly of background (Cheng 1999) (Sinclair 1991). The only factor controller in this method is

the number of samples for type I and II errors (errors of separating anomalies from background). Increasing the number of samples obtained better results.

1.1 Geological Setting

Khooni area is located at 60 kilometers of North East of Anarak and 270 kilometers of Esfahan, and belongs to Central Iran geological zone. According to some instances expressing Lead and Zinc minerals forming in this area, make reconnaissance of favorable area and forming potential maps of these minerals preparation as an essential fact.

Stratigraphy of the study area is from Pre-Cambrian to Quaternary. Outcrops in western area, mainly consisting of units of Cambrian metamorphic and in the eastern part are volcanic and pyroclastic of Eocene units with dominant composition of andesite and trakey andesite which have been cut by monzonite dikes. There are outcrops of Cretaceous limestones at the northwest end of the area that unconformity have been laid on the older units. Low altitude and lowland areas is covered by old alluvial terraces, sediments of plains and young and river formed alluvial. In general, the Lithology of the study area is formed from lithological units, including units of metamorphic schists to Quaternary young sediments (Fig. 1), (Heydarian dehkordi et al 2014)

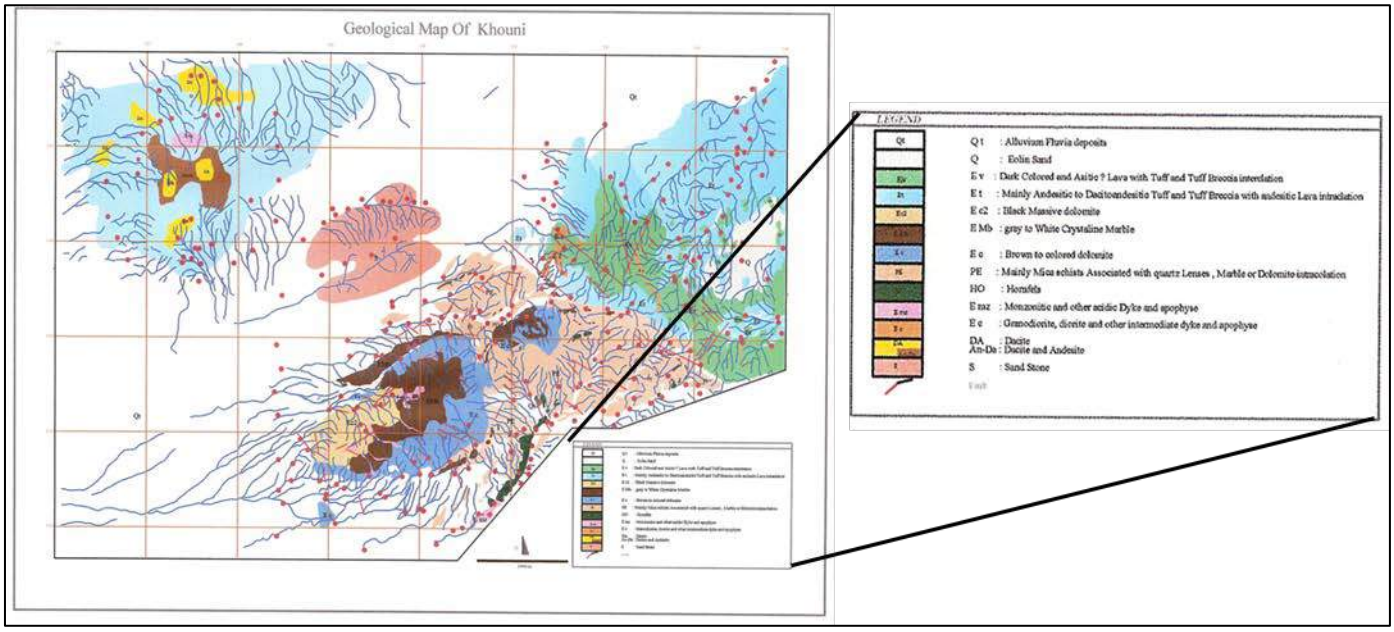

Figure 1. Geological map of khooni district(Pourjabar 2005)

2 SEPARATION ANOMALY FROM THE BACKGROUND

Investigating data are from geochemical analysis of stream sediments for 22 elements in Khooni area which are processed for separating anomaly from background., initially, corrections on the data includes the estimation and replacement of censored data and adjustment of row sets were done. Then, some statistical parameters were calculated and histograms were plotted and the data were normalized for Pb and Zn elements.

Initial investigation of the raw data showed that all elements followed an un-normal distribution with positive skewness (Fig. 2), and therefore the logarithmic conversion was used for converting all data to a normal distribution. Figure 3 showing histograms of normal distribution of lead and zinc elements.

2.1 Spatial U Statistics

Suppose that two populations (A and B) have normal distributions with means of μ_A

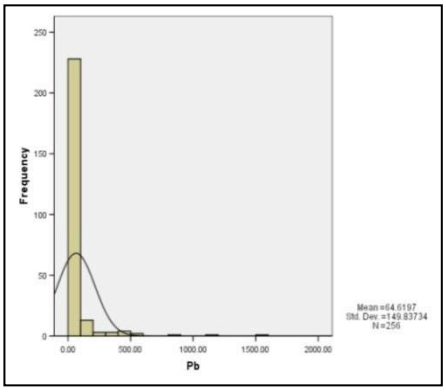
and μ_B, and variances σ_A^2 and σ_B^2 respectively. Independent random samples $(x_1,\ldots, x_n)$ are collected, and the aim is to distinguish between the populations A and B. A new random variable

$$U = \frac{1}{n}\sum x_i \quad (1)$$

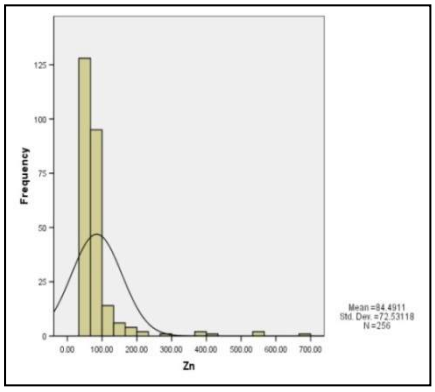
can be constructed (U-statistic) with the following properties: $\sigma^2(U)\frac{1}{n}\sigma_A^2, E(U) = \mu_A$ if all samples are from population A, and $\sigma^2(U)\frac{1}{n}\sigma_B^2, E(U) = \mu_B$ if all samples are from B. Thus the means of U for samples from A or B are the same as means of X for A or B. but the variances of U for A or B are different from the variances of X for A or B by the factor (l/n). This factor depends only on sample size n. More generally, instead of an arithmetic average, a weighted average U is used with:

$$U = \sum_{i=1}^{n} W_i x_i \quad (2)$$

Where $\sum W_i = 1,\ 0 \le W_i \le 1$ Then $\sigma^2(U) = \sum W_i^2\sigma_A^2, E(U) = \mu_A$ if all samples are collected from population A, and $\sigma^2(U) = \sum W_i^2\sigma_B^2, E(U) = \mu_B$ if all samples come from B. In general, $\frac{1}{n} \le \sum W_i^2 \le 1$, $\sum W_i^2 = 1$ if and only if $i = k$ with W_k=1 (and W_k=0, when $i \ne k$) which implies that U= x_k; $\sum w^2 = 1/n$ if and only if W_i = 1/n, i=1,...,n, for the arithmetic average. Different types of weighting in Eq. (2) may result in a different variance $\sigma^2(U)$ depending on the factor $\sum W_i^2$. but the smallest variance is achieved for the arithmetic average (Cheng 1999).

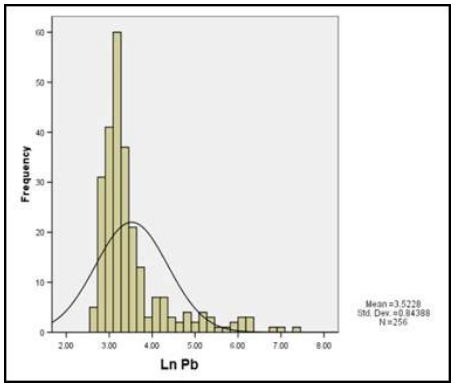


Histogram of Pb- Raw Data

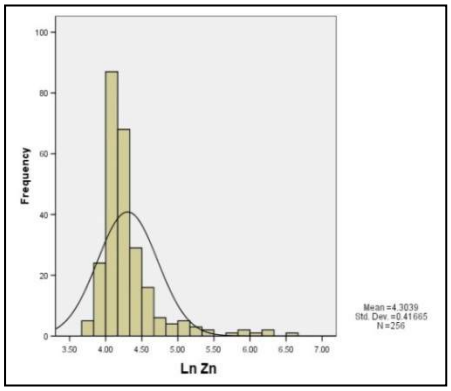


Histogram of Zn- Raw Data

Figure 2. Histograms of raw data



Histogram of Pb- Normal Data



Histogram of Zn Normal Data

Figure 3. Histograms of normal data..

In the preceding discussion, all values were assumed to originate from a single population (A or B). In general, we do not know from which population the values come. However, by inspecting the geometrical characteristics of the

geochemical anomalies (the element concentrations and spatial arrangements of samples), we may notice that anomalous samples often occur in groups which correspond to geographically distinct areas. Values of samples and the geometry of anomalous areas have been considered in anomaly separation by previous authors for example by Sinclair (1991). An experimental study of average values of samples was presented by Govett et al (1975). These authors reported that for systematic sampling (grid sampling), averaging values of samples is useful for separating populations. The idea can be generalized as follows (Cheng 1999).

Suppose that a given area consists of two subareas shown schematically as A and B (Fig. 4) representing anomaly and background respectively. The anomalous area A could be circular, elliptical or belt-like in shape.

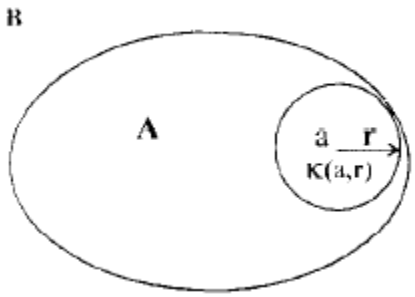


Figure 4. Circular moving window with variable radius. A is anomalous area. and B is background area. k(a,r) is circular vicinity around sample location a with radius r. Samples in k(a,r) are weighted and averaged to generate U values (Cheng 1999).

A new statistic, U is constructed that considers a spatial zone of influence. Let α_i, indicate the location of the ith sample in the study area and X_i, the element content or value of this sample; choose any sample, say α_i, from the set of samples and create a circular neighbourhood around it denoted as $k(\alpha_i,r)$ with the radius r ($0 \le r \le r_{max}$). The value of r can be assigned in such a way that $k(\alpha_i,r) \subset A$ if $\alpha_i \in A$ $k(\alpha_i,r) \subset B$ if $\alpha_i \in B$. A function for $k(\alpha_i,r)$ can be defined as follows: (Cheng 1999).

$$\mu_{k(\alpha_i,r)}(\alpha_j) = \frac{r-d(\alpha_i,\alpha_j)}{r} \quad (3)$$

Where $d(\alpha_i, \alpha_j) \le r$ represents distance from sample location α_j to α_i.This function has the properties: $0 \le \mu_{k(\alpha_i,r)}(\alpha_j) \le 1$, $\mu_{k(\alpha_i,r)}(\alpha_j) = 1$ if $\alpha_i = \alpha_j$, and $\mu_{k(\alpha_i,r)}(\alpha_j) = 0$ if $\alpha_j \neq k(\alpha_i,r)$,where $\notin$ indicates "does not belong to". A new value $U_i(r)$ for sample α_i can then be defined as a linear combination of $x_{i:}$ (Cheng 1999).

$$\mu_{k(\alpha_i,r)}(\alpha_j) = \frac{r-d(\alpha_i,\alpha_j)}{r} \quad (4)$$

With

$$\bar{X}_i(r) = \sum_{j=1}^{n} w_j(r) X_j \quad (5)$$

$$S_i(r) = \sqrt{\sum_{j=1}^{n} w_j^2(r)} \quad (6)$$

$$w_j(r) = \frac{\mu_{k(\alpha_i,r)}(\alpha_j)}{\sum_{j=1}^{n} \mu_{k(\alpha_i,r)}(\alpha_j)} \quad (7)$$

where μ and σ are the mean and standard deviation of X_i in the whole area. A new statistic $U_i^* = U_i(r_0)$ can then be defined where r_0 is the value yielding: (Cheng 1999).

$$|U_i(r_0)| = max_{\ 0 \le r \le r_{max}} |U_i(r)| \quad (8)$$

The value of U_i^* for sample α_i, has the following normal distribution: If $\alpha_i \in A$: (Cheng 1999).

$$U_i \sim N\left(\frac{\mu_A - \mu}{S_i(r_0)}, \frac{\sigma_A}{\sigma}\right) \quad (9)$$

and, if $\alpha_i \in B$:

$$U_i \sim N\left(\frac{\mu_B - \mu}{S_i(r_0)}, \frac{\sigma_B}{\sigma}\right) \quad (10)$$

Where $\mu_B \le \mu \le \mu_A$, so that $U_i^*(r_0)$ has a mean equal to $(\mu_A - \mu)/(S_i(r_0)) > (\mu_A - \mu)/(\sigma) > 0$ if α_i belongs to A and $U_i^*(r_0)$ has a mean equal to $(\mu_B - \mu)/(S_i(r_0)) < (\mu_B - \mu)/(\sigma) < 0$ if α_i belongs to *B*. If α_i is located on the boundary between A and B then r_0 should be close to zero and therefore $U_i^*(r_0)$ is reduced to $(X_i - \mu)/(\sigma)$ which is

equal to the original standardized value of X_i. The value $U^*(r_0)$ can be easily classified. The value of $U_i^*(r_0)$depends on the total number of samples within $k(\alpha_i, r)$. It is also associated with the location of α_i. Thus if α_i is located near the boundary between A and B, there can only be relatively few samples in $k(\alpha_i, r)$ and the value of $U_i^*(r_0)$ will be close to the original standardized value of X_i. of course, the value of $U_i^*(r_0)$ also depends on the density of samples collected in the area. The sampling density may influence the ability of the method to distinguish between geochemical populations (Cheng 1999).

3 DISCUSSION

This section, discussed the separation of Pb and Zn anomalies with regard to location of the samples, Radius is 18 meter. After determining the value of U for each sampling point, were Plotted the graph of the frequency distribution of U values for Zn and Pb elements with circular neighborhood with shape circular neighborhood of study area that was shown in Figure 5.

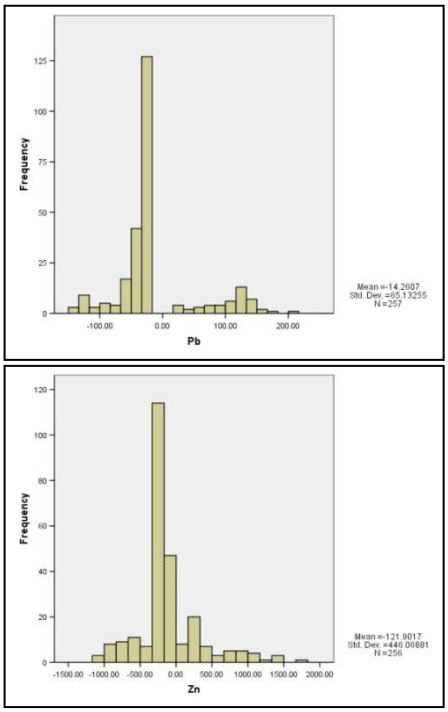

Figure 5. The frequency distribution graph of U values for Pb and Zn elements with circular shape neighborhood.

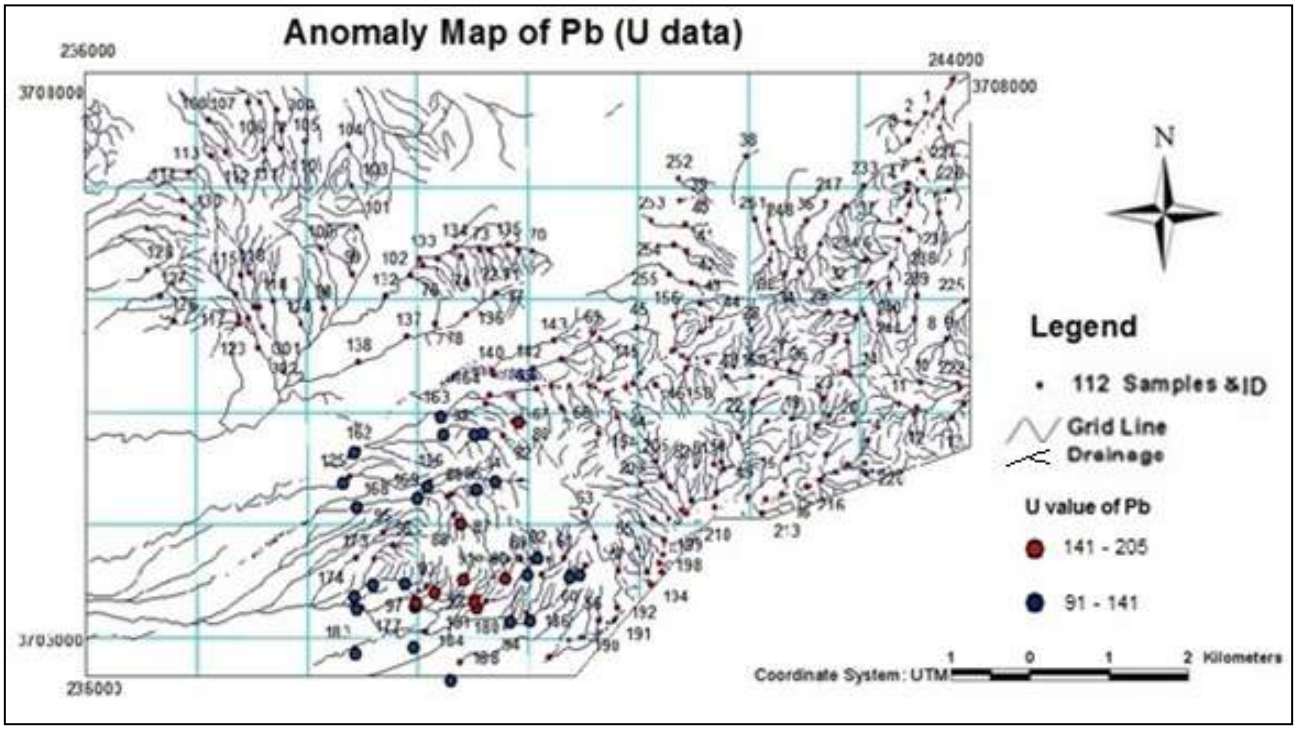

Figure 6. Lead anomaly map using $\overline{U} + 2S$ and $\overline{U} + 3S$ criteria to show probable and absolute anomalies samples

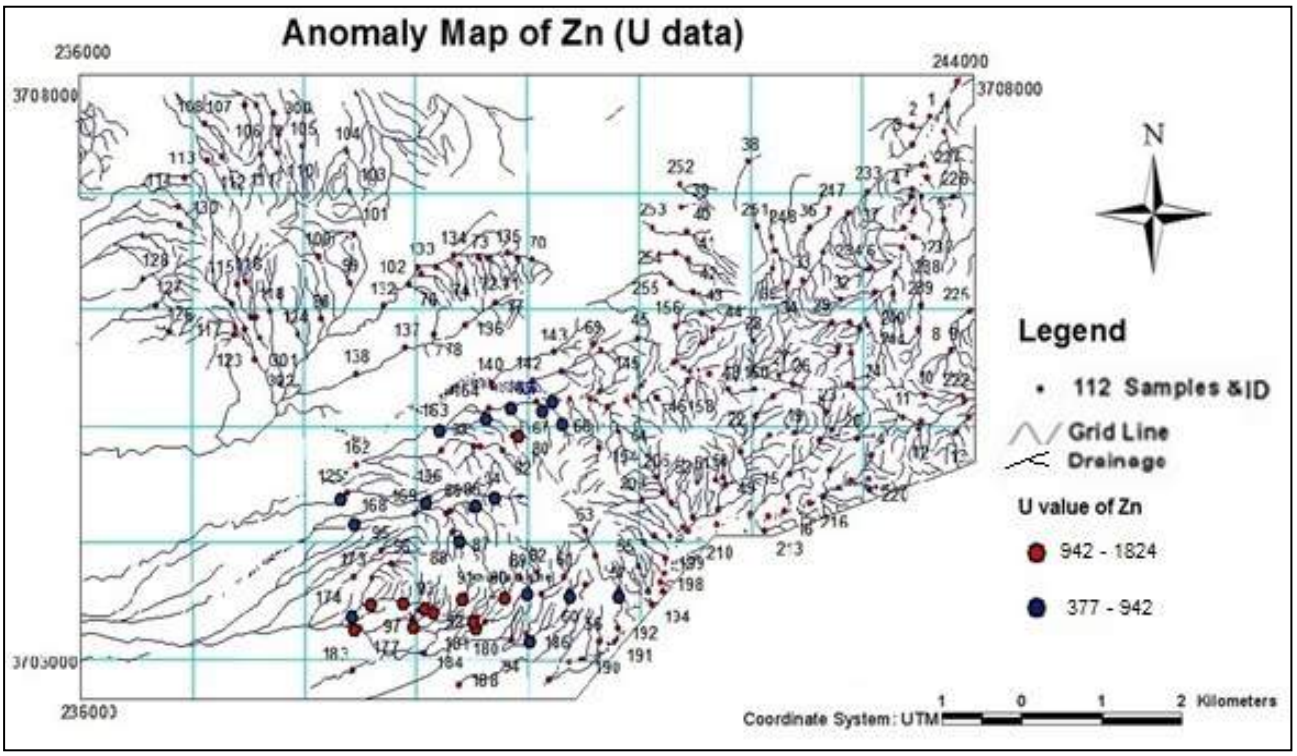

Figure 7. Zinc anomaly map using $\bar{U} + 2S$ and $\bar{U} + 3S$ criteria to show probable and absolute anomalies samples

As shown in figure 5, data have been divided to the anomalous (positive) and background (negative) values. In order to separating probable and absolute anomaly using U values, $\bar{U}+2S$ and $\bar{U}+3S$ thresholds are used respectively. The calculated results for Pb and Zn were shown on Geochemical map (Fig. 6,7). According to the Figure 6 and 7, the blue and red points represents the samples of Probable and absolute anomalies respectively. Results show that specified samples as anomaly samples include high regularity and less dispersion, also in comparison of $\bar{U}+2S$ and$\bar{U}+3S$, $\bar{U}+2S$ criterion provides larger halos and $\bar{U}+3S$ criterion refer to absolute anomalies. Considering geochemical maps of the study area, northwest and southwest districts of the Khooni Mountain are introduced as Pb and Zn anomaly areas.

4 CONCLUSION

Separation anomaly of background is one of the most important steps in geochemical studies**.** U spatial statistic method is a weighted mean, which consider sampling point coordination and their spatial relation in estimation of anomaly areas. The aim of this study is to separate anomaly area of Pb and Zn elements and providing anomaly map for these elements, in khooni area that is located in Isfahan province. The first is done correction data of 256 samples from the area and finally anomaly maps of elements was plotted based on U spatial statistic to study geochemical maps, were identified southwest and northwest of khooni mountain as Lead and Zinc
anomaly area. Also specified samples as anomaly samples, by using U-statistics, consists of high regularity and less dispersion.

Separation of Anomaly from Background Using Concentration-Perimeter (C-P) Method in Nakhilab Region, Northwestern Of Zahedan

N. Mazraee
Department of Geosciences, University of Sistan and Baluchestan, Zahedan, Iran

A. A. Daya
Department of Mining Engineering, University of Sistan and Baluchestan, Zahedan, Iran

M. Boomeri
Department of Geosciences, University of Sistan and Baluchestan, Zahedan, Iran

ABSTRACT Separation of anomaly from background is a fundamental task in geochemical exploration. There are many methods for this purpose. These methods are varies from simple statistical methods to complex fractal methods. In the current study concentration-perimeter (C-P) method was used for separation of anomaly from background. The concentration-perimeter method applied to stream sediments data (N=213) in Nakhilab region, northwestern of Zahedan. As, Ag, Cu, Au elemental concentrations were used in the current study for finding thresholds values. Based on these threshold values different population defined.

Keywords: Concentration-perimeter (C-P) approach, anomaly separation, Nakhilab region

1 INTRODUCTION

The determination of geochemical anomalies from backgrounds is fundamentally crucial for interpretation of geological evolution and the ore-forming processes. Mineral exploration based on stream sediment data has been widely used for different types of ore deposits; in this regard, separation of geochemical anomaly classes based on stream sediment data is an important stage to delineate potential areas for mineral exploration (Deng et al. 2010; Zuo 2011). Determination of elemental thresholds is important for mapping of ore deposit prospecting and reconnaissance (Carranza 2008). There have been some classical statistics methods for delineation of anomalies from background such as histogram analysis, box plot, summation of mean, and standard deviation coefficients and median (Tukey1997). The statistical methods consider only the frequency distribution of the elemental concentration paying no attention to spatial variability; the information about the spatial correlation is not always available (Daya 2014a). In addition, these methods are only applicable to cases where geochemical data follow a normal distribution (Afzal et al. 2012; Daya 2014 a,b; Bai et al. 2010; Carranza 2008; Davis 2002). Fractal and multifractal models, established by Mandelbrot (1983), have been widely applied in different branches of geosciences since 1980s, e.g., Agterberg et al. (1993), Cheng et al. (1994), Turcotte (1986)), and Meng and Zhao (1991), Daya (2014a ,b).. Bolviken et al. (1992) and Cheng et al. (1994) proved that geochemical patterns of various elements have fractal dimensions. Several fractal models have been proposed in geochemical data analysis including concentration–area (C– A) by Cheng et al. (1994), number–size (N–S) by Mandelbrot (1983), and concentration-perimeter (C-P) by Daya (2014b). The concentration-perimeter (C-P) fractal model is related to the C-A and perimeter-area (P-A) fractal models (Daya, 2014b).

The aim of this study was to use the application of C–P fractal model to distinguish geochemical anomalies in terms

of Cu, Au, As and Ag for further mineral exploration in Nakhilab sheet, southeastern of Iran. The elemental anomalies are correlated with geological particulars of the sheet.

2 CONCENTRATION-PERIMETER (C–P) MODEL

Concentration-perimeter (C-P) model is very similar to C-A fractal method and can be deduced from C-A and P-A (Cheng, 1995) fractal models. C–P fractal model has the general form of:

$$P(\rho \leq v) \propto \rho^{-a1} \; ; \; P(\rho \geq v) \propto \rho^{-a2} \quad (1)$$

where P(ρ) denotes the perimeter with the concentration values greater than the contour value ρ, υ represents the threshold, $-a1$ and $-a2$ are fractal dimensions, and P(ρ) is the perimeter enclosed by the contour value ρ on a geochemical contour map resulting from the interpolation of the original data by weighted moving average method (Daya, 2014b).

3 GEOLOGICAL SETTING OF THE NAKHILAB REGION

The study area is located in northwestern of Zahedan city, SE of Iran. The study area is located in boundary of Loot Block and eastern flitch zone In Iran. It is probably a part of Iran's eastern flitch zone. Loot Block in contact with Iran's eastern flitch zone occurred in a very metamorphosed, faulted, sheared, and brecciated zone. From the upper cretaceous to quaternary the study area experienced different mountainous phases including Laramide and Alpine. These mountainous phases have an effective impact in developing the geological setting of the study area. Another important feature of the study area is that it is near the active Nehbandan fault system. Loot Block is more dynamic in its eastern part where the study area is located. The study area is highly brecciated and has faults with general trend of NS and NE-SW. The folding systems in the study area are normal anticline and normal syncline. Their trend is NW-SE to NS.

In the study area lithological units comes from upper cretaceous to quaternary ages. The study area occurred in a tectonic regime that Ophiolites complex was present. The lithological units according to 1:250,000 geological map of Nakhilab sheet divide into three parts which are metamorphic, sedimentary and igneous rocks (Fig 1). Metamorphic unit itself divides into three parts. The first consists of serpentine and harzburgite. Their trend is NS and generally occurred in a folded, fractured, and transformed units. The second group consists of marble, phyllite, serisite, and schist. Theses metamorphic rocks are widespread and its strike in the study area is NS. The last (third) group of metamorphic rocks consists of chlorite, epidote, schist, and mica schist. Their strike in the region is NS. This unit is affected by tectonic activity and as a result is highly fractured. Sedimentary rocks are very widespread in the study area. The most abundant of them are shale, sandstone, limestone, marl, and conglomerate (Fig 1). There are many igneous rocks in the study area. The most important of them comes from Oligocene. It consists of granite, granodiorite, and monzonite. Alteration phenomena are obvious in the igneous rocks and these rocks are much altered (Fig 1).

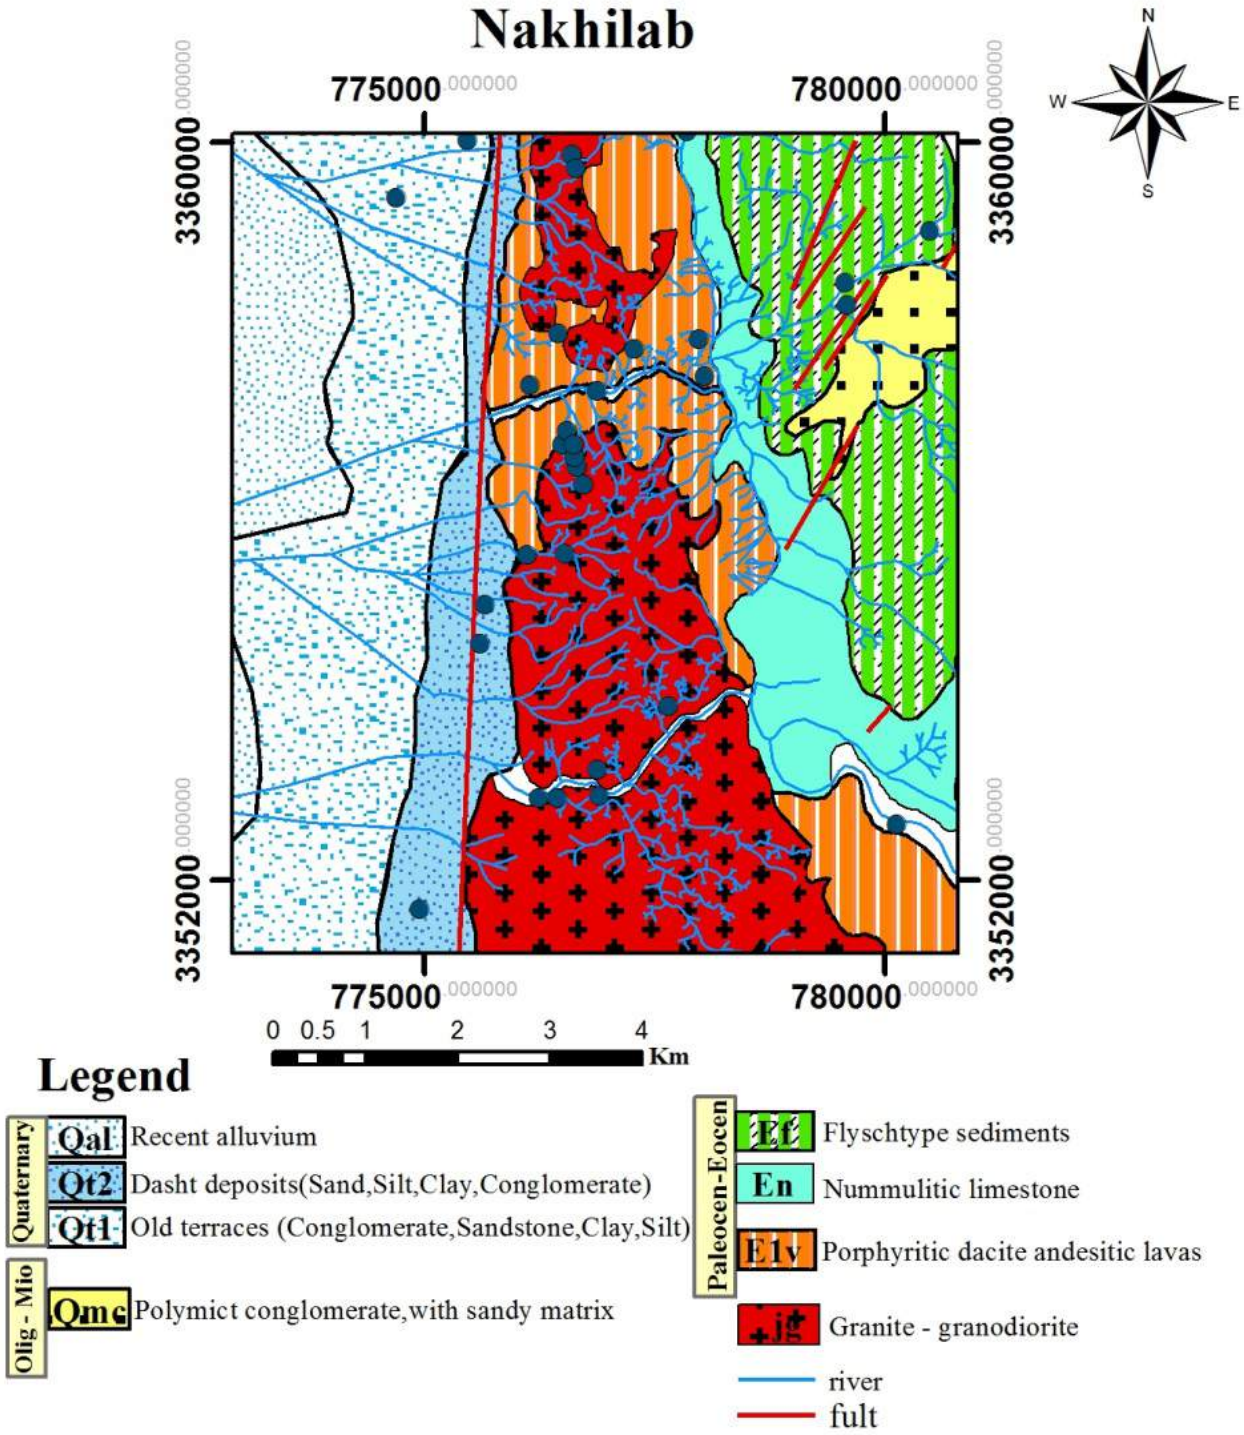

Figure 1. Geological map of Nakhilab region

4 GEOCHEMICAL DATA

Four elements (As, Au, Cu, and Ag) from 213 stream sediment samples were used to identify geochemical anomalies. Stream sediment samples of the −80 mesh (0.18mm) fraction were collected from the center of the streams. Concentrations of the elements were determined by X-Ray fluorescence spectrometry (XRF) and atomic absorption spectrometry (AAS). International standard samples (JSD1, JSD2) and replicates were analyzed after every 10 samples for checking accuracy and precision. Mean deviations between the measured concentrations and reference values were less than 10%.

Statistical analysis was carried out by SPSS 16 software. Statistical results revealed that mean values of Cu, As, Ag and Au mean values are 2.8812, 1.1838, 0.1482 ppm and 0.0012 ppb, respectively. Their distributions are as shown in Fig. 2. Table 1 lists the statistical parameters of As, Au, Cu, and Ag.

Table 1. Statistical parameters of raw data based on stream sediments geochemical samples analysis

Parameters	Au (ppb)	As (ppm)	Cu (ppm)	Ag (ppm)
Mean	0.0012	1.1838	2.8812	0.1482
Median	0.0010	1.1000	2.7600	0.0950
Variance	0.000001	97.788	89.438	0.558
Max	0.017	1.32	1.431	11.00
Min	0.0010	3	2.080	0.0800
Standard Deviation	0.0016	9.8634	9.547	0.7471

Nakhilab region was modeled using 12450 cells. The area was gridded by 250×250 m cells, which were determined based on the geometrical properties of the studied area and sampling spacing (David, 1977). Arsenic, Au, Cu, and Ag distribution models were obtained via Inverse Distance Squared (IDS) method using Rockworks software. This procedure is suggested because it eliminates the undesired smoothing effects caused by the usage of Kriging method. Since the IDS method clarifies the ore grade boundaries and ore concentration values, it is more desirable to use IDS method instead of Kriging which inherently has rather high amounts of truncation errors for the upper and lower boundaries of ore grades.

The proposed gridding pattern is put to use because the fundamentals of C–P fractal method is based on the existence of partition function, and the sampled data cannot be utilized effectively; also, since one cannot sample the entire study area, and for evaluation and estimation of any parameter, i.e., ore grade, gridding of the area is inevitably a desired mandate. By this method the problem of over sampling will not enter into picture because the C–P fractal method will automatically eliminate any probable grid related problem in division of the area into smaller elements and the original fractal character is preserved. Concentration–Perimeter relations were computed by assigning an area of influence to each sampled point and summing all elemental perimeters whose concentration lies below a given value. This procedure was repeated for different elemental concentrations. Carrying on this procedure is not cumbersome because there is a regular gridding of 250 m×250 m cells. The evaluated grades in cells were sorted out based on decreasing grades and cumulative areas.

The grid models derived from IDS method for As, Au, Cu, and Ag were used as inputs to Rockworks software package. The C–P plots consisting of the concentrations of As, Au, Cu, and Ag (ρ) versus the perimeters with the concentrations of As, Au, Cu, and Ag which were greater than or equal to ρ were obtained. There were three enrichment steps for Au, Cu, and Ag and four enrichment steps for As (Fig. 3). Based on the C-P log–log plot, there were four enrichment steps for As within the threshold values of 10, 25, and 80 ppm. The population below 10 ppm and between 10 and 25 ppm was the low and moderate enrichment steps of As, respectively. Furthermore, the population higher than 80 ppm had the high enrichment step of As in the studied area. Moreover, C–A log–log plot of Cu demonstrated three enrichment steps for this element with the threshold values of 27, 53 ppm. Low and moderate Cu enrichment steps were below 27 ppm and between 27 and 53 ppm; but, high enrichment step had a high value of As, which was higher than 53 ppm. Gold had three enrichment steps in the studied area

based on Au C–P log–log plot (Fig. 3). Their threshold values were equal to 0.0024 and 0.013 ppb. Lower than 0.0024 ppb was a low Au enrichment step in this area, the moderate one occurred between 0.0024 and 0.013 ppb, and population of higher than 0.013 ppb had high enrichment step of Au.

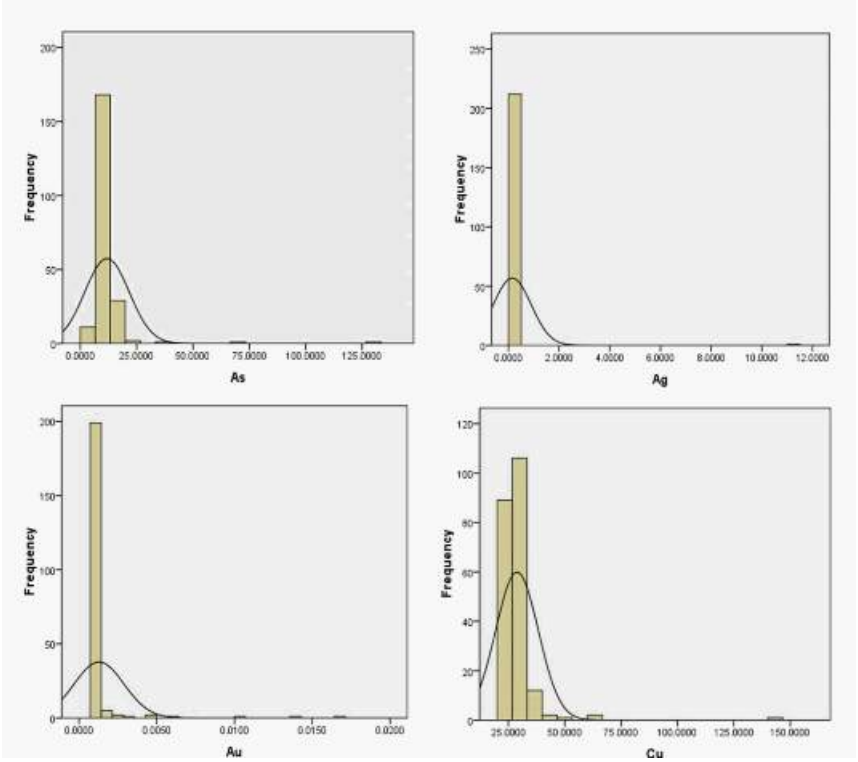

Figure 2. As, Ag, Au and Cu histograms

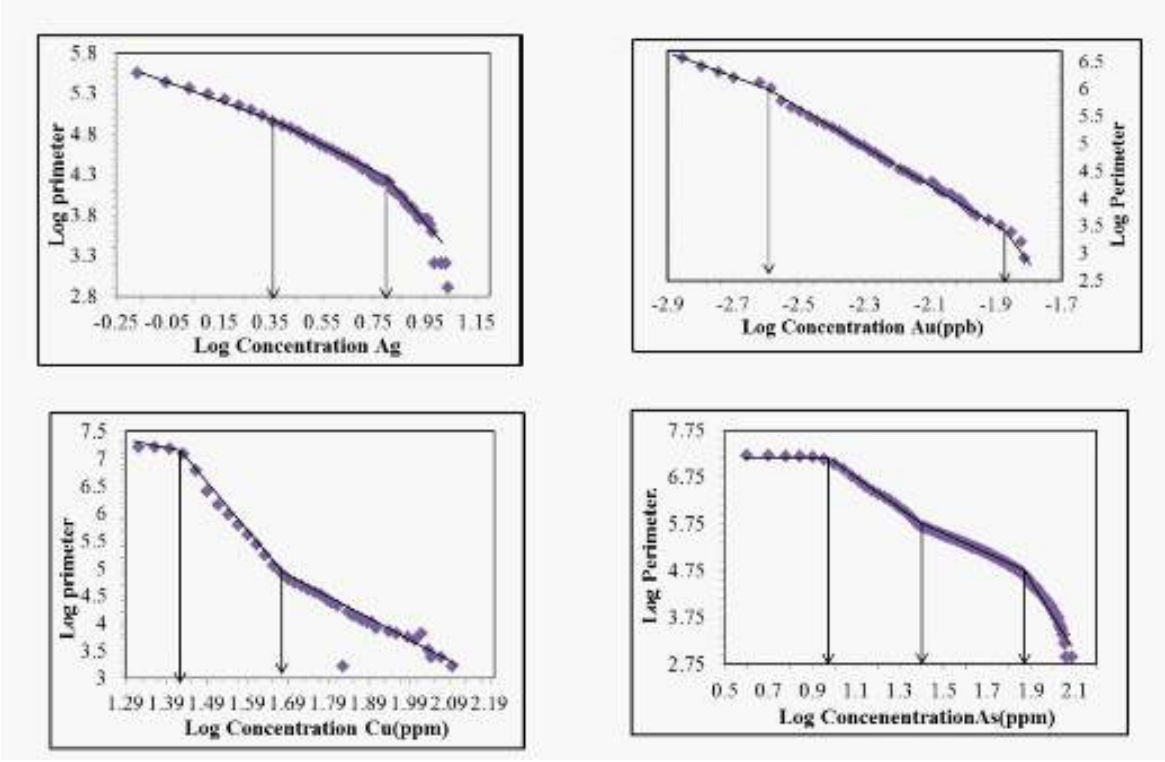

Figure 3. C-P log–log plot of Ag, Au, Cu, and As

Geochemical maps of the elements were obtained using Rockworks software package. Based on the results of the C-P method, As, Au, Cu, and Ag anomalous maps were drawn (Figs. 4). According to the elemental anomaly maps resulted from C-P

plots, the high intensity of As values existed in the central part of the area and correlated with moderate Au anomalous location (Figs. 3). Most of the Au anomalies were located in the western and central parts of the area, especially very high-intensity Au anomalies. Cu anomalies were located in the western parts of the area (Figs. 3). According to the anomaly maps, it can be concluded that Cu and Ag anomalies were simultaneously located in the western part of the studied area and corresponded to Au anomaly. From this point of view, it can be said that the studied area could be very important for Au mineralization and its western part can be the target of future exploration.

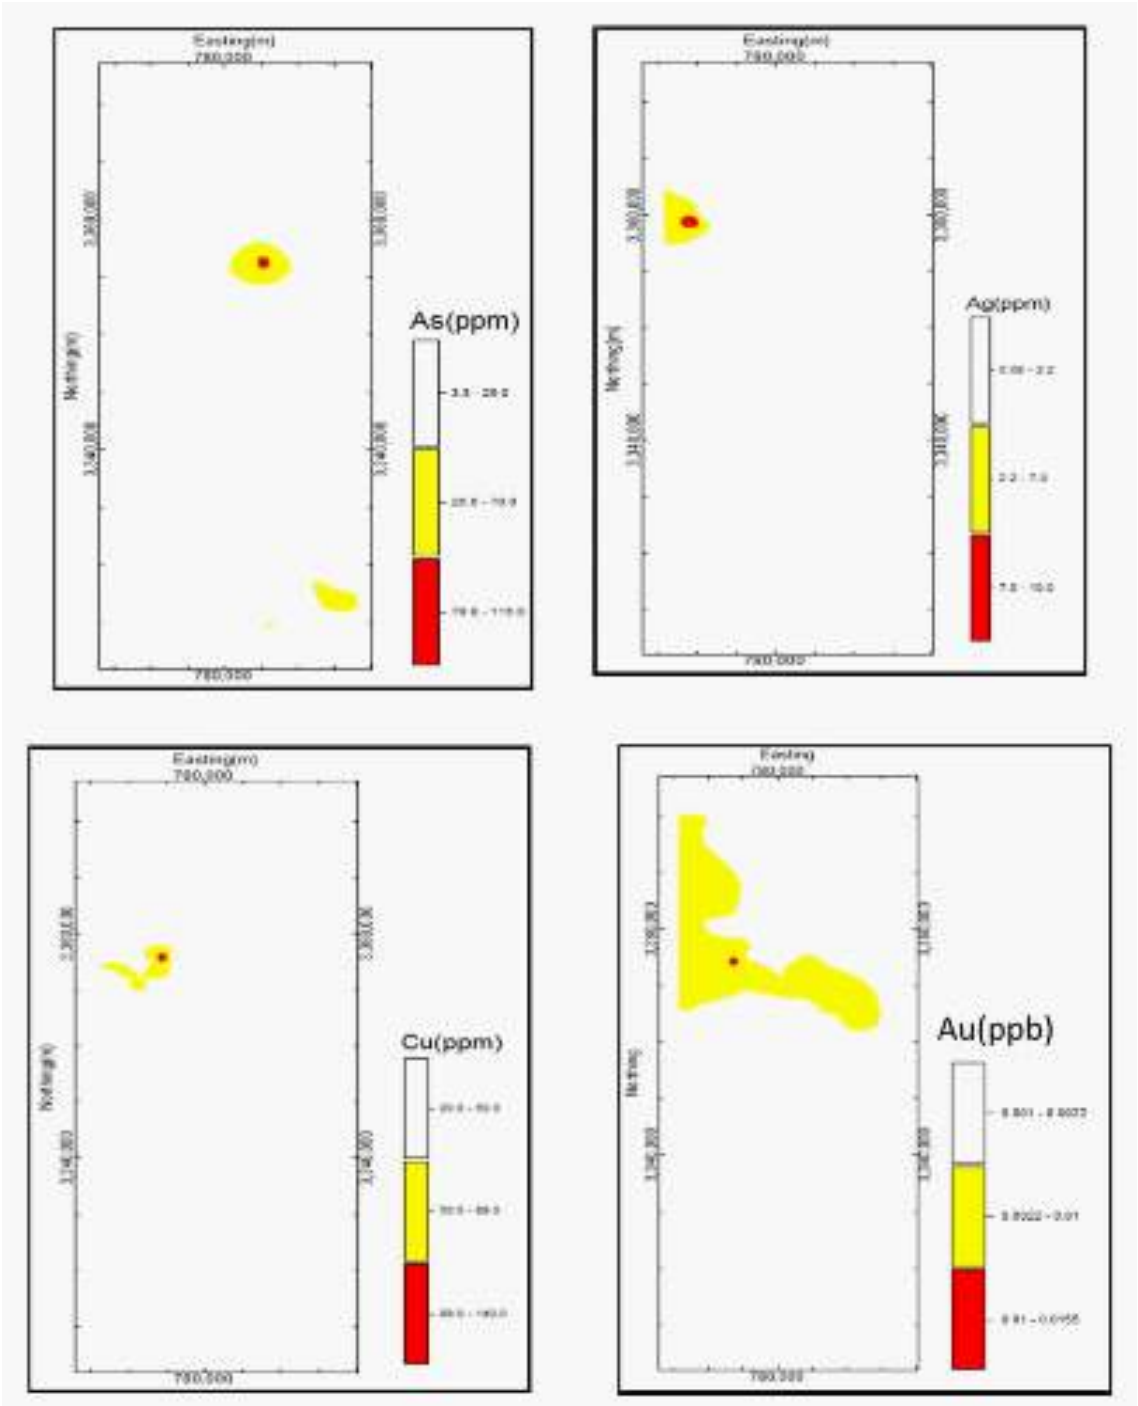

Figure 4. As, Au, Cu, and Ag anomalies obtained from the C–P plot

5 CORRELATION OF C–P MODEL WITH GEOLOGICAL SETTING

The resulting threshold values obtained from the C-P method was compared and correlated to specific lithological units. High enrichment step of Au resulting from the C–P method was situated in the western part of the studied area and correlated to the

conglomerate, sand, clay, , and silt. There was also moderate enrichment step of Au in the northwestern and central parts of the studied area which correlated to granite and granodiorite, and porphyritic dacite andesitic lava. In addition, there was a good relationship between the positions of faults and Au anomalies in the central parts of this area, which was a positive parameter, because silicified and quartz-sulfide veins occurred along these faults and Au particles existed in these veins and veinlets (Hashemi and Afzal , 2013). High enrichment step of As resulting from the C-P method was located in the central part of the studied area and correlated to the granite and granodiorite. It was also located near the faults in the central part. There were moderate As anomalous areas in the southeastern parts. In the southeast, As anomalies correlated to porphyritic dacite andesitic lava. It can be deduced that Ag element can be a very good element for tracing Au mineralization in the studied area. Based on the C-P method, very high concentration of Cu was located in the western part of the region, intersected the faults, and correlated to conglomerate, sand, clay, and recent alluvial. There were high intensive anomalies for Cu in the western part of the area based on the C-P method, which correlated to Au anomalies and sedimentary rocks according to the geological map.

6 CONCLUSIONS

Study on Nakhilab region reveals the potential use of the C–P method for geochemical anomaly separation as a useful tool for geochemical and mineral exploration. The advantages of this method rely essentially on its simplicity, and easy computational implementation. Based on the C-P method, there were three geochemical enrichment steps for Cu, Au, and Ag and four geochemical enrichment steps for As. According to the maps of anomalies by the C-P model, positions of high concentrations of Ag and Au values were the same, located in the western part of the studied area, and correlated to conglomerate, sand, clay, and silt. It can be deduced that Ag can be a good geochemical indicator for tracing Au mineralization in this area. From the maps of anomalies, Au, Cu, and Ag anomalies were simultaneously located in the western part of the studied area. From this point of view, the studied area could be beneficial for the formation of Au mineralization and its western part can be the target for future exploration. There was also a good relationship between locations of faults and Au, Ag, and Cu anomalies in the central parts of the studied area, because silicified and quartz-sulfide veins occurred along these faults and Au particles existed in these veins and veinlets. The western and central parts of the studied area were the most important parts and future, more detailed explorations including lithogeochemical sampling must be focused on these sectors.

Spatial Association Analysis Between Hydrocarbon Fields and Sedimentary Résidual Magnetic Anomalies: A Case Study from the Algerian Triassic Province

K. Allek, A. Bouguern
Laboratory of Earth Physics, University of Boumerdes, Algeria

D. Boubaya
University of Tebessa, Algeria

M. Hamoudi
USTHB University, Algiers, Algeria

ABSTRACT The presence of Sedimentary Residual Magnetic (SRM) anomalies over hydrocarbon accumulations and their contribution to exploration remain somewhat controversial despite encouraging results and an improved understanding of genetic links between hydrocarbon seepage-induced alterations and near-surface magnetic minerals. These uncertainties still exist because shallow-sourced SRM anomalies are not associated exclusively with hydrocarbon. The cause of these anomalies may well be microseepage related, *but* could also *result* from others sources such as cultural features or detrital magnetite. To deal with this particular purpose, we explore the spatial association between known hydrocarbon fields within the Algerian Triassic province basin and SRM anomalies using GIS-based weights of evidence statistical approach. The results indicate that the known hydrocarbon fields are strongly associated with particular classes of anomalies. These results are significantly useful for further exploration in the case of the study region, and can also be extended to regions with similar characteristics.

Keywords: Sedimentary residual magnetic, hydrocarbon fields, spatial association analysis

1 INTRODUCTION

Airborne magnetic surveying has been used in oil exploration for many decades. It traditionally applied to quickly and economically screen large areas for mapping depths to basement and bedrock structures that control emplacement of hydrocarbon in overlying sedimentary basins. Recent years have seen a surge in interest for the application of magnetic data to the detection of intra-sedimentary shallow-sourced anomalies associated with hydrocarbon microseepages. It has been well documented that most oil and gas accumulations leak hydrocarbons, creating alteration features close to the surface that can be identified using geochemical methods as well as any of geophysical techniques such as gamma-ray spectrometry, induced polarization and magnetic (Saunders et al., 1993; Foote, 1996; Schumacher, 2000; Peres-Peres 2011; Curto et al., 2012; Flekkoy et al., 2013).

The first time that has been shown the presence of magnetic anomalies in levels near surface, associated with the presence of underlying hydrocarbon deposits was in late seventies. It was made independently by Donovan et al. (1979) and by Berezkin et al. (1978). Advances made in processing aeromagnetic data and an improved understanding of seep mechanisms and alteration processes that could result in formation of authigenic (formed in place) magnetic minerals has promoted the magnetic method from a reconnaissance tool to a valuable exploration technique for detecting hydrocarbon by mapping short wavelength magnetic anomalies assumed to

be in relationship with hydrocarbon seep-induced near-surface magnetic minerals, either in onshore or offshore basins (Foote, 1996; Burazer et al., 2001; Stone et al., 2004; Curto et al., 2012; Schumacher and Foote, 2014; Menshov et al., 2014). This seep-induced magnetic minerals has led to some development of analytical methods that allow subtle anomaly identification. Foote (1996) developed a method referred to as "Magnetic Bright Spots (MBS)" - which provide valuable clues to an underlying oil or gas accumulation. Studies from onshore and offshore examples (Schumacher and Foote, 2006; 2014) reveal stunning results. The exploration leads and prospects associated with a MBS anomaly are 4 to 6 times more likely to result in a commercial oil or gas discovery than a similar prospect without such an anomaly. Stone et al. (2004) described a simple micromagnetic aureole search methodology which is intended to the recognition of annular/aureole-shaped anomalies. The test study from a high-resolution aeromagnetic survey performed over Muglad Basin of southern Sudan has successfully revealed an annular anomaly correlating directly with the Jarayan oil field.

Despite the good consistency of results obtained from published studies, this method did not penetrate into subconsciousness of practicing geophysicists from industry. If data processing techniques can often remove the influence of deep magnetic basement rocks, this is not always the case when it comes to discriminate between the effects of shorter wavelengths anomalies which can result both from authigenic ferromagnetic minerals than possible syngenetic magnetic sources. Gay and Hawley (1991) and Gay (1992) remained skeptical about the origin of near-surface intra-sedimentary magnetic anomalies supposedly caused by hydrocarbon microssepages. They cite examples of many false anomalies caused by detrital magnetite, tuffs, "black sands" in stream channels and cultural contamination from surface and near-surface iron. It is this skepticism that appears to deter many petroleum geophysicists.

Because of this controversy about the presence, origin, and exploration significance of magnetic mineralization associated with hydrocarbon accumulations, we decide to carry out a more analytical and more objective methodology, using GIS-based Weights of Evidence (WofE) approach to verify the genetic links between SRM anomalies and hydrocarbon seepage environments. This method has been extensively applied for mineral potential mapping; however, the present study represents its first application to hydrocarbons exploration. The Oued Mya Basin which contains numerous oil and gas producing fields as well as the giant gas-deposit of Hassi R'mel provides an ideal case study.

Our aim was to investigate the spatial association between SRM anomalies and the known hydrocarbon fields within the study area to answer the question whether the spatial distribution of these magnetic anomalies is controlled by the underlying oil/gas fields. First, we use the WofE technique to establish a quantitative characterization of the spatial relationship. Next, we reveal the characteristics (wavelengths and amplitudes) of the type of anomalies assumed to be induced by hydrocarbon microseepages. Finally, we show evidence of the convenience of large-scale aeromagnetic data for such tasks when acquired at relatively low altitude and at suitable accuracy.

2 HYDROCARBON SEEPS

It has long been recognized that most oil and gas accumulations leak hydrocarbons due to high pressures at depth. This leakage occurs vertically or near-vertically from the reservoir to the surface through fractures in rocks and planes of weakness between geological layers or along fault discontinuities (Schumacher, 2010, Salati, 2014). Except some macro-seeps encountered sometimes in certain regions, that manifest themselves as the visible presence of oil and gas seeping to the surface, most of hydrocarbon seeps have no

visible and direct evidences of their presence (microseeps), but cause several chemical reactions and microbial oxidation in the rocks and soils and also cause changes in Eh and pH. Such changes in the near-surface soils destabilize many compounds, increase the solubility of the elements and induce mineralogical alterations such as red beds bleaching, clays formation, and creation of secondary carbonates, sulfides, and magnetic minerals (Schumacher, 1996; 2014; Srinivasan et al. 2014; Salati, 2014).

Eventov (1997) have reviewed some of the most documented theories concerning the formation of the diagenetic magnetite, caused by hydrocarbon seepages. According to these theories, the hydrocarbon-induced reducing environment can lead to the precipitation of a variety of magnetic iron oxides and sulfides, including magnetite (Fe_3O_4), maghemite (γ-Fe_2O_3), pyrrhotite (Fe_7S_8), and greigite (Fe_3S_4). Schumacher (1996) provided a model for hydrocarbon-induced magnetic minerals. In accordance with this model, upward-migrating light hydrocarbons reach near-surface oxidizing conditions, aerobic hydrocarbon-oxidizing bacteria consume methane (and other light hydrocarbons) and decrease oxygen in pore waters. With development of anaerobic conditions, the activity of sulfate-reducing bacteria results in

Sulfate ion reduction and oxidation of organic carbon to produce bicarbonate ion and reduced sulfur species which in turn combine with available iron to form iron sulfides and oxides. For their part, Machel and Burton (1991) suggested that magnetic minerals could be either produced or destroyed under the influence of hydrocarbons seeps. On the basis of extensive investigations conducted in major oil fields of several basins in China, the results of mineralogical analysis reveal that the enhanced magnetic susceptibility relating to the hydrocarbon microssepages are caused by secondary magnetite and the subsequent low-temperature oxidation products (maghemite) (Liu et al., 2004).

Diagenetic magnetic minerals created by hydrocarbon microseepage has been reported to occur over a wide range in *depth*, from surface soils to strata as deep as 1500 m (LeSchack and Van Alstine, 2002). The identification of anomalous magnetic minerals over oil and gas accumulations has been established by magnetic susceptibility measurements and magnetic mineralogy analysis of surface soils, drill cuttings and cores from oil wells. Saunders et al. (1991) documented increases in magnetic susceptibility that were caused by high concentrations of authigenic magnetic minerals (magnetite and probably maghemite) occurring just below the grass roots. Foote (1996) reported that most magnetically enhanced zones detected in high resolution ground and airborne magnetic surveys over hydrocarbon reservoirs are thought to occur at depths of 60–600 m. Peres-Peres et al. (2011) revealed the presence of authigenic magnetite at a depth of about 600 m by analyzing drill cuttings from Venezuelan and Colombian oil fields.

3 MATERIALS AND METHODS

3.1 Study area

This study was developed in a region within the Triassic province of Algeria, in fact a large basin located on the northern-central part of the Saharan Platform. It lies at the Northern part of the Oued Mya depression, between 0° 40' - 4° 48'E longitudes and 31° 06' - 33° 55'N latitudes. This study region as a whole consists of a number of structural units: Djorfa saddle, Tilrhemt dome, and parts of the Benoud trough and Touggourt saddle (Fig. 1).

The current structural scheme is the result of several tectonic phases which the most important are the Panafrican, the Hercynian, the Triassic-Jurassic extension, the Austrian, and the major Alpine phase. The Tilrhemt dome is the most important anticline structure in the region with ENE-WSW direction, and probably Hercynian age. According to the geological map, mostly Cretaceous formations outcrop in this area, whereas Neogene-Oligocene and sand dunes dominate in the rest of the region (Fig. 2).

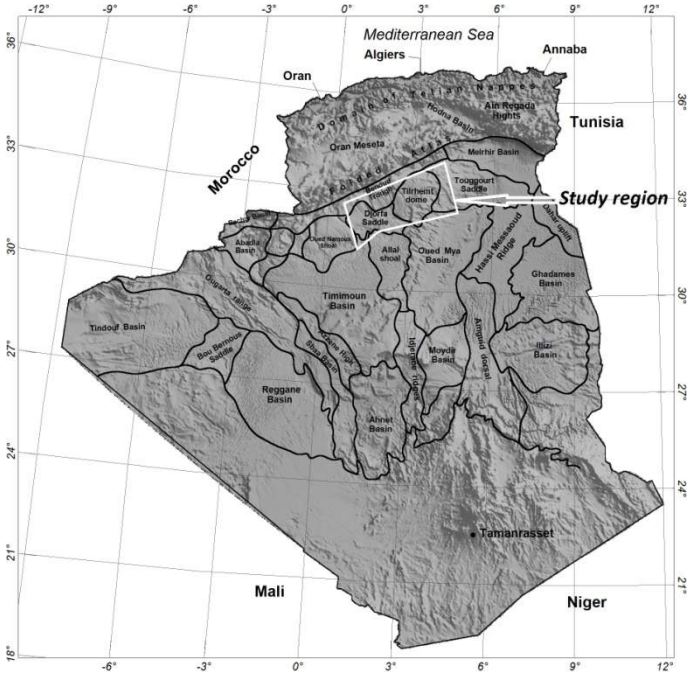

Figure 1. Algerian territory, showing defined structural units and the study area location.

The study area contains the giant Hassi R'mel gas field and numerous oil and gas deposits exploited at the Triassic and Cambrian-Ordovician levels. The Saharan Triassic which is the main petroleum objective, consists of sediments of varied continental environments; namely, fluvial, floodplain, lake, sebkha, and wind (Baouche et al., 2009). The region was first investigated in 1951 which led to the drilling of the first well south of Berriane. The encouraging results led to the discovery of the Hassi R'mel field in 1956, which was put on production in 1961 and proved to be one of the world's largest gas fields. The Field extends 70 km from north to south and 50 km from east to west (Bencherif, 2003). Exploration increased the subsequent decades leading to the discovery of several oil and gas fields in the region.

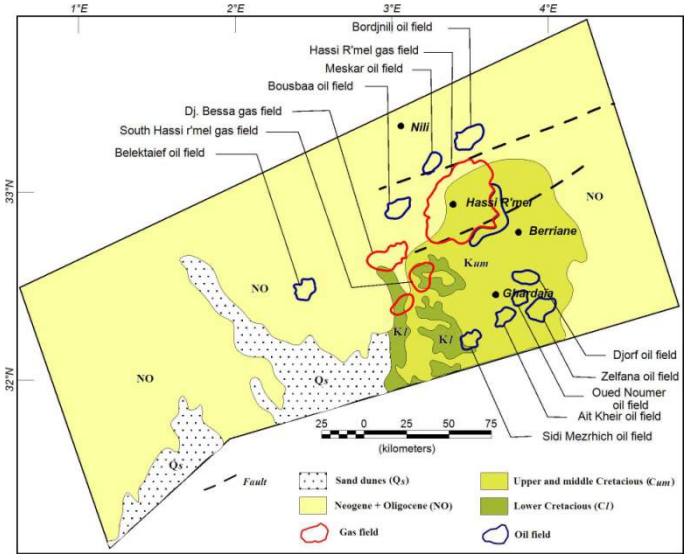

Figure 2. Simplified geological map and oil-gas fields location

3.2 Survey

The regional airborne magnetic survey over the Oued Mya region was part of the nationwide aeromagnetic survey of Algeria. The survey was completed by Aeroservices Limited in 1974 on behalf of the *SONAREM* (*Société Nationale de la Recherche et d'Exploitation Minière*). The aeromagnetic data were acquired with a nominal terrain clearance of 150 meters using a high resolution (0.02 nT) optically pumped cesium vapor magnetometer. Traverse lines were oriented N160° (NNW-SSE), with a spacing of 5 km. Tie-lines (Control-lines) were oriented perpendicular to traverse lines with a spacing of 25 km. Tie-lines were also flown along the survey boundary when not parallel to the traverse line direction. Readings were taken at one-second intervals, yielding at an average aircraft speed of 165 km/h a magnetic measurement about every 46 m along the flight path. The survey contains 13,980 line-kilometers, and covers surface of 56,900 km². Variations in the magnetic field resulting from different aircraft induced noise were electronically compensated.

In order to ensure the *quality* of measurements, the maximum diurnal change allowed was less than 3 nT for any 3-minute chord (period) of time. Data were re-acquired when this condition is exceeded, with any re-flown line segment crossing a

minimum of two control lines. Several data processing procedures: such as tie-line leveling, IGRF calculation and removal, lag effect correction and microlevelling, were carefully achieved to get the most out of the detection of subtle anomalies. Although this survey is very widely spaced, it is acquired at a relatively low height, and there are sufficient reading along each flight line such that micromagnetic anomalies close to flight lines are well identified.

3.3 Enhancement of SRM anomalies

It should be noted that for airborne magnetic data, the flight altitude, sample spacing along flight lines and line spacing play an important role in the detection of high wavenumber weak magnetic anomalies. In Algeria, most available aeromagnetic surveys were accomplished at the reconnaissance scale and, thus far they have been mostly used to define the main basin structural features. On the other hand, They are at an accuracy and at a height that makes them suitable for the detection of subtle anomalies when they are close to a flight line. However, processing the survey as grided data would tend to obscure any isolated narrow anomalies. That's why all filtering computations, performed in this study to isolate subtle anoamlies, were carried out on profile data.

To highlight Sedimentary Residual Magnetic (SRM) anomalies, the most contentious problems are to remove cultural influence and basement magnetic signal. These SRM anomalies are often masked by much stronger magnetic anomalies caused by underlying magnetic formations and/or by cultural features. However, if the basement magnetic sources generally can be distinguished by their large wavelenghts, this is not always the case when one has to do with the cultural sources. Randomly scattered oil well casings, metal storage tanks, pipelines, and other cultural features on or near the ground surface alters magnetic data acquired for hydrocarbon microseepage purposes. These sources create short-wavelength high-amplitude signatures in total field magnetic intensity maps and they can mask the effect of seep-induced anomalies and sometimes even confused with them.

We used the radial power spectra of the anomalous field (Spector and Grant 1970) to help distinguish anomalies caused by near-surface intrasedimentary sources from anomalies caused by cultural sources and those from basement rocks. The diagenetic magnetic signal is generally recognized by its longer “wavelength” (compared to cultural features and background noise). The very long basement effects and very short cultural sources were removed by applying a selective band-pass filter. Afterward, amplitudes of the Analytic Signal of the isolated Sedimentary Residual Magnetic (AS-SRM) anomalies were calculated to deal with distortion and polarity effects of anomalies so that they can be more easier studied and categorized.

4 SPATIAL ANALYSIS APPROACH

4.1 Weights of Evidence method

Weights of evidence (*WofE*) is a Bayesian statistical method for assessing the degree of spatial association and for combining evidence to test a hypothesis. It determines the probability of an event to occur under certain conditions. The method was originally developed for a non-spatial application in medical diagnosis, later it was extensively used for mineral potential mapping in a GIS environment (Bonham-Carter, 1994), and soon after adapted for landslide susceptibility analysis, hazard modeling, fires and so on. The WofE method is applied here to investigate the spatial associations between interpreted Sedimentary Residual Magnetic (SRM) anomalies and mapped hydrocarbon fields within the Oued Mya Basin. The importance of the weights depends on the measured association and permits to provide an insight into the characteristics of the SRM anomalies related to seep-induced magnetic minerals. This method could be used as spatial evidence in hydrocarbon prospectivity mapping.

A detailed explanation of the mathematical formulation of the WofE modeling method is available in Bonham-Carter (1994). The method uses a log-linear of the Bayesian probability model to estimate the importance of evidences by a pair of weights, one (positive weight W^+) for presence of the evidence H, and negative weight (W^-) for absence of the evidence H.

$$W^+ = ln\left(\frac{P(H|A)}{P(H|\bar{A})}\right) \quad (1)$$

$$W^- = ln\left(\frac{P(\bar{H}|A)}{P(\bar{H}|\bar{A})}\right) \quad (2)$$

where P() denotes probability, H is the presence of hydrocarbon pattern (it corresponds to area occupied by hydrocarbon field), $\bar{H}$ is the absence of hydrocarbon pattern, A is the presence of points of interest (corresponds to center-points of picked SRM anomalies), $\bar{A}$ is the absence of points occurrence.

The weights (W^+ *and* W^-) provide a measure of spatial association between the training points and the binary theme H. They are calculated for each class of the picked SRM anomalies. The value of the weight W^+ is positive, whereas W^- is negative, indicates that there are more SRM anomalies on binary theme H than would occur due to chance. Conversely W^+ would be negative and W^- positive for the case where fewer points occur than expected. If the picked anomalies A are distributed randomly with respect to the binary theme H, then both of weights will have a value of zero, or very close to zero.

The difference between the weights is known as the contrast, C. Thus:

$$C = W^+ - W^- \quad (3)$$

The contrast is an overall measure of spatial association between the set of points A and the binary theme H, combining the effects of the two weights. It is the best estimator in a large area and when a large number of points occurences are considered (Bonham-Carter, 1994). Hence, for a positive correlation, C is positive; C is negative in the case of negative spatial correlation.

The studentized confidence value *s(C)*, defined as the contrast *C* divided by its standard deviation, corresponds approximately to the statistical level of significance defined by standard z-tests, and provides a useful measure of the significance of the contrast (Raines, 1999). The standard deviation of C is calculated as:

$$s(C) = \sqrt{s^2(W^+) + s^2(W^-)} \quad (4)$$

In the spatial analysis, as applied in this work, a simplified and intuitive approach similar to that suggested by Turner (1997), was adopted. The surface of the study area and the binary pattern H are expressed in number of unit cells, and each training point is assumed to occupy a single unit cell. That way, the weights W^+ and W^- can be calculated by means of map crossing functions as follows:

$$W^+ = ln\left(\frac{\frac{Number\ of\ points\ A\ (picked\ anomalies)\ \boldsymbol{inside}\ the\ pattern\ H}{Total\ number\ of\ \ points\ A}}{\frac{Number\ of\ unit\ cells\ \boldsymbol{inside}\ pattern\ H\ not\ occupied\ by\ points\ A}{Total\ number\ of\ unit\ cells\ of\ the\ study\ area\ not\ occupied\ by\ points\ A}}\right) \quad (5)$$

$$W^- = ln\left(\frac{\frac{Number\ of\ points\ A\ \boldsymbol{outside}\ the\ pattern\ H}{Total\ number\ of\ points\ A}}{\frac{Number\ of\ unit\ cells\ \boldsymbol{outside}\ pattern\ H\ not\ occupied\ by\ points\ A}{Total\ number\ of\ unit\ cells\ of\ the\ study\ area\ not\ occupied\ by\ points\ A}}\right) \quad (6)$$

A unit cell of 1 km x 1 km was used. This was chosen for two reasons: the scale of the present aeromagnetic survey, and expected dimensions of SRM anomalies so that each cell can contain only one training point. The total number of unit cells area (1 km²) in the study area map is 56900 cells, while the surface occupied by the hydrocarbon fields represents 3120 cells, i.e. a little more than 5% of the total area. Thus, the areas occupied by oil and gas fields represent 2 and 3% respectively.

4.2 Application of the method

To the authors' best knowledge no study has investigated quantitatively the spatial association between known oil and gas accumulations and magnetic anomalies arising from shallow sedimentary section. In the most literature reviewed the characterization of this spatial correlation results from visual analysis (Burazer et al. 2001; Stone et al., 2004; Curto et al., 2012; Menshov et al., 2014).

In the application of the WofE method, hydrocarbon-related thematic map was overlapped with all 342 picked AS-SRM anomalies (Fig.3). The Weights of the Hydrocarbon-related theme in the model was calculated by using the relationship of the area covered by the oil and gas fields and the number of picked anomaly points that fall onto it. On the basis of this intersection, weights, contrasts and Studentized confidence values were calculated using equations (3, 4, 5, and 6).

Initially all 342 picked anomalies are treated as being either present or absent in the model, and are not weighted by characteristics such as anomaly size or amplitude. The results show relatively low values of contrast 'C' (0.6 - 0.7) for oil and gas fields whether taken separately or together (Tab. 1). This indicates that the picked AS-SRM anomalies are practically *uncorrelated* with known hydrocarbon fields within the study area because of a somewhat random distribution of these anomalies as shown in figure 3.

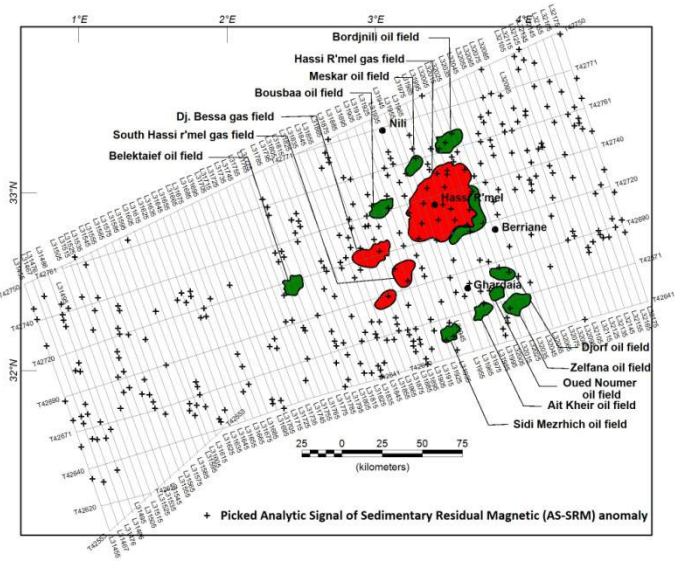

Figure 3. Location of picked AS-SRM anomalies

Table 1. Summary of spatial association defined by weights of evidence model

Theme	W-	W+	C	St(c)
Oil	-0.01	0.58	0.59	2.0
Gas	-0.03	0.60	0.63	2.7
Oil+gas	-0.05	0.68	0.73	4.1

The magnitude of the analytic signal of picked anomalies ranges from 1.5 to 13.7 nT/km with an arithmetic mean of 2.8 nT/km and standard deviation of 1.8 nT/km. Their width ranges between 1.38 and 8.8 km with an average value of 3.27 km and standard deviation of 1.2 km. To give a quick visual summary of the picked anomalies, they were divided into ten class intervals (bins) according to their wavelengths and their magnitude values (Fig. 4). The number of ten bins is chosen according to Sturges' rule, which suggests that the number of intervals should be as close as possible to $1+log_2(N)$, where N is the number of anomalies. Magnitude of AS-SRM (Fig. 4a) shows a skewed distribution to the right with a large number of anomalies (nearly 65% of all anomalies) in the lower value class (leftmost side). An almost similar shape is obtained for the width of the anomalies (Fig. 4b), which exhibits some right-skew.

The problem with this distribution of anomaly classes is that some of the classes have a very small number occurring in them. This gives rise to a very noisy and unreliable

weights, with poor estimates. The alternative is to calculate weights for classes whose intervals are selected so that each bin holds the same number of picked anomalies, and to examine the variation of the weights and contrast at each amplitude and wavelengths intervals.

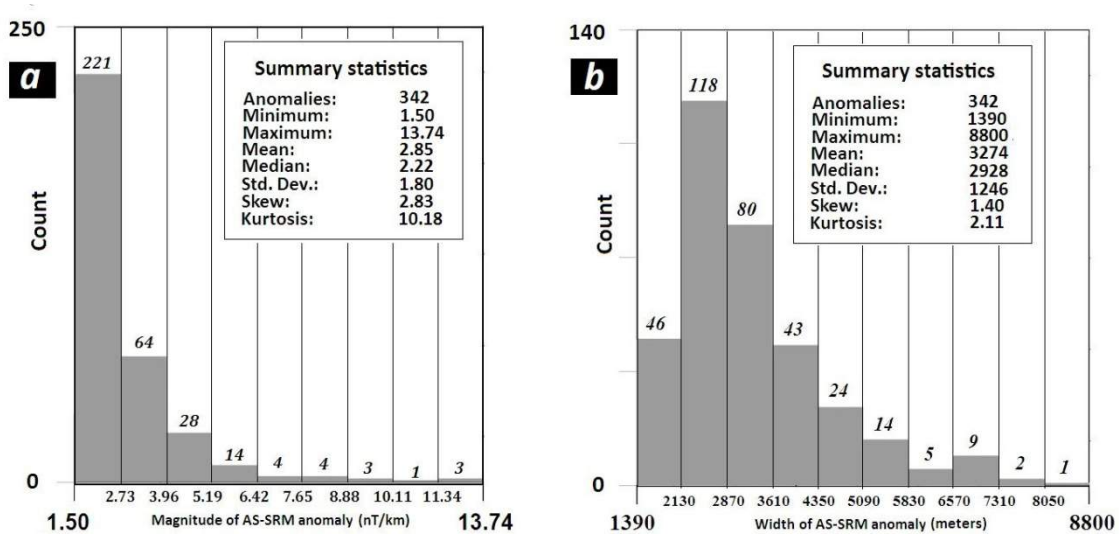

Figure 4. Frequency histogram of AS-SRM anomalies according to: (a) amplitude, (b) width.

5 RESULTS AND DISCUSSION

This study synthesizes results of the research work to develop and demonstrate the existence of relationship between oil and gas reservoirs distribution and Hydrocarbon Seepage-Induced Magnetic anomalies. Both gas and oil fields were alternately used as binary patterns in the weights of evidence (WofE) modeling for assessing their spatial association with AS-SRM anomalies, and to distinguish them from any other shallow-sourced magnetic signatures.

All picked anomalies were classified into 10 bins with varied width such that each bin contains 10% of the total of anomalies (i.e. about 34). The set of picked anomalies that fall into a defined class is used to calculate the weights for both oil and gas fields binary patterns, one weight per class, using the overlap relationships between the hydrocarbon fields and the various classes on the anomalies. Tables 2 and 3 report summary of weights, contrast and Studentized (*Confidence* C_S) for amplitude (nT/km) and size (km) for each class of AS-SRM anomalies respectively.

Table 2. Variation of weights for different amplitudes (nT/km) of AS-SRM anomalies with respect to hydrocarbon (gas and oil) fields

Class amp. (nT/km)	No. of anom.	W^+	W^-	Contrast (C)	Confidence

>5 km	4	0.848876	-0.081355	0.930231	1.735263

It can be observed that the strongest spatial correlations are related to certain class of anomalies. They are defined by contrasts C > 1.5, and confidence C_S > 3.5 implying statistically significant for the classes of AS-SRM anomalies believed to result from near-surface sources induced by hydrocarbon microseepages have wavelengths in the intervals 3.3 - 3.6 km and 4.1 - 5.0 km and amplitudes ranging from 3.0 to 3.5 nT/km.

Plot of data over flight line No. 31905 located in the central part of the study area is presented in Figure 5. The analytic signal profile shows two anomalies with amplitude values of 2.9 and 3.5 nT/km and width of 4.9 and 3.8 km, which occur above Bousbaa oil field and South Hassi Rmel gas field respectively.

The identified near-surface anomalies in the Algerian Triassic basin suggests a possible relationship between certain type of sedimentary residual anomalies and hydrocarbon fields emplacement. This hypothesis has been supported by the statistical model which enabled the quantitatively characterization of the degree of spatial relationship.

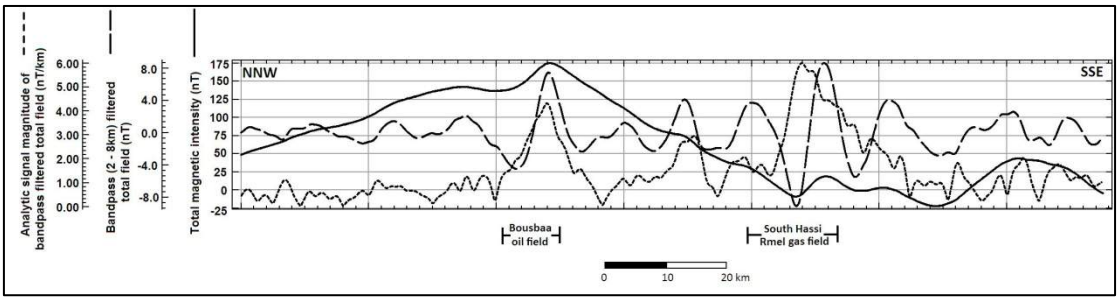

Figure 5. Aeromagnetic flight line profile L31905 across the Bousbaa oil field and the South Hassi Rmel gas field

6 CONCLUSION

Despite the availability of a large aeromagnetic coverage, these data were not always exploited in an optimal and rigorous way. In fact, they were only related, in the best of cases, to screen large areas for mapping depths to basement and bedrock structures. the results obtained from GIS-based weights of evidence analysis demonstrate that regional aeromagnetic data when acquired at relatively low altitude and at suitable accuracy can provide important information about intra-sedimentary features and residual anomalies attributed to long-term hydrocarbon microseepages. The application of spatial association analysis using GIS-based weights of evidence technique has successfully identified a particular class of sedimentary residual magnetic anomalies correlating directly with known underlying oil and gas accumulations within the Algerian Triassic basin. Even

though this approach is empirical, it nonetheless provides support for determining successful and cost effective exploration strategies in predicting areas of high hydrocarbon potential where little or no exploration activity exists.

High resolution aeromagnetic surveys are certainly more suitable for this venture allowing to improve the definition of the observed aeromagnetic field so that small seep-induced effects can be better defined in order to detect more of them and to interpret them more accurately.

Structural Controls of Gold Deposit Mineralization in Zarshouran Mine, Takab, Iran

H. Hassani, V. Farahani
Faculty of Mining and Metallurgical Engineering, Amirkabir University of Technology, Tehran, IRAN

ABSTRACT Zarshuran gold deposit is located in northenwest Iran at Takab region. Zarshuran gold deposit has reserve of 6.74 million tons with 1 gram per ton cut off grade and 4.01 grams per ton average gradeZarshuran gold mineralization is similar in many ways to scattered epithermal deposit in sedimentary rocks, especially carbonates (carlin type). Deposit contains very fine grained scattered gold and high content of arsenic and sulfide. The hosted rocks for mineralization are Black shale and Chaldagh limestone. Silicification, argilic-seserisitic and alunitealteration are the most important alteration in this region. The studied area of Zarshuran is a part of Tabriz-Bazman igneous sub-zone and it is part of Imankhan anticline. The main faults of this region (Tabriz-Bazman) form a network which is dependent on a riedel type shear zone. In this work, first ,the DataMine and Rockworks software has been used to study the structure of regional faults and folds (like determining fold axis, fold dependent fractures, etc.), then faults and fold dependent joints are divided into groups. Geological dependency of different structural elements of the region has been matched on third order branched fractures mechanism of clockwise shear area with final trend of N130 and N155 and mineralization is occurred along extension of these trends. Field surveys, fractures and boreholes investigations showed that mineralization and ore deposition is consistent with the area fractures.

Keywords: Gold, structural, fault, fold

1 INTRODUCTION

Zarshouran gold deposit is located in southeast of West Azerbaijan Province with 5 kilometer distance from north to northeast of Zarshouran village and 25 kilometer distance from north of Takab City (Ojaghi, 1996). This area is among deposits with priority which was the subject of various geological and mineral activities. According to 47 drilling wells by Iranian and foreign companies, the estimated deposit of this area is 11.04 million tons with average fineness of 7.72 gr/ton with limit of 1 gr/ton (Minerals Production, 2004).

Gold mineralization in Zarshouran deposit is considerably similar to disseminated epithermal deposit in sedimentary rocks specially carbonated ones (carlin type). Gold is either scattered in a deposit in very fine-grained form with high levels of Arsenic and Sulphide or mixed with organic carbon in Zarshouran area and formed organic gold-carbon complex with high purity (Ojaghi, 1996). Studied area is geologically located at Iran central zone and is part of Sahand – Bazman (Orumiyeh – Dokhtar) magmatic sub-zone that central Iran transitional zone (Sanandaj-Sirjan) is in its southward (Alavi et al, 1982).

Sahand – Bazman main faults are forming a network which depends on a riddle zone (Alavi, 1994). Here we segregate joints of folds and faults and calculate fractures of mineralization in related district.

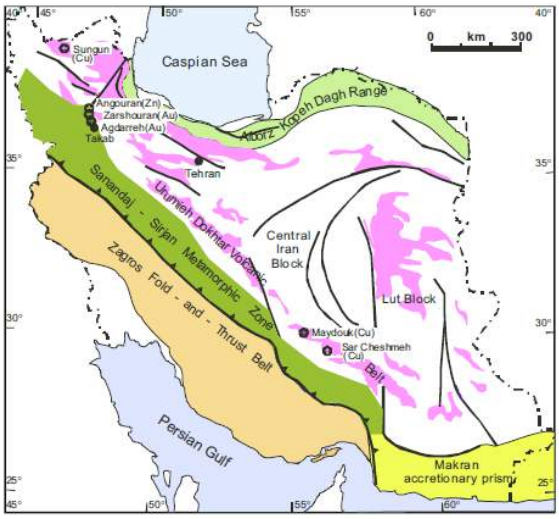

Figure 1. Takab district and Zarshouran epithermal deposit in approximation with Cenozoic –Quaternary magmatic belt, Orumiyeh – Dokhtar which is parallel with Zagros trust and Sanandaj – Sirjan transitional zone (Minerals Production, 2004).

2 REGIONAL GEOLOGY

Zarshouran deposit is located in center of Takab-Shahindezh area that according to Iran's Geological-Structural divisions is part of Orumiyeh – Dokhtar Zone. The most part of this zone includes metamorphic rocks such as Schist, Marble, Ganeiss and Amphibolites that construct the highest mountains (Bolgheis Mountain with height of 3330 and Ghebleh Dagh Mountain with height of 3208 m) at the middle of this area in northwest-southeast direction (Alavi et al. 1982).

Stratum layers in Takab region respectively includes Precambrian metamorphic rocks, late Precambrian – pre-Cambrian and Cambrian – Ordovician sedimentary rocks, Paleozoic metamorphic rocks, diorites, granodiorites and granites, sedimentary rocks, Oligo-Miocene igneous rocks, Pliocene beds and quaternary rocks (Ojaghi, 1996).

Gold sources are located in Ophiolite rock foundations and greenschists of these deposits but mineralization and centralization are performed by magmatic processes such as Tertiary-Quaternary magmatism processes and related hydrothermal solutions which resulted in enrichment of younger rocks (Daliran, 2008).

2.1 Main Structural Procedures in Sahand – Bazman Magmatic Zone

As studied region is part of Sahand – Bazman Magmatic Zone, it is required to review the results of some structural analyses about this magmatic belt and geometrical relation of its main elements.

Sahand-Bazman main faults are constructing a network which depends upon a shear zone that its fractures are developed up to third rank. Primary thrust of right-lateral shear zone which is N125-130 will move in ladder form on the basis of performance of second grade faults and its final and current thrust will be N140. This recommended pattern is extended in all districts of Iran and represents that deformation of every structural zone may depend upon its main thrust and movement of adjacent blocks. Figure 2 is indicating geometrical relations of fractures (Monfared, 2011).

3 Zone Geology

3.1 Rock Units and Present Minerals

Zarshouran deposit is part of southwest crest of anticline in 1:100000 Takhte Soleyman form which generally includes sequential mountains adjacent with deep V valleys. As indicated in figure 3, main rock units in this deposit are as follows:

1. Chlorite Schist Mylonites
2. Serpentine Schist
3. Chal Dagh Crystallized Lime
4. Carbonated Black Shale
5. Recrystallized Lime
6. Porphyry Quartz

And other units.

Gold mineralization in Zarshouran deposit is considerably similar to disseminated epithermal deposit in sedimentary rocks specially carbonated ones (carlin type) (Monfared, 2011).

Some minerals which may be deposited with gold are Orpiment, Realgar, Stibnite, Sphalerite, Galena, Getchellite, Cinnabar, and copper minerals which may be used to

extract Hg, zn, pb, Ascu, and sb. Gangue of this deposit includes quartz, fluorine, barite, and calcite. Paragenetic sequence of Zarshouran deposit is similar to type of carlin and both includes gold, mercury, arsenic, etc. that are formed in late hydrothermal stages (Mehrabi et al, 2003).

It can be concluded that Imankhan schists, Ghal Dagh limes and zarshouran black shale are for Precambrian period which are uplifted by an specific force and being covered with Neogene young units and a long-term fold layer (Monfared, 2011).

3.2 Structural Geology and Region's Tectonics

Structural elements were investigated in 70 Km^2 around of Zarshouran deposit. The studied zone is located in middle part of southwest crest of Imankhan anticline with high protozoic core. This anticline has bilateral plunge with NW-SE (N 125) direction and ellipse form which length and width are respectively about 8 km and 2 km. Imankhan metamorphic complex in located at center of this anticline (Monfared, 2011). Main faults of this area which are affecting deposit's faults and fractures are as follows (figure 4):

1. Tabriz – Zanjan structural line: this line (Zanjan and Mianeh faults) are among the main and basic faults that are located in 70 kilometer of deposit with general direction of northwest – south east (N 130). This is one of the most important structures of northern zone (Monfared, 2011).
2. Shavand fault and parallel faults systems: this is a reverse and right-lateral fault with eastward inclination and N 155-160 direction which is about 65 to 70 kilometer. This thrust with nearest distance of 5 kilometer from studies zone is very important because of its specific role in reformation and generation of mine joints system.
3. Structural Thrust of Ghezel Ozan River: this is located in west of Takab or Ghezel Ozan (more than 200 kilometer width) which is in east of Takhte Soleyman block and has more than 80 kilometer of coincidence with Ghezel Ozan River (Monfared, 2011).
4. N 45 Rock Foundation Thrusts: width thrusts with 42 to 48 direction and staple on main Zagros thrust and Sahand-Zanjan fault. Main thrusts of this field are Sefidroud thrust system (left handed), Talesh-Mianeh thrust (right handed), Aras-Marand (left handed) and eastwart Sahand Block thrust. These have significant role in structural genesis of Iran. This system has considerably affect Imankhan anticline and deposit zone. Frequency of related joints had specific role in mineralization of investigated zone (Monfared, 2011).

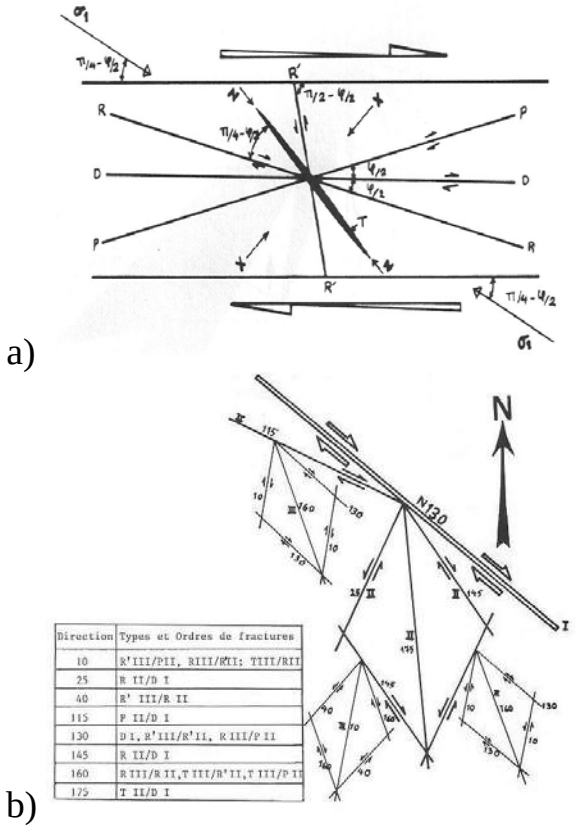

Figure 2. a) Sahand – Bazman faults' system to third grade; b) geometrical relations of 1 and 2 grade fractures (Monfared, 2011)

4 REVIEW OF STRUCTURAL ELEMENTS AND FRACTURES IN STUDIED ZONE

As indicated in figure 3, layers and joints systems were investigated in 4 main structural survey routes, 54 main structural stations, 5 subsidiary structural stations and sampling from 789 joints. 613 items of total

sampled joints were related to Precambrian units, 176 items were related to neogene units that 77 joints were measured in quartz porphyry mass and the others were measured in Oligomiocen sedimentary layer. This progress was performed through analytical methods on Wolf three-dimensional diagrams and Rock Work software diagrams to provide geometrical relations between joints and folds.

4.1 Joints Between Folds

Mentioned joints were formed immediately after impacts of tectonic tensions during various stages of folds formation and their subsequent developments affected by shear deformations, rotary displacements and etc. Four joint systems shall be determined in accordance with folds which are 1) right handed inclined joints (Dd); 2) left handed inclined joints (Dg); 3) longitudinal joints (L); 4) transversal joints (T) (Monfared, 2011). Considering rotation of joints systems of this group around folds, it will be beneficial to understand fold's geometry for realizing better special relation between fractures distribution.

Calculation of bedding of anticline's crest by RockWork software revealed that their transversal rotation will be conical (Figure 5a).

As major part of our study is located in Imankhan anticline's southward crest, local investigations are required for assessing changes of related reformations and may result from transversal shear faults system's performance specifically N 25 system (shear west-east faults). According to figure 5 (a), conical fold's axis is N205/33 which is approximate to anticline's crest incline. Aforesaid processes will develop Z form folds in investigated zone (figure 6). Considering related thrust and direction of southwest crest (N 125) of Imankhan anticline in westward structural survey, there are various joints in this area with average conditions of 004.70, 125.31, 241.76 and 303.57 which are main joints' system depending upon folds in this region (figure 5 b).

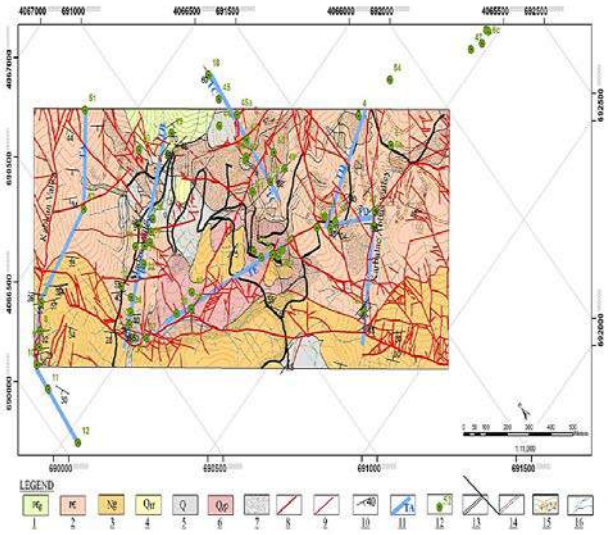

Figure 3. Geology/structural map of Zarshouran gold deposit, structural surveys and sampling stations:
1) Precambrian (Imankhan Schist); 2) Precambrian (Chal Dagh & Ghare Dash Units); 3) Neogene sedimentary – magmatic layer; 4) travertine; 5) alluvium and embankments; 6) quartz porphyry; 7) mineral and diverse units; 8) main fault; 9) subsidiary fracture; 10) bedding; 11) structural survey; 12) structural sampling stations; 13) access road; 14) exploration trench; 15) topography; 16) channel.

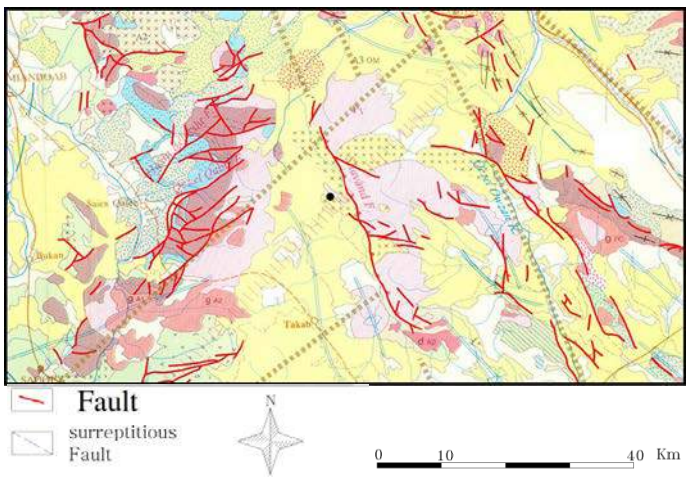

Figure 4. Structural units and elements of current study (SH: Shavand Fault; TB: Takab-Bojar fault thrust; QO: Ghezel Ozan fault thrust (or Takab Eastward Fault); TM: Talesh – Mianeh fault thrust; ZF: Zanjan fault from Zanjan – Tabriz structural line (Monfared, 2011).

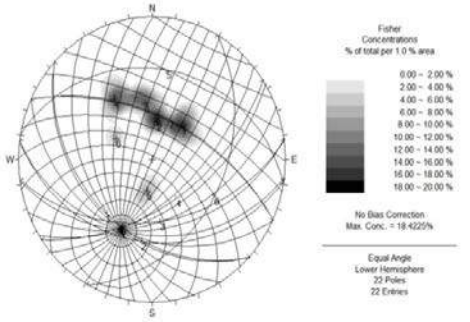
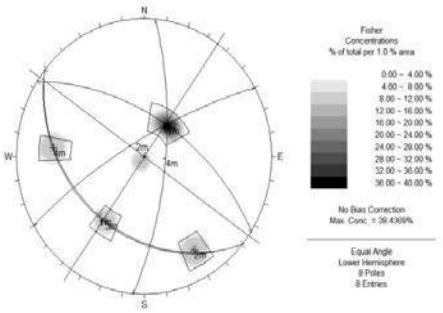
4.2 Joints Which Depend Upon Shear Movements

These joints which are relating to shear tectonics are developed in studied area and had formed in latest periods of transition (Monfared, 2011). Shavand reverse dip-slip and right handed fault with 5 kilometers distance from the deposit is located in Shavand and Kouh Ghebleh foothills (figure 4). Its direction is N155 and its length in outcrop is 65 kilometer. Fractures of this shear field have considerable impacts on development of region's fractures and may result in formation of related systems up to 3rd grade in rock units. Expected direction of these joints shall be in accordance with figure 2. Obviously, development of shear faults may require formation of different T, P, D, R, R fractures (figure 2). Distribution of different fractures of a right handed fault with N130 tension is indicated in figure 2 (b) which can be generalized to thrust of Shavand fault (N155). Assuming that Ø = 30 (angle of internal friction), fractures tension will be calculated up to third grade and mean of probable tensions in eight main systems are summarized in table 1.



a)



b)

Figure 5. a) Conical fold in southward crest of Imankhan anticline considering performance of right slip transversal fault. b) Bedding and fractures of folds in west survey (AB) of studied zone.

(a) (b)

Figure 6. a) Z form micro fold in lime layer of black carbonated schist of Ghaldagh lime field in eastern side and out of the area between Karbalaei Abbas Valley and Maldarasi. b) Z form subsidiary fold in border of Chaldagh greenschist and lime which indicates normal conditions of anticline crest. This fold is located in northwest corner and entrance of deposit's valley.

According to aforesaid information, it will be possible to analyze joints distribution of shear tectonics and distinguish them from other joints which are related to folds. Moreover, considering the importance of rotary movement in shear tectonics, it will be easy to recognize reasons of consequent changes of fractures' tension. Summary of main faults' thrust in Zarshouran district and related fractures (up to third stage) are presented in tables 1 and 2. Considering results of geometrical analysis, reformation in a right handed shear area may justify current structural relations. Structural curve of folds and fractures which are resulted from rotary movement and their relation with main regional faults can be analyzed in this pattern. Accuracy of this pattern is confirmed on the basis of structural analyses of Sahand-Bazman magmatic zone (figure 2) and related data.

5 MINERALIZATION AND ITS RELATION WITH STRUCTURAL FACTORS

Structural factors and fractures have important role which made researchers to investigate them as a positive sign for exploration of new mineral deposits. Faults, crushed zones and fractures which are relating with folds are appropriate places for upward movements of mineral solutions and their sedimentation in upper zones. Chemical actions and reactions of these hot fluids with subsidiary stones in their flow may result in separation of some metals and replacement of other ones. Accordingly, sedimentation may occur in different stages and on the basis of various environmental conditions such as Eh, PH, thermodynamic conditions and physical and chemical specifications of elements in different stages which may result in formation of an economical deposit.

Data resulted from explorative holes, analysis of samples, and field observations revealed that primary source of mineralization is in Zarshouran carbonated black shale units and Chaldagh lime units which had formed an economical deposit near surface by the impacts of various volcanic and tectonic elements. Comparing structural map of investigated zone (figure 3) and position of drilled holes (figure 11) indicate direct relation between increase of gold carat and purity of other metals in fault and fracture zones. For example, hole no. 1 of F11 fault (figure 3) was stopped in 30 meter dept and 25ppm and 24ppm purity was recorded respectively for gold and silver. Investigating log of hole no. 3 revealed that this hole had broke F1 fault in 45 meter dept and indicated respective purity of 18ppm and 13ppm for gold and silver. These were highest purity in mentioned holes that had recorded in junction of faults. Figure 12 is indicating one of the faults in studied zone. Plants, erosion of rocks and formation of soil had hide deformation and layers of mineralization resources. Surface adjustments provided required conditions for observing conditions of this layer.

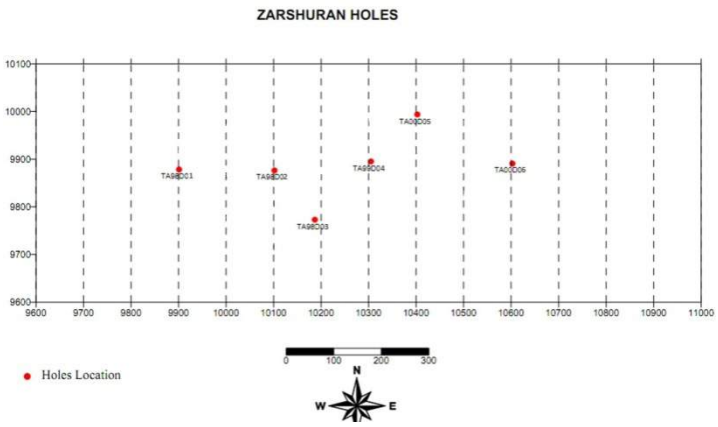

Figure 11. Some Of Drilled Holes In Investigated Zone.

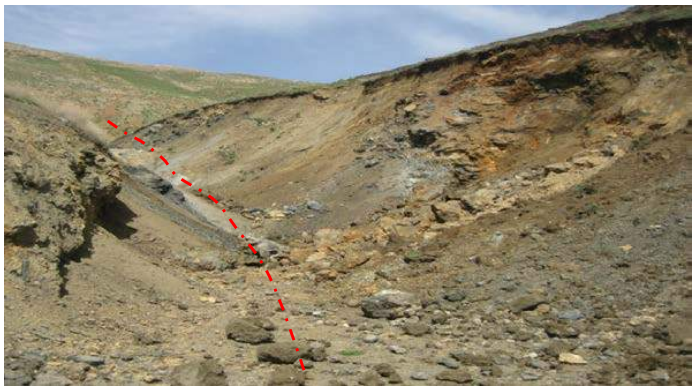

Figure 12. Faults of the investigated zone. Black shale and intense deformation of wall rocks (eastward) are recognizable.

6 RESULTS

Results of geological, field and structural studies, and analysis of samples are as follows:

1. Geometrical dependence of various structural elements in investigated zone (figure 2) are in accordance with combined performance of right handed shear fields with total thrust of N130 and N155.
2. Shear movement is indicating density and significance of regional fractures and development of magmatic phenomena in cenozoic era. These movements and related results (deformation and magmatism) had started in late of upper cretaceous and intensified in third era. The main faults which had affected Eocene rocks can be used as an example.
3. All faults in magmatic belt are relevant with fractures in right handed shear (inclined) zone which at least had developed up to third grade.
4. Basic thrust of N 40-45 is very important for structure of this area. Regional faults of investigated area and even morphology of valleys and channels are affected by this system.
5. It seems that uplifting of lower layers and formation of Imankhan anticline in north of mineralization zone had resulted in genesis of some tension faults and a crushed zone in Shaldagh and Zarshouran rock units which commonly includes lime and shale formations. Removal or decrease of pressure

will provide required conditions for injection and activity of mineralization solutions.

6. Undersurface data and log of drilled holes were reviewed to recognize mineralization host rocks and their development in Zarshouran deposit. The result revealed that host rock of Zarshouran gold deposit is Chaldagh lime unit together with Zarshouran unit.

7. According to data gathered from drilled holes and their logs, it can be concluded that lower schist units (Imankhan) had not affected by mineralization while mineralization solution had respectively penetrate from these schist layers to Chaldagh lime unit and Zarshouran unit.

8. According to performed studies, it is recommended to drill more systematic holes with less distance in Chaldagh lime unit.

Rock Mechanics and Geotechnical Applications

A Numerical Study on Deformation Measurement of Rock Materials using Electrical Resistance Strain Gauges

Elektrik Dirençli Gerinim Ölçer kullanarak Kaya Malzemesi Deformasyonu Ölçümü üzerine Sayısal bir Çalışma

ABSTRACT This study aims to point out the importance of adhesive type on strain measurement and examine the accuracy of the elasticity modulus determination using the electrical resistance strain gauges glued on solid materials. For this purpose, numerical analysis via finite element method was carried out to examine the adhesive type and thickness considering mechanical properties of adhesives. Numerical studies indicated that deformation levels significantly changed for different models of adhesive types widely used in strain gauge applications. Up to 51% strain loss was obtained through the numerical model for the adhesive interlayer. According to the obtained results from numerical analyses, thin adhesive layers with low elasticity modulus suggested the most proper results. These findings pointed out that adhesive type must be taken into account for electrical resistance strain gauge usage since there is no adhesive guide for users in standards.

Keywords: Deformation, electrical resistance strain gauge**,** strain

ÖZET Bu çalışma elektrik dirençli gerinim ölçer metodu ile deformasyon ölçümü üzerindeki yapıştırıcı etkisine dikkat çekmeyi ve bu yöntemin güvenilirliğinin test edilmesini amaçlamaktadır. Bu kapsamda, yapıştırıcıların mekanik özellikleri dikkate alınarak sonlu elemanlar yöntemi ile yapıştırıcı türü ve kalınlığının etkilerinin incelenmesi için sayısal analizler gerçekleştirilmiştir. Sayısal modelleme çalışmaları yapıştırıcı türüne bağlı olarak ölçülen deformasyon miktarlarının önemli ölçüde değiştiğini göstermiştir. Yapıştırıcı modellerinin %51 oranına kadar birim deformasyon kayıbına yol açmış olduğu sonucu elde edilmiştir. Bu çalışmanın sonuçlarına gore, ince ve düşük elastisite modulü değerlerine sahip yapıştırıcı katmanların daha doğru değerler ölçülmesine olanak sağladığı görülmüştür. Bu bulgular ışığında, elektrik dirençli gerinim ölçer ile birlikte kullanılan yapıştırıcı türünün ilgili standartlarda yer alması gerekliliği görülmüştür.

Anahtar Kelimeler: Deformasyon, elektrik dirençli gerinim ölçer, gerinim

1 INTRODUCTION

One of the ways of measuring rock material deformation is the use of electrical resistance strain gauge which is also applied to measure deformation of other solid materials such as concrete, steel and glass (Hoek, 1965; Ozdogan, 1985; Kahraman, 2003; Komurlu, 2012; Brotons at al., 2014).

It is widely known that the electrical resistance strain gauge was invented by American engineers Edward E. Simmons and Arthur C. Ruge in 1938. First application of the strain gauges was the measurement of the water tank wall deformation to define applied stress. In this first experience, ordinary cigarette paper was

glued on the tank, and a small wire with end-connections glued on the paper was used. Then, Ruge and his team developed the strain gauge devices (Feder, 2000).

The place of deformation measurement via the electrical resistance strain gauge can change the results for rock core specimens tested (Ulusay et al., 2005; Komurlu and Kesimal, 2014; Ocak, 2008; Ocak and Seker, 2012; Roberts, 2013; Howarth, 1984). Additionally, undesired results can be obtained as a consequence of non-homogenous distribution of mineral particles through rock materials. According to the ISRM suggestions, strain gauges should not encroach within half of specimen diameter of specimen ends. In addition, strain gauge lengths should be greater than ten times of the maximum mineral particle size of rock material (ISRM, 2007). However, the effect of adhesive interlayer between strain gauge and rock specimen is omitted on deformation measurements, here.

There is also no definite strain gauge adhesive type in standards (ASTM D7012-10; TS 2030; AS 1012.17-1997). Strain gauges are very sensitive to any strain case and transition from the adhesive interlayer. However, these devices can not directly measure the rock deformations. Since the adhesive interlayer transfers the deformation of rock sample onto the strain gauges, it has influential effect on deformation measurements of rock materials. Physico-mechanical parameters i.e. surface shape, porosity, polymerization, thickness and stiffness are also some important variables to affect the strain transfer ability of the interlayer (Lorenzis et al., 2001). Rock strain is transmitted through a stress field varying with the change of adhesive type. Therefore, a portion of the rock strain can also be absorbed by adhesive material (Ansari and Libo, 1998).

In addition, stress transition through intersurfaces has an important role on the sense of deformation by strain gauge and reversible work of adhesive induced by deformation on adhesive interlayer (Cammarata, 1994). Adhesive solidification time shouldn’t be denied as well, since it significantly affects the properties of the intersurface between adhesive and adherends of rock and strain gauges. Waiting time to place strain gauge after the surface treatment with adhesive is critical especially for fast setting glue products. Temperature increases due to exothermic reactions of adhesive polymerization, hence stress at intersurfaces also varies in accordance with the thermal specification of adhesive type (Jiang et al., 2001). Initial stress on strain gauges before loading the rock samples can vary with strain of adhesives during the solidification reactions. The intrinsic stress applied on rock surface due to adhesive polymerization can also change the rock surface stress field underneath the strain gauge (Hutchinson, 1996). With respect to micro-mechanical framework, lacking of guidance about adhesive details can cause some inaccuracy in measurements of strain-stress.

The most commonly used strain gauge adhesives for solid specimens i.e. rocks, concretes are single component cyanoacrylate, two component epoxy and two component polyester based adhesives (TML Co., 2013). Physical properties of adhesive, curing temperature, clamping pressure, duration and thickness are thought to effect the sensitivity of the interlayer. Pore development during polymerization have also an important role on the stress-strain transition via adhesive interlayer material (Lorenzis et al., 2001; Cammarata, 1994; Ansari and Libo, 1998; Park and Eagar, 2004).

Thin cyanoacrylate layers can be easily set by clamping gently at the room temperature, whereas epoxy based adhesives need to be applied with high temperature, high clamping pressure and time. Quick curing time of cyanoacrylate is a significant advantage having also better/thin interlayer when manually bonded. Cyanoacrylate has the fastest setting among all adhesives since it can almost reach its maximum strength within several minutes (Becker, 2010; Senchenya et al., 2007). Therefore, the application process of strain gauge should be as fast as possible due to the fast

solidification characteristics of such adhesives.

Since two components of epoxy or polyester type adhesives must be consumed with ideal proportions for well polymerization, one component cyanoacrylate has an important advantage to increase the application practicality. There are various types of cyanoacrylate adhesives whose viscosities can change within a large range. Cyanoacrylates with high viscosities can be cured having thick layers under gently applied clamping pressures. On the other hand, low viscous cyanoacrylates can easily flow down and decrease the bonding efficiency between rock and strain gauge.

2 METHODS & MATERIAL MODELS

To investigate the effect of adhesive material type and the thickness of interlayer on strain measurements, a series of finite element analyses were carried out using ANSYS software. Eight node solid brick elements (Solid65) were used for three dimensional modeling of rock which has capability of three degrees of freedom at each nodes: transition in the nodal x, y and z directions, cracking under tension and crushing under compression. Rock material was modeled considering the linear elastic material properties that define behavior of the elements. This model predicts the failure of brittle materials in accordance with the Willam Warnke failure criteria used for concrete, rock and other cohesive-frictional materials such as ceramics (William and Warnke, 1974). Material of loading platens was modeled with Solid185 as a rigid steel having a 400 GPa Elasticity Modulus. Contact surface between rock and loading platens were simulated with Conta174 and Targe170 contact pair. Friction coefficient between rock and steel of loading apparatus was taken as 0.3 for all analysis. Two types of adhesive materials were modeled with different thicknesses to compare deformation measurements obtained. One of the adhesives in finite element analysis (adhesive 1) was modeled in accordance with a data sheet of epoxy adhesive (Akfix, 2013a). Model of adhesive 2 was created considering a technical data sheet of another adhesive which is cyanoacrylate based widely used type in strain gauge applications (Akfix, 2013b). Input parameters of adhesives and rock material models are given in Table 1.

Table 1. Input data for numerical models

Input Parameter	Rock	Adhesive 1	Adhesive 2
Poisson ratio	0.25	0.35	0.40
Elast. Modulus (GPa)	20	2.56	1.33
σ_t (MPa)	4	21.86	9.70
σ_c (MPa)	40	-	-

To investigate the effects of thickness differences arisen from personal application details or adhesive type, adhesive layers with length of 30 mm (same with strain gauge length) were modeled with two different thicknesses of 0.5 mm and 1.0 mm. Cylindrical rock samples with the diameter of NX core size and height to diameter ratio of 2 were modeled as stated in ISRM suggestions (ISRM 2007). Mesh dimensions for rock cylinders and adhesive layers were selected as 2x2x2 mm and 2x2x0.25 mm, respectively. A figure for the model of strain gauge on rock specimen and loading platens is given in Figure 1.

3. RESULTS AND DISCUSSIONS

According to the numerical analysis performed for each of the models, the failure load was achieved at the strain level of 2.26×10^{-3}. To assess the sensitivity of adhesive interlayer, inner and outer surface strains were separately obtained (Table 2). For all conditions, there was a significant difference between the strains of rock (inner) and gauge (outer) sides of adhesive layer. Table 3 shows the ratio between the measured (from the adhesive model) and input elasticity modulus values for the rock models. These findings suggest that significant amount of changes can be encountered in elasticity modulus values due to the differences in adhesive strains between rock and gauge sides.

Table 2. Strains of inner and outer adhesive surfaces

Adhesive type - thickness (mm)	*Inner Strain ($x10^{-3}$)*	*Outer Strain ($x10^{-3}$)*
Adhesive 1-0.5	2.14	1.95
Adhesive 1-1.0	2.03	1.50
Adhesive 2-0.5	2.17	2.00
Adhesive 2-1.0	2.09	1.59

Table 3. Ratio between measured and real elasticity modules

Adhesive	Elasticity Modulus (E_{rock})
Adhesive 1-0.5	1.16
Adhesive 1-1.0	1.51
Adhesive 2-0.5	1.13
Adhesive 2-1.0	1.42

Figure 1 and Figure 2 demonstrate the strain variations through the adhesive. Adhesive types and thickness were seen to significantly affect the measured deformations considering the obtained results from the numerical studies. The results confirmed that stress-strain curves become more representative for the rock surface strain as the adhesive interlayer thickness decreases (Jones, 2009; Liao et al., 2013; Kinloch, 1987). There was significant strain loss through the adhesive interlayer especially for the condition of higher interlayer thickness. It is evident here that the characteristics of adhesives and handling of gluing have an important role on deformation measurements since both mechanical and physical properties of the adhesive interlayer vary with application details (TML Co., 2013).

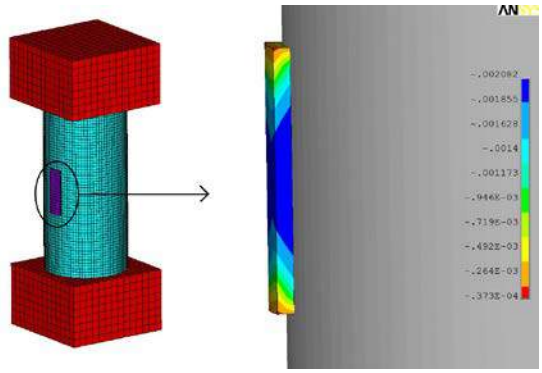

Figure 1. Numerical models of strain gauge and rock

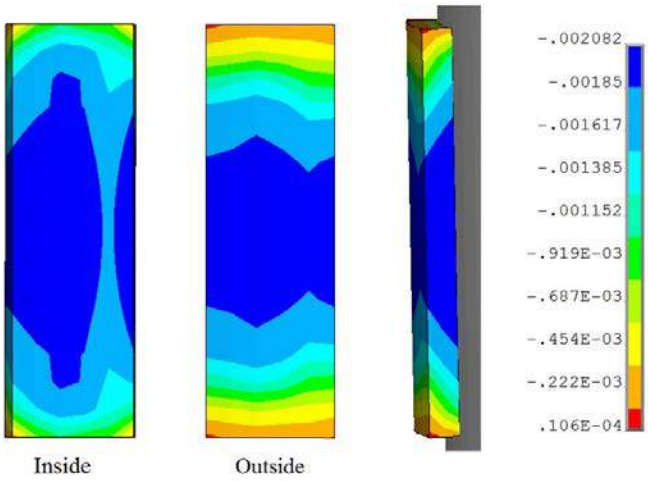

Figure 2. Strain difference between inner and outer surfaces of adhesive layer

Even though the numerical models consider ideal conditions such as perfect adhesion on rock surface and neglect some personal details, 1.51 times greater elasticity modulus than those of rock material was obtained considering the outer surface of the model for epoxy based adhesive.

Considering the adhesive strain which is always known to be less than the strain of rock surface, adhesive giving maximum deformation can be appraised as the most idoneous to be used. It was observed from the analyses that the ratio between predicted (real) and measured elasticity modulus of the models increased with a decrease in the elasticity modulus of adhesive. This data confirms the increase of the deformation sensitivity of adhesive interlayers with a decrease in the elasticity modulus (Paul et al., 2004; Turusov and Kuperman, 2014; Komurlu et al., 2014).

4. CONCLUSION

In this study, different strains up to 1.51 fold were obtained from rock surface and adhesive surface of strain gauge side. Lack of knowledge about standard strain gauge adhesive and acceptance of strain measured with any adhesive may cause important misleading in determination of deformation modulus. Also, ideal gluing application details should be taken into account through the studies to eliminate inaccuracies originating from personal details. For more accurate results, the thickness of the adhesive interlayer should be as thin as possible. This study also showed that increase in elasticity modulus was found to increase the strain loss through the interlayer of adhesive.

A Review of the Properties of Foam Mine Fill

M. Hefni, F. Hassani
McGill University, Montreal, Canada

ABSTRACT Foam mine fill is the new material proposed for backfilling mines, and is fabricated by mixing stable foam into a mixture of tailings, binders, and water. This paper investigates the effects of both binder dosage and the amount of foam used upon the mechanical and physical properties of foam fill, mainly in regards to compressive strength, porosity and density.

Samples were prepared using tailings from a copper mine as the inert material, Normal Portland Cement as the main binding agent, and a foaming agent with a foam generator. Samples were cured for 7, 14 and 28 days and were then subjected to unconfined compressive strength (UCS) testing. Select samples were subjected to mercury intrusion porosimetry, so as to study the microstructural properties. An empirical model was then developed, using a response surface methodology to establish a relationship between the investigated parameters.

Keywords: Foam mine fill, binder dosage, compressive strength, porosity, density

1 INTRODUCTION

The disposal of mine tailings is a significant issue in the mining industry, particularly as mine production increases. Many mines re-use mine tailings for backfilling, which is a method for reducing environmental exposure to tailings, maintaining underground stability, and increasing ore recovery (Benzaazoua, Belem & Bussière, 2002).

This paper introduces a new type of backfill called 'foam mine fill' (FMF). This proposed backfill material is similar to cellular concrete, as air bubbles are entrained in cement or lime mortar, resulting in a cellular structure (Narayanan & Ramamurthy, 2000). Air voids can occupy up to 70% of the volume of concrete, which makes it light- weight, and thus can be used for a wide range of civil applications, including backfilling (Tarasov et al. 2010; Panesar, 2013). Unlike cellular concrete, the incorporation of air bubbles into a mixture of tailings, binder and water makes foam fill a potential new backfilling material. Furthermore, a preliminary investigation on foam fill samples found that pulp densities should be optimized before adding the foam, in order to produce consistent samples without foam segregation or losses (Hefni et al., 2014).

This new lightweight material would provide safer working conditions for miners, especially in underhand cut and fill mining where miners work beneath backfilled stopes. Some claim that the new material has many advantages, especially in terms of weight reduction, rheology improvement and cost minimisation (Cellcrete Technologies Inc., 2013).

This research carries out an in-depth study of foam mine fill by investigating its mechanical and physical properties, and ultimately exploring its potential applications and advantages. The paper presents the results of a laboratory experimental study, in which foam fill samples were prepared and tested for UCS after 7, 14, and 28 days of curing. Furthermore, it adopts response surface methodology (RSM) in order to establish a relationship between the parameters investigated and the response observed.

2 EXPERIMENTAL PROGRAM

2.1 Materials

2.1.1 Tailing

In this research, a copper tailing with the specific gravity of 2.9 g/cm^3 was used to prepare the foam mine fill samples. The tailing primarily consisted of quartz and albite, as well as small amounts of calcite, muscovite, actinolite, rhodoch anorthite, chalcopyrite, biotite, pyrrhotite, epidote, and chlorite. The particle size distribution of the tailing, as shown in Figure 1, was determined using sieve analysis, in accordance with ASTM C136-06 (ASTM International, 2006a).

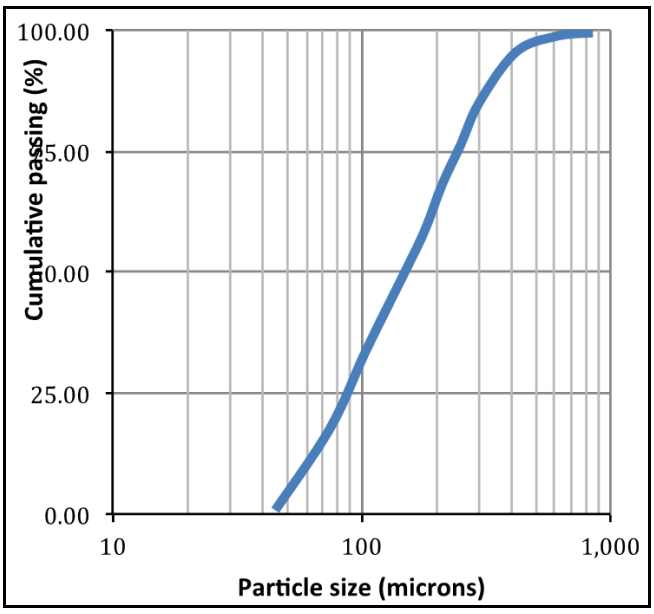

Figure 1. Particle size distribution of copper tailing

2.1.2 Binder

The use of a binder is the most costly component of backfill material, as it represents 75% of the total backfill costs (Hassani & Archibald 1998). This study used normal Portland cement, provided by Lafarge Canada, and with a specific gravity of 3.15 g/cm3, as the binder, since it is used in most Canadian mines. However, other binders, such as slag, fly ash or a blend of different binders are also being considered for further investigation.

2.1.3 Foaming agent and foam generator

Within this research it was essential to use both a high quality foaming agent and an aerator machine in order to ensure foam consistency. Based on previous experimental investigations, inconsistent foam yields samples with different physical and mechanical properties, despite their having the same mixture design (Marquez & Hassani, 2010). These problems were resolved by using the Stable Air® system, which uses Stable Air admixture (complies with ASTM C260 standard) and the Stable Air M100 aerator (ASTM International, 2010a). The foaming agent is a liquid air−entraining admixture consisting of a unique blend of synthetic materials (Cellular Concrete Technologies, Inc. 2013). Admixture is diluted with water to a ratio of 1:120, combined with compressed air, and processed through a patented foam generator in order to output Stable Air foam with a consistent density of 69 kg/m3.

2.1.4Sample preparation and curing

FMF samples were prepared using cylindrical, polyvinyl moulds, with dimensions of 4 inch high and an internal diameter of 2 inches. Samples were cured for 28 days inside a curing chamber, where the relative humidity was kept constant at 90% ± 2%, and temperature was controlled at 25°C ± 2°C to simulate underground conditions. Furthermore, grinding was used to flatten the surface of the samples, in order to make them suitable for the UCS test.

2.2 Methodology

2.2.1Experimental design

Foam fill samples were prepared using three different levels of both binder dosage and amounts of entrained air (Table 1). Pulp density was optimized to 78% to avoid foam loss or segregation. Equation 1 and 2 display the formula used to calculate the binder dosage and mass of foam in the foam fill base mix.

Table 1. Levels of factors tested

Factor	Level 1	Level 2	Level 3
Binder (%)	5	7	9
Air volume (%)	0	10	20

$$\text{Binder (\%)} = [M_b / (M_b + M_t)] \times 100 \quad (1)$$

$$\text{Mass of foam (kg)} = \text{fill vol.} \times \text{air \%} \times \rho_f \quad (2)$$

Where:
M_b = Mass of cement (kg).
M_t = Mass of tailing (kg).
ρ_f = foam density (kg/m^3)

Furthermore, face centred central composite design (FCD), a type of RSM design, was adopted to analyse the experimental results, as well as to develop an empirical model through a statistically designed experiment (Anderson & Whitcomb, 2005). The design establishes a relationship between the factors studied and the response observed, via first-degree or second-degree polynomial models.

Therefore, nine total numbers of runs were required, and Table 2 shows the mixture characteristics of the foam fill samples that were prepared. The response analysed the UCS values after 28 days of curing. DOE PRO® software (SigmaZone, 2013), which calculates the main effect of each factor, and finds which factor has the biggest influence on the UCS values, was used to analyse the results. Furthermore, this software can detect any interactions between these factors. Finally, mercury intrusion porosimetry (MIP) was conducted to investigate the microstructural properties for two selected samples.

Table 2. Mixture characteristics of the samples prepared

Run#	Binder %	Air%
1	5	0
2	5	10
3	5	20
4	7	0
5	7	10
6	7	20
7	9	0
8	9	10
9	9	20

2.2.2 UCS test

UCS tests were conducted in accordance with ASTM D2166-91 (ASTM International, 2006b) on triplicate foam fill samples after 7, 14, and 28 days of curing, from which the overall average was taken. The tests were conducted immediately after removing the samples from the humidity chamber.

3 RESULTS AND DISCUSSION

3.1 Strength Development of Foam Fill

The UCS results displayed in Figures 2, 3, and 4 show the strength development of foam fill samples at different amount of entrained air and with different curing days. In average, 60-80% of the compressive strength is achieved after seven days of curing. This can be explained by the use of Portland cement as the main binding agent, since it has a higher hydration rate than any other binders.

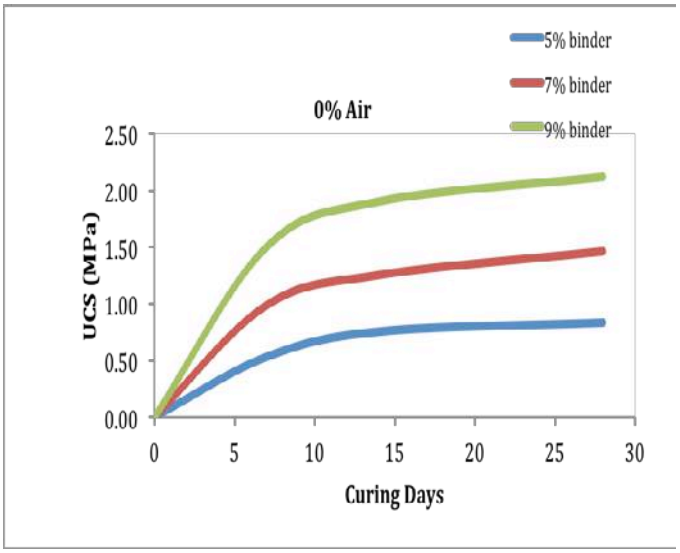

Figure 2. Effect of curing age on UCS at 0% air

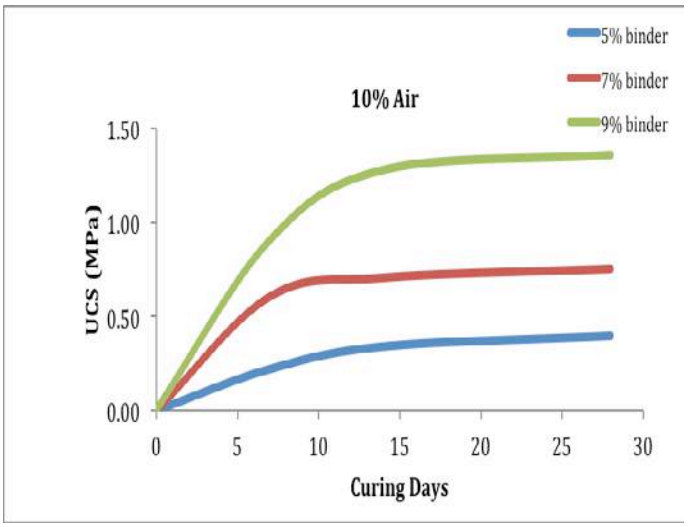

Figure 3. Effect of curing age on UCS at 10% air

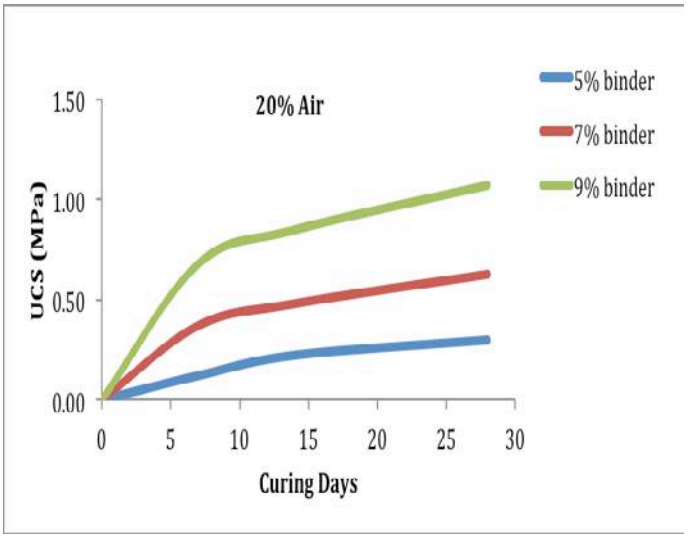

Figure 4. Effect of curing age on UCS at 20% air

3.2 Effect of Binder Dosage and Amount of Air Entrained Upon Foam Fill Properties

The relative effects of both the investigated factors and the interactions between them, in terms of compressive strength, can be graphically represented in ordered horizontal bars by a Pareto chart (Figure 5). This chart clearly shows that the main factors responsible for strength development in foam fill compressive strength, in order, are binder dosage, air volume, quadratic effect of air volume, interaction between binder dosage, and air volume, and finally quadratic effect of binder dosage. Furthermore, they were all found to be statistically significant with a p-value < 0.05.

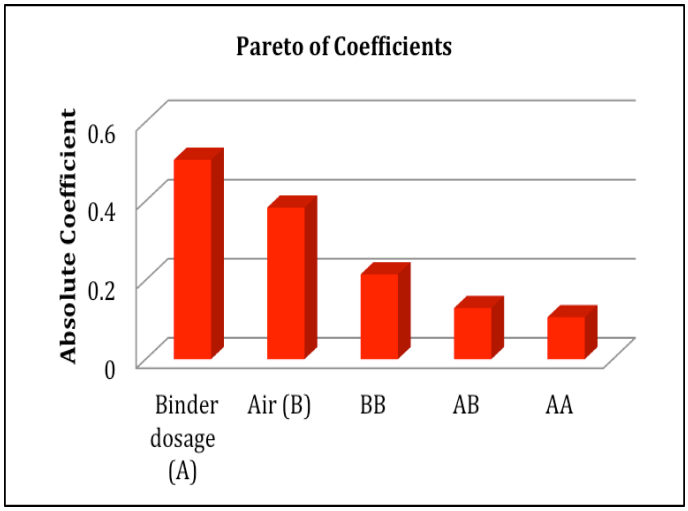

Figure 5. Pareto chart of the relative effects of FMF compressive strength

An empirical model was developed after analysing the data with DOE PRO® software (Equation (3)). Based on this model, measured UCS values were plotted against predicted values in the residual plot shown in Figure 6. The experimental and predicted data can be fitted in a straight line with a R^2 value of 0.9939

$$USC_{28days}\ (MPa) = 0.45 - 0.055A - 0.036B - 0.0065\ AB + 0.027A^2 + 0.0021B^2 \quad (3)$$

Where:
A = Binder dosage in %
B = Air volume in %

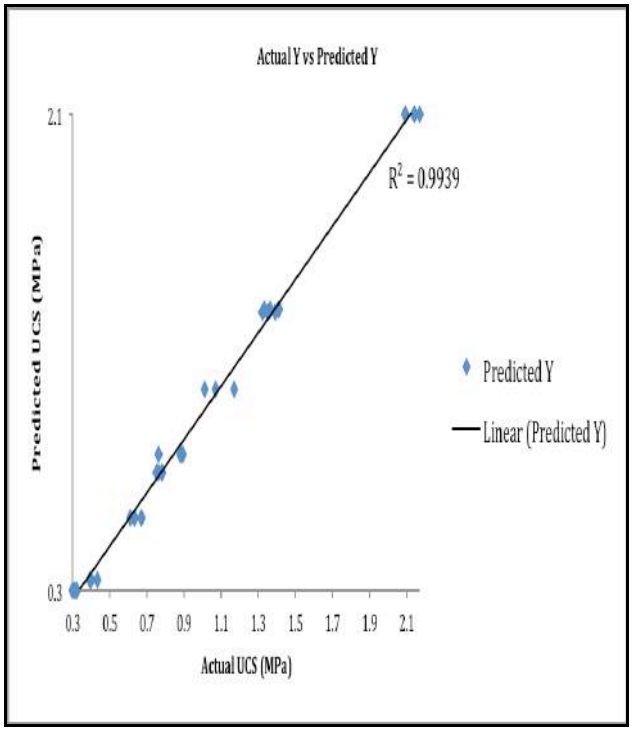

Figure 6. Residual plot of measured and predicted results

The surface response obtained is graphically represented in Figure 7, while Figure 8 shows the top view of this surface.

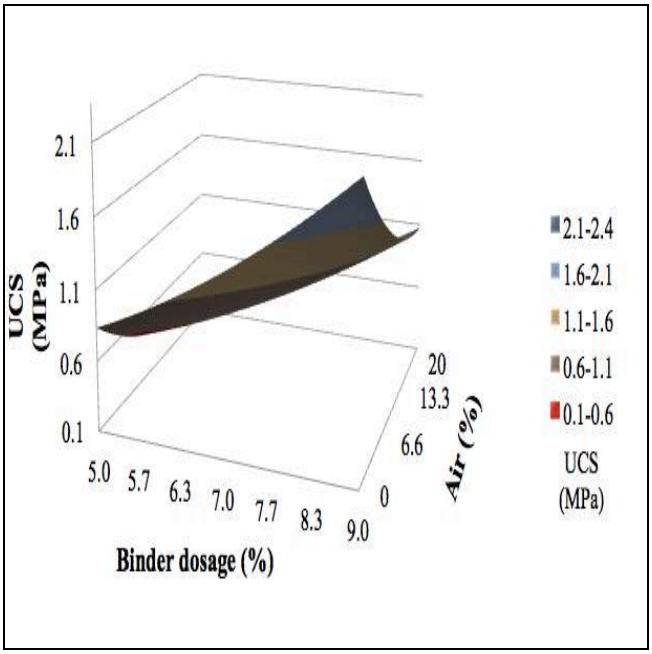

Figure 7. Response Surface of 28 day UCS in 3D view

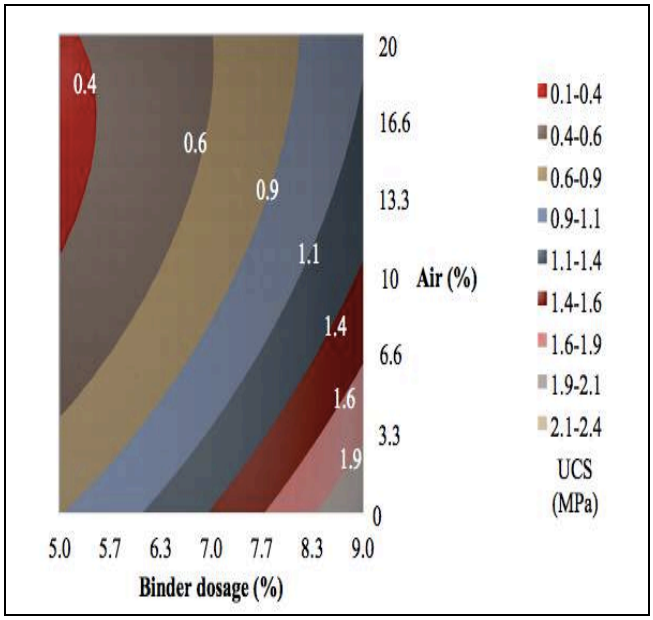

Figure 8. Contour map of 28 day UCS in 2D

The contour map in Figure 8 is used to predict the UCS value for any given binder dosage and air volume. Moreover, it displays an inverse relationship between the amount of air entrained and UCS. On the other hand, there is a direct relationship between binder dosage and UCS. This can be explained by the addition of air in a more porous sample, and hence its decrease in UCS value. This can also be illustrated in Figure 9, in which fill density decreases with the addition of more air.

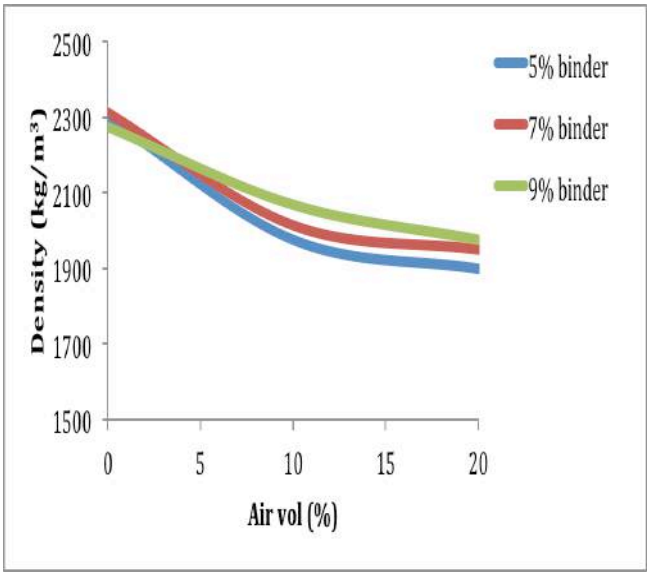

Figure 9. Effect of air volume in 28 day fill density

Finally, the decreases in UCS values are not linear. UCS drops dramatically by 5% for every 1% of additional air. This has been observed when air volume is increased from 0% to 10%. However, when air volume increases from 10% to 20%, UCS drops by 3% for every 1% of additional air. This explains the non-linearity of the empirical model obtained.

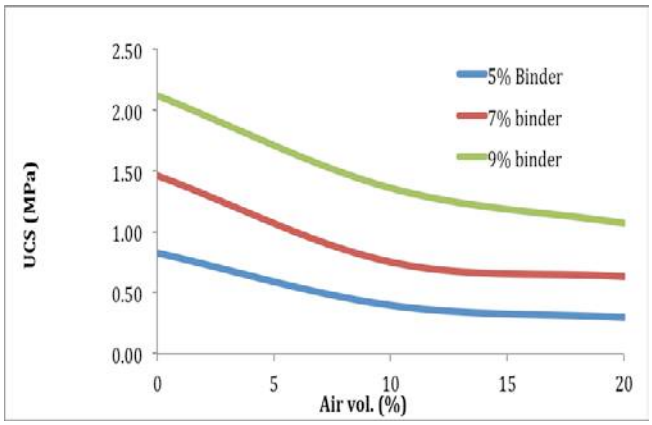

Figure 10. Effect of air volume in 28 day UCS

3.3 Foam Fill Microstructural Properties

In order to investigate the microstructural properties of FMF and its influence upon UCS results, MIP was conducted on two selected samples after being cured for 28 days, one of which had 0% air while the other had 20% air. Binder dosage and pulp density were kept constant at 9% and 78%, respectively.

Figure 11 displays the differential pore size distribution of the FMF samples, where the size of pores can range between 200 and 0.006 µm. Morover, at 0% air most of the pores are in the 1 to 10 micron range, while at 20% air most pores are in the range of 1 to 50 microns. Therefore, those samples with a higher air volume contain a notable increase in pores sizes and frequency. The total porosity of foam fill samples at 10% air and 20% air were 32.66% and 40.57%, respectively (Figure 12). This explains the higher UCS value obtained from the sample with 0% air at 2.13 MPa, in comparison to the sample with 20% air at 1.06 MPa.

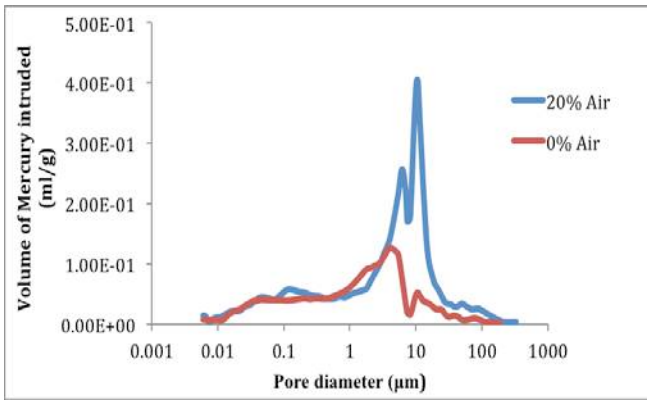

Figure 11. Differential pore size distributions of foam fill samples

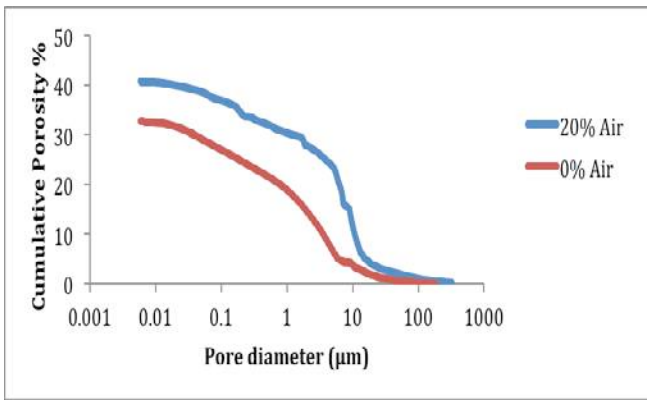

Figure 12. Pore size distributions of foam fill samples

4 CONCLUSION

An empirical model using RSM was developed in order to investigate the properties of foam fill, and it found that UCS values decrease non-linearly in relation to an increase in the amount of entrained air. Moreover, fill density decreases with the increase of the amount of entrained air, which was demonstrated by investigating the microstructural properties, and particularly the increase in porosity at 20% air. This results in a lighter filling material, which can provide a safer working environment for miners. However, the use of foam fill might be restricted, due to its high consumption of binders for maintaining an equivalent strength. There is the potential for foam fill to be used in mines where there is a shortage of tailings. The addition of air can complete the void in fillings, and reduce mining costs of buying sand or tailings from other mines for backfilling purposes.

ABSTRACT Nowadays ground-based Synthetic Aperture Radar Interferometry (GBInSAR) is used internationally as a leading edge tool for the near real time monitoring of slope movements on landslides and open pit mines for either safety-critical and background monitoring purposes. The success of the technology relies mainly on its ability to rapidly measure slope movements with sub-millimetric accuracy over wide areas and in almost any weather conditions. In recent years, GBInSAR has experienced significant improvements in its performances, thanks to the development of more advanced radar techniques on both data processing and sensor performances. In this paper an advanced data processing chain able to simultaneously measure a wide range of deformation rates, across four orders of magnitudes, from very fast movements (up to 150 mm/hour) to extremely low displacements (few mm/month), is presented. The new processing may result in an early detection of slow movements making possible to support mine planning activities, to review extraction methods, mine design, ground support and monitoring practices before movements start to interfere with operations and any problem become difficult or too expensive to be managed. The processing method is presented along with recent successful studies in several Brazilian iron ore mines with different characteristics, owned by Vale S.A. In the sites radar data have been integrated and compared to displacement measurements acquired by radar images and total stations over tens of prisms, in order to improve the interpretation of the local slope movements. This technique could be applied to support long term monitoring in extensive areas adding to the traditional systems and also to define target areas for deeper investigations.

Keywords: Slope monitoring, Open pit, Synthetic aperture radar interferometry (GBInSAR)

1 INTRODUCTION

In the surface mining industry a comprehensive slope monitoring program, aimed at managing potential large-scale instabilities and able to detect at the same time local scale movements, should represent an integral part of every effective slope management system. Among all the parameters to be considered and included in an effective slope monitoring program displacements, either surface or sub-surface components, play a crucial role. In fact, in open pit mines large failures are usually preceded by small scale slope movements, sometimes limited to few centimeters of total displacement and typically characterized by temporal evolutions ranging from several hours to several weeks or months.

The capability of providing advanced notice over the whole slope of impending instability conditions, through the accurate and timely measurement of precursors to slope collapses clearly represents an outstanding benefit for the staff of the pit

involved in the management of geotechnical risk.

The use of ground-based Synthetic Aperture Radar (GBInSAR) in open pit mines is today a standard practice for safety critical monitoring of the pit walls. SAR radar units are effectively used to get a better understanding of the spatial distribution of slope movements and for the provision of alerts in the event of progressive movements that can potentially lead to slope failure, thus aimed at assessing the safety of workers and increase the mine productivity.

Early detection of ground failure allows mine operators to plan and implement appropriate actions (evacuation plans) with sufficient notice to minimize the effect of the failure on personnel safety and mine productivity. GBInSAR radar technology presents the advantages of high accuracy of the measurements, long-range capabilities, limited impact of atmospheric artifacts on the measurement performances, and possibility to simultaneously acquire the response over a large area of the slope without reducing the acquisition time (Antonello et al., 2004; Bozzano et al., 2011; Farina et al, 2011, 2013; Pieraccini, 2013).

The long datasets typically acquired by GBInSAR systems installed in open pit mines (years of continuous data) thanks to the long range and the resulting possibility to monitor the pit slopes without relocating the radar during blasting as it often happens with real aperture radar characterized by shorter working range, have recently made it possible to measure very slow movements over long time periods. Such a possibility makes possible to use slope monitoring radar not only to measure fast movements potentially leading to failures of the slope but also slow movements over years. Here we present the results of advanced data processing algorithms for GBInSAR data developed by the authors able simultaneously to measure a wide range of displacement rates, across four orders of magnitudes, from very fast movements (up to 150 mm/hour) to extremely low displacements (few mm/month), with very high accuracy level (1/10 mm). These advanced capabilities open the doors of a new concept of radar monitoring, where radar also becomes a valuable source of information to better understand the slope behavior before movements start interacting with mining operations. In fact, early recognition of ground movements allows reviewing extraction techniques, mine design and ground support before the instability become difficult or expensive to mitigate. Vale's iron ore geotechnical team, have successfully implemented the advanced monitoring based on the IBIS radar GBInSAR, not only for fast movements but also develop a robust geotechnical model of the slope by taking advantage of the possibility to monitor very slow deformations over a time period of several months. In these sites radar data have been integrated and compared to displacement measurements acquired by total stations over tens of prisms and satellite images in order to improve the interpretation of the on-going ground instability issues. Text is typed in this field as justified.

2 GBINSAR FOR SAFETY-CRITICAL AND LONG TERM SLOPE MONITORING

A ground-based SAR system with Interferometric capabilities is characterized by a limited number of moving parts, being composed by a radar sensor with a couple of small horn antennas that illuminate the monitored area while sliding along a long linear scanner (Pieraccini, 2013). Modern GBInSAR systems perform a full resolution scan of the observed area in a short time (e.g. less than 3 minutes). Fast scan time means reduced impact of atmosphere on radar data and higher sensitivity to the onset of potential failure thanks to the higher sampling rate. The radar used in the two Vale mines described in this paper, are IBIS units. IBIS radar is produced by the Italian company IDS (Farina et al., 2011).

Slope monitoring radar based on real aperture radar technology (typically large dish antennas used to scan the observed scenario) were originally introduced into the

surface mining industry for near real time monitoring of specific “critical” areas of the pit, providing alarms in case of fast movements potentially leading to the failure of a portion of the slope. Due to the constraints induced by the spatial resolution achievable using real aperture radar, by their consequent limited working ranges and the significant time needed to acquire a single radar image those areas have been limited to small sectors of the pit where movements were first detected by conventional monitoring systems such as total stations or geotechnical sensors. The introduction of GBInSAR systems into the mining industry from 2010, thanks to its longer working range (resulting in wider spatial coverage) combined with its fast acquisition, made possible to revolutionize the typical application of slope monitoring radar, passing from a “tactical” use focused on critical areas to a combined and joint “strategic” and “tactical” use. GBInSAR systems in fact are effective used to either cover every few minutes large areas detecting movements over the entire pit slopes and at the same time to follow fast movements in specific sector of the pit, providing alarms in case of fast acceleration.

A further recent advance in the use of slope monitoring radar is associated with the capabilities of GBInSAR to acquire long datasets in combination with innovative processing algorithms to extend the measurable velocity by those systems, including not only fast movements (e.g. mm/day, cm/ day) but also very slow movements (mm/month, mm/year). Any device aimed at measuring displacement can measure it only when the total displacement occurred between the acquisitions used to measure it is substantially over the noise level of the instrument. Considering the typical accuracy of GBInSAR systems (up to 1/10 mm), it follows that in order to detect slow movements such us mm/month or mm/year it is necessary to consider long time intervals in order to give enough time to the movement to exceed the measurement noise. This concept can be easily explained by referring to the interferograms (the maps showing the raw phase variation, proportional to the total displacement) extracted from a radar dataset (Fig.1).

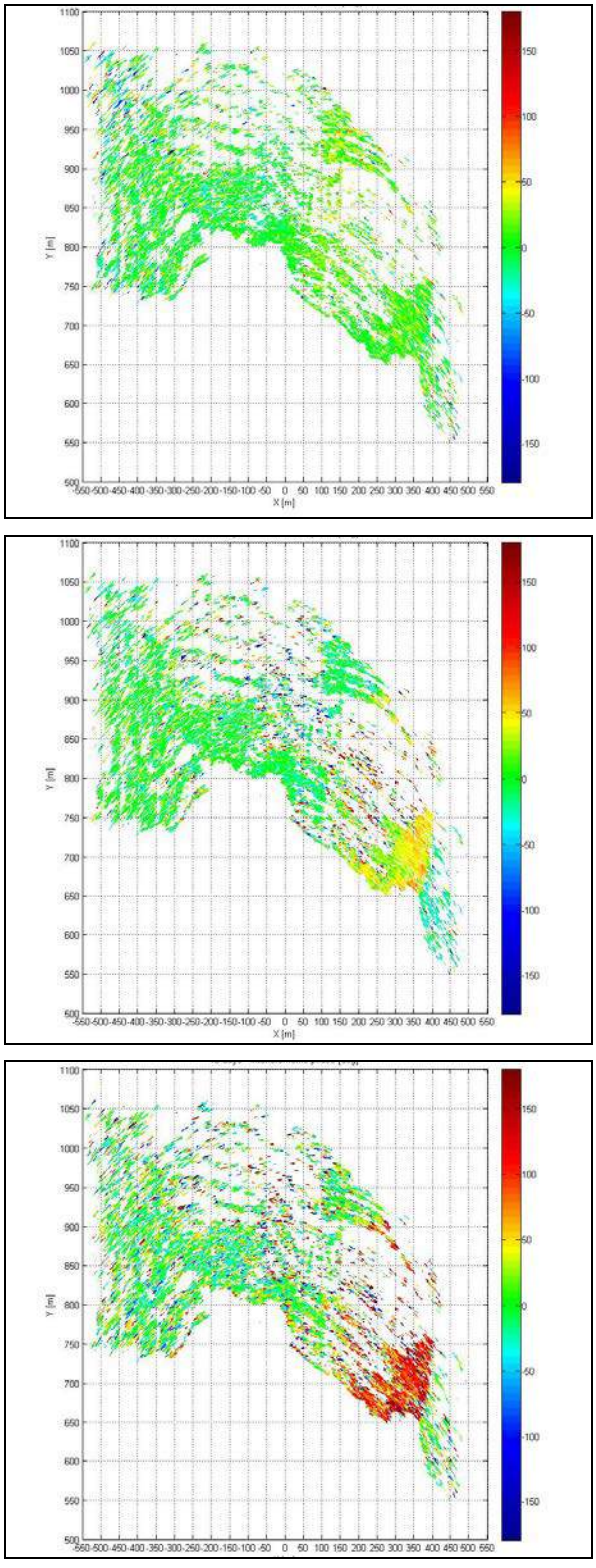

Figure 1. Interferometric phase over 5 minutes, 10 days and 15 days.

From those maps it is clear that the moving areas (yellow and red pixels) can be detected only starting from the interferograms covering a time interval of about 10 days. Unfortunately, since GBInSAR data are

based on the measurement of the signal phase, thus being affected by the phase-wrapping phenomenon, computing the interferomatric phase on a longer time interval leads to possible missing detection of faster movements. Moreover, long time interval between consecutive images typically introduces temnporal de-correlation of the radar signal, thus increasing the noise of the displacement measurement. The only way to detect fast and slow movements in a unique real-time processing chain relies in the combination of parallel processing done at different temporal scales.

The authors have developed an algorithm able to process in real time data at different temporal scales (e.g. for fast movements by processing every consecutive image acquired every 3 minutes, then by processing data every 12 hours, 24 hours, etc. for slower movements). This new processing chain, called “multiscale”, allows to automatically and accurately measure displacements across four orders of magnitudes (from up to 150 mm/h to few mm/month). The algorithm combines the standard high-performance real-time processing routines for safety critical purposes, with an advanced routine able to track slow moving areas with average velocities below a few mm/month.

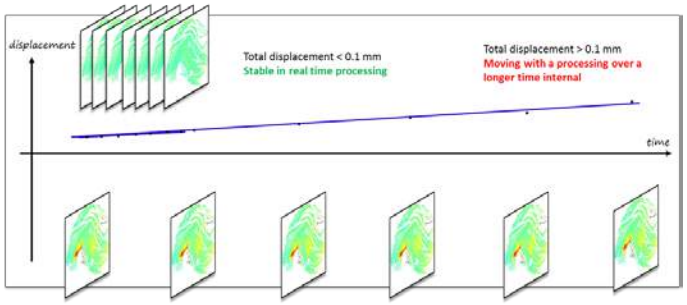

Figure 2. Conceptual scheme of the multi-scale approach.

To simplify the concept of the proposed new processing method, let’s consider an area with slow movements, e.g. 2 mm/month. By processing data every 3 minutes in real time, the movement will not be detected (and the area will be considered stable) until it will exceed the minimum sensitivity to movement of the radar. Considering that 2 mm/month corresponds to 0.06 mm/day and that the minimum sensitivity to movement of the radar is 0.1 mm, this means that before the radar will be able to detect some movement it will take at least a couple of days. If in parallel to the real time processing another processing is run with data under-sampling (e.g. by processing one radar image every 12 hours), after a couple of days that movement will be detected. The multi-scale approach simultaneously analyses the data at different temporal scales and select from each temporal scale the most reliable displacement measurement. The multi-scale approach is composed of following two main steps:

–parallel displacement analysis at different time scales

– merging of the multi-scale analysis into a single multi-scale displacement map

The merging process merges all the single-scale measurements into a single overall displacement map. The merging is performed by dividing the observed displacement velocities into independent (zero-intersection) ranges. Each velocity range is estimated by a correspondent single-scale analysis.

The result of the multi-scale processing is the extension of the velocity range measurable with a slope monitoring radar. By referring to the landslide velocity scale proposed by Cuden and Varnes (1996) slope monitoring radar, thanks to the new proposed processing approach can extend the range of velocity covered adding to moderate and slow landslides very slow (below 1.6 m/year) and extremely slow (below 16 mm/year) events.

In the following sections the results of the multi-scale algorithm used in two test sites in Brazil are presented.

3 GEOLOGICAL AND GEOTECHNICAL OVERVIEW OF VALE’S IRON ORE MINES IN IRON QUADRANGLE – BRAZIL

Vale´s iron south division mines (DIFL), are located in the west part of the Iron Quadrangle (IQ). on the Moeda and Don

Bosco Synclines and Curral Homocline ranges as presented in Figure 3.

The Iron Quadrangle , located in Minas Gerais State (Brazil), in the southern border of São Francisco Craton is one of the most important mineral provinces of the world and concentrates world class mines of gold, iron and manganese mostly. The structure is delineated by the roughly quadrangular arrangement, with Paleoproterozoic Banded iron Formations (BIF) of the Minas Supergroup, as proposed by Dorr (1969).

The iron ore host is composed of hundreds of metres of iron ore rich, banded and heterogeneous metamorphic rocks belonging to the Itabira group/Caue Formation, which constitutes the intermediate chemical member of the Minas Supergroup, a meta-sedimentary sequence. These rocks were submitted to greenshist metamorphism at west and reached amphibolite facies in the east portion (Door, 1969).

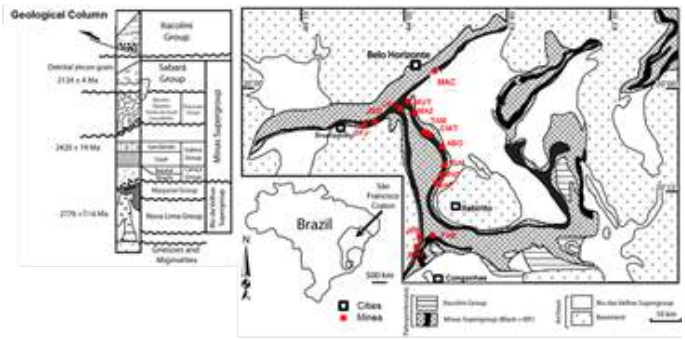

Figure 3. Vale - DIFL mines locations and Iron Quadrangle geological settings

The iron ore deposits present a millimeter to centimeter rhythmic alternation banding of ferrous minerals (hematite, martite and goethite), and no ferrous minerals (quartz, dolomite or amphibolite). Originally called Itabirites as defined by Dorr (1969), these iron deposits are classified as Superior Type according to Gross (1980). The main ore lithologies are: hematite (Fe ≥62%), and itabirite (30< Fe<62%). The main waste rocks are: phyllite, quartzite and intrusive metabasic rocks.

Banding is the most typical characteristic that defines a strong heterogeneity and anisotropy. This variation could be controlled by the original sedimentary bedding, tectonic setting, metamorphic grade, hydrothermal or supergene processes. However, the superposition of these processes causes partial or total mineralogical and textural changes. Usually the mines vary from 200 m to 500 m in depth, covering all set of possible weathering profile from completely weathered to the fresh rocks. As the depth weathered profile, generally seen in tropical countries, many mines presents high percentage of low intact rock strength. These rocks, described as weak are invariably the result of weathering of the original compact prototype imposed by leaching, alteration and/ or dissolution process.

In these mines, more than 70% of exposed slope rocks are weak and the failure mechanisms are conditioned by rock mass strength. However, this proportion can be lower for deeper mines increasing hard rocks percentage to 50%.

Figure 4 presents a typical cross section showing the main rock types and the slope geometry.

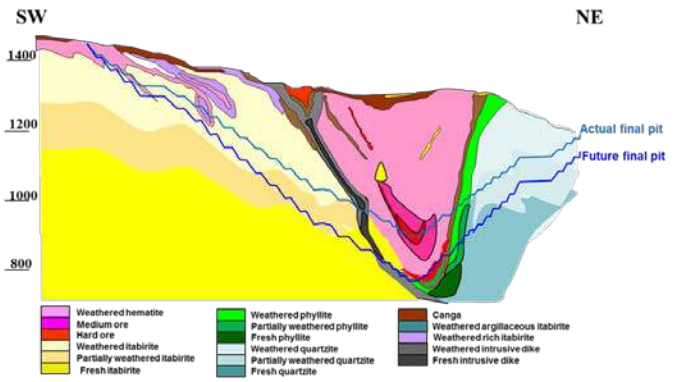

Figure 4. Typical geological cross section presenting the main rocks and weathered profile for Vale iron ore mines.

The weak rocks are more susceptible to instability under shear stress mechanism on intact mass strength due to the reduced rock strength values and secondary over high stress conditions in the slope toe. On the other hand, the hard rocks present failure mechanisms commonly associated with discontinue issues and associated characteristics.

Therefore, due to the dual slope behaviour it`s possible to find all sort of soil and rock

failure mechanisms, that can vary in geometry and velocity.. The deformation velocity observed in hard rocks are generally fast (mm/day), and for weak rocks are considered very low (mm/month) and directly associated with the rain season

For slope instabilities an ideal data acquisition interval is as closer to the continuous monitoring as possible to offer more information in shorter period and increase the ability to detect slow as well rapid and unexpected failures. In addition, high accuracy is essential to detect the early stages of movements and increase the efficiency to detect small failures as described by Osasan & Afeni (2010).

Regarding this issue Kayesa (2006), cited that an efficient monitoring program has to provide the necessary information to the geotechnical team to identify the security levels, record rock and slope deformation, and involve an accurate timing and precision survey necessary to evaluate and support mining operations to manage slope stability. In relation to time data collection an efficient slope monitoring system needs to be able to detect failure, even the small one, in the early stages to prevent failure with a considerable time advantage to avoid it. Girard (2001), pointing out that for safety in mining operations deformation signals must be detected and treated in proper time.

Monitoring these movements is the main challenge for the slope stability team and the GBInSAR technology represent an important assistance to characterize and understand the slope deformations

4. RADAR MONITORING AT VALE MINE SITES WITH GBINSAR

In one of the Vale mine located in the Iron Quadrangle until 2011 Vale's geotechnical team implemented a conventional slope monitoring network using conventional sensors like extensometers and prisms measured by a total station. The data acquired by these sensors until 2011 were limited in space and time thus providing uncertain results on the slope movements occurring on the slope.

For this reason in 2011 Vale included in the slope monitoring program an IBIS slope monitoring radar together with an improve in the prism monitoring. First results, thanks to the real time processing of data acquired every 5 minutes, allowed to exclude the presence of acceleration in the 10 months covered by the radar monitoring. The multi-scale algorithm, thanks to the longer temporal scale processing, at the same time allowed to clearly detect the presence of a moving areas. The average cumulative displacement recorded by the radar for specifically area was 25 mm over 10 months, thus showing a very slow average displacement rate of 0,10 – 0,15 mm/day. The maximum velocity within the same area recorded by the radar on some specific points in the lower part of the wall was of 0.20 – 0.25 mm/day, corresponding to a total cumulative displacement of almost 60-70 mm during the 10 months. Other minor and very localized movements were detected as well (Figure 5).

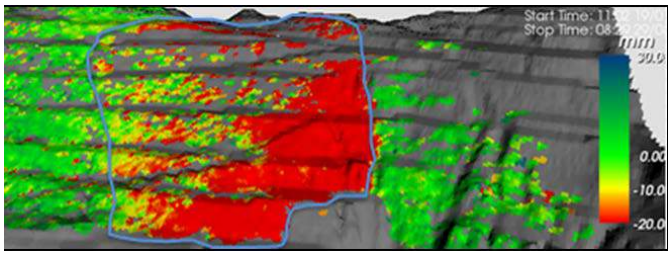

Figure 5. Radar image indicating the movement in the main slope of the closed mine.

Vegetation represents one of the problems of using the radar technology, because it increases the noise level of the radar data. Despite the presence of vegetation in the mine, the IBIS results were very good and able to clarify the temporal and spatial displacement pattern on the pit slopes while subject to a very slow movements.

Another example came from a mine with a network of 100 prisms. Initially an IBIS-FMT mobile radar unit was installed in a frontal position at an average distance of 1.000 m from the wall. Since the vegetation on the slope was introducing some noise in the radar data, IDS developed a dedicated processing tool that improved the quality of

the radar results, reducing the amount of noise thus reaching the expected results.

While the radar was installed in the first position, from July to September (dry season), by using this new processing methodology it was possible to correlate the spatial distribution of the slope movements detected by the radar to the point-wise measurements of the prisms confirming the average velocity of 1 mm/day for the upper part of the wall.

In September the radar was moved to a farther distance (1.250 from the main wall) because the operations in the pit where starting to cover the view to the lower part of the main wall from the original installation site. However, because of the first rainfall occurred in November, the area where the radar was installed started to move thus resulting in the need to move the radar again in early December. The monitoring restarted from a new location at 1.900 m of distance from the wall. From this new location it was possible to cover even the fast movements occurring on the west wall in addition to the slow movements still visible in the upper part of the south wall.

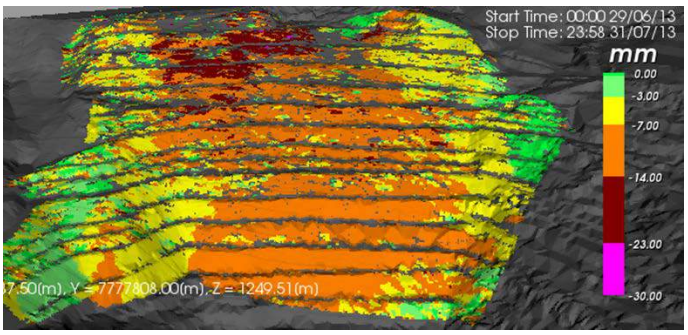

Figure 6. Radar map from position 1 covering a period of 30 days.

At the apex of the rainy season, with rainfall up to 80 mm/day, the displacement accelerated in some specific points both walls up to values of 30-40 mm/day. The rainfall reached peaks of 300 mm/day during this season. In this period the radar data resulted more reliable in comparison with the data acquired by the total station over the prisms (that was almost unable to operate during the heavy rainfalls) and provided more precise information. After the peak of the rainy season, the velocity returned to expected rate, between 0.5 to 3 mm/day.

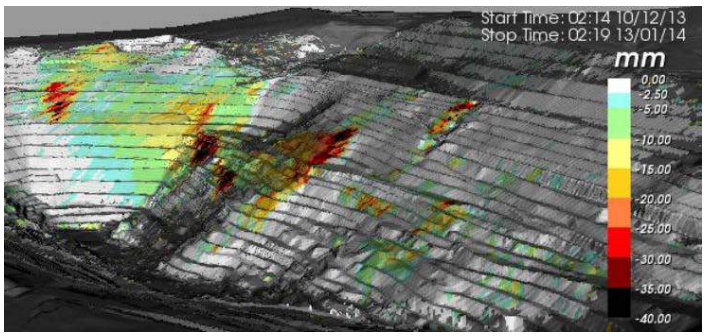

Figure 7. Radar map from position 3.

In the first very moment the radar monitoring was used to define the velocity of the global slope movements and then the radar data supported the definition of the velocities compatible with the operations at the toe and on the wall.

The monitoring results from prisms and radar were then used to calibrate a 2 D, Phase 2 and 3D, Abacus models.

5. CONCLUSIONS

The paper presents the results of advanced data processing algorithms developed by the authors for GBInSAR systems able simultaneously to measure a wide range of displacement rates. Those algorithms have been successfully applied to radar data acquired in some of the iron mines owned by Vale S.A. Brazil.

In the presented case studies radar data have been integrated and compared to displacement measurements acquired by satellite images, total stations over tens of prisms, in order to improve the interpretation of the on-going deformations. The use of integrated approaches combining the capabilities of detecting fast and slow movement supported by prism and field inspections can lead to the timely detection of slope movements in iron ore mines such as showed in the present paper.

The capability to detect at the same time fast movements and slow movements over large areas open the doors of a new concept of radar monitoring, where does not only represent a valuable tool for safety critical monitoring of the pit slopes, but also

becomes a valuable source of information to better understand the slope behaviour before movements start interacting with mining operations. In fact, early recognition of ground movements allows reviewing extraction techniques, mine design and ground support before the instability become difficult or expensive to mitigate.

Analysis of the Effects of Stoping Overbreak/Underbreak on the Effectiveness of Support Systems for Hard Rock Mining

B. S. Lukhele, T. Zvarivadza
School of Mining Engineering, University of the Witwatersrand, Johannesburg, SA

ABSTRACT Underground support systems are essential in all underground excavations. Support systems ensure that excavations are kept stable and safe for people to work in. There are different types of excavation techniques used to excavate underground excavations but the mining industry mainly uses the drilling and blasting technique to excavate in hard rocks. In the underground drilling and blasting excavation method, drilling is an essential component. Inaccurate drilling can lead to stoping overbreak/underbreak which has potential to affect the effectiveness of the support systems used.

One of the objectives of this research was to determine in detail the factors contributing to stoping overbreak/underbreak in hard rock mining. An extensive investigation done at one of the hard rock mines in South Africa using data acquired and analysed, pointed out that factors such as geological structures and general excavation conditions prior to face preparation and drilling contribute to stoping overbreak/underbreak. This research also analysed the effects of stoping overbreak/underbreak on pillar support and the overall support systems at the mine. It was found that significant impact on pillar support is only evident should the overbreak or underbreak be concentrated to pillars which are of close proximity to each other. Pillars that have a pillar width of 7 m and less are at risk of failing as Factor of Safety (FOS) decreases to below 1.5. This is due to the changes that occur to the tributary area supported by one pillar which expands half way to the previous and next pillar. Should two consecutive pillars be affected by overbreak or underbreak, then the stability of the pillars decreases significantly.

This research noted that the overall support systems utilised at the investigated mine are effective and that stoping overbreak/underbreak does not affect the overall stability because there are numerous factors that have to interact in order for the effects of overbreak or underbreak to be substantial.

Keywords: Support systems, stoping overbreak/underbreak, pillar support

1 INTRODUCTION

Rock engineering is concerned with safe design of excavations in in-situ rock masses and the evaluation of rocks behaviour. The rock engineering department at a mine is responsible for ensuring that all the underground excavations are adequately supported and that they are excavated according to design standards. Safety of the workers is the main priority of the rock engineering department. Rock support is considered a system because it combines different components to ensure that excavations are kept stable by means of adequate support. Underground excavations tend to disturb the virgin stresses of an in-situ rock mass and in return the rock mass reacts by opposing the disturbance in order to balance out the stresses.

This paper presents a study on the effects of stoping overbreak/underbreak on the effectiveness of support systems for hard rock mining. Factors contributing to stoping overbreak/underbreak are determined and strategies which can be applied in order to minimise stoping overbreak/underbreak are put forward.

Underground excavations support is considered an important parameter when it comes to design and safety of excavations. Properly supported underground excavations

provides safe working environment, hence the need to address challenges posed by stoping overbreak/underbreak on the effectiveness of support systems.

1.1 The Stoping Overbreak/Underbreak Challenge

Hard rock mining underground excavations encounter occasional stoping overbreak/underbreak which have an impact on the overall support systems utilised. Stoping overbreak is due to excessive fracturing of peripheral blast-holes and results in greater excavated dimensions as compared to planned dimensions while stoping underbreak refers to the volume of intact rock material left unexcavated as compared to the planned excavation dimensions. Geological structures also affect underground excavations especially if the geological structures are intersected by the excavations. Stoping overbreak/underbreak tends to have an effect on pillar dimensions which in turns affects the pillar strength and also the effectiveness of the secondary support systems such as rockbolts.

A geology complex that is highly faulted and intersected by geological structures presents geotechnical challenges on the stability of underground excavations established in it.

1.2 Support of Underground Excavations in Hard Rock Mining

Underground support systems are regarded as one of the key components in ensuring safety and stability of underground excavations. Support systems designs have to account for the different types of excavations and their dimensions. Competent support systems are developed by geotechnical engineers with solid knowledge of rock behavior and factors contributing to the behavior. The installation of different types of support has to undergo strict quality control in order to ensure that adequate support is provided at all times.

There are a number of objectives that support systems tend to achieve. The objectives are related to the application of the support systems and the reinforcement provided by these support systems. The objectives are as follows (De Vries, et al., 2011):

- Ensuring that there is “zero displacement” of the rock mass by applying support that has sufficient stiffness to withstand movement.
- Maximise the support elements mechanical properties by controlling displacement of the surrounding rock with a combination of support systems.

2 RESEARCH APPROACH

Data were collected based on the parameters that were required to analyse the effects of stoping overbreak/underbreak on the effectiveness of the support systems. The data was collected using a routine underground inspection sheet which ensures that all the appropriate parameters are captured during inspection. The dimensions were measured using a digital measuring laser tape.

This information was necessary in analysing the condition of the excavations after blasting prior to drilling of new blast holes. The excavations dimensions were also collected in order to determine the extent of the overbreak/underbreak.

2.1 General Information

The research focussed on the geological structures intersected by excavations and their influence on excavation. Geological information was gathered during daily inspections. From each of the bords and splits ends, the following geotechnical information was gathered:

- rock type
- fault/shear zone
- dykes/sills/contacts
- joints
- brows
- blast induced damage
- weathered zone

2.2 General Excavation Conditions

The data collected under general face conditions were gathered after each advance of the face and were categorised into the categories given in table 1.

Table 1. General excavation conditions

Face conditions	Hangingwall conditions	Sidewalls conditions
• Face barred • Loose slabs on the face • Sockets on the face • Water seeping on the face	• Hangingwall barred • Loose slabs on hanging wall • Support installed to face • Support adequate	• Sidewalls barred • Loose slabs on the sidewalls • Water seeping from the sidewalls • Sidewalls Support required

2.3 Face Preparation and Drilling Accuracy

It is important to drill blast holes in their optimal position to ensure that there is interaction between the blast holes for good fragmentation and also to avoid stoping overbreak/underbreak. Data was collected from stoping faces and it was organised into marking data and drilling data. The face marking data was collected during face preparation while the drilling data was collected during drilling and after the drilling operation was ceased.

Table 2. Face preparation and drilling accuracy

Face marking data collected	Drilling data collected
• Face centre line not straight • Face horizontal lines not straight • Face vertical lines not straight	• Holes drilled off position • Holes less than 1m apart • Holes drilled on an uneven face

2.4 Pillar, Bords and Splits Dimensions

Data of pillars, bords and splits dimensions was collected to determine the extent of the overbreak/underbreak and analysed to check its potential impact on support. The data collected was from the pillars, bords and splits and categorised under excavation data as follows:

- mining height(m)
- bord width(m)
- pillar width(m)
- depth of reef(m)

2.5 Support Installation

The data for support installation was collected and organised into the following categories.

- last row of support from the face
- rockbolts face plate not firmly against hangingwall
- rockbolts per row
- rockbolts spacing

3 STOPING OVERBREAK/UNDERBREAK DATA

Data related to stoping overbreak/underbreak was gathered and grouped according to geotechnical conditions. The geotechnical conditions were necessary in identifying the extent that geological structures have on underground excavations. General excavation condition data was necessary in determining the potential causes of stoping overbreak/underbreak of mining underground excavations.

Stoping overbreak/underbreak has a direct influence on the effectiveness of the support

system especially in bord and pillar mining. Pillar robbing and excessive damage to hangingwall, sidewalls and stope face resulting from stoping overbreak/underbreak affects the overall effectiveness of the support systems. Factors contributing to stoping overbreak/underbreak were determined and their effect on the effectiveness of support systems was analysed. The following factors were found to be amongst contributors to stoping overbreak/underbreak:

- Geological structures
- Drilling accuracy
- Blast-hole pattern
- Blast timing
- Charging-up procedure

These factors were investigated to determine their impact on underground mining operation, stoping overbreak/underbreak and on hard rock mining support systems.

3.1 Geological Conditions Data

The geotechnical data indicated the different geotechnical parameters that are likely to contribute to stoping overbreak/underbreak. The geotechnical parameters were used to determine the effects of geological structures on the excavations at the mine. Pyroxenite is the main rock type and one of the entire inspected panel had Pyroxenite either on the hangingwall or sidewalls.

3.2 General Excavation Conditions Data

General excavation conditions evaluation involved inspecting face, hangingwall, sidewalls and backends conditions. Most common in all the inspected areas was loose slabs that required barring down because of the hazards that they pose and the likelihood of Fall of Ground (FOG). Table 3 show the parameters evaluated for the face, hangingwall and sidewalls conditions.

Table 3. Aspects considered and corresponding parameters investigated

Aspect	**Investigated parameters**			
Face conditions	Face barred or not	Presence of loose slabs on the face	Presence of sockets on the face	Water seeping on the face or not
Hangingwall conditions	Hangingwall barred or not	Presence of loose slabs on hangingwall	Support installed to face or not	Adequacy of support
Sidewall conditions	Sidewalls barred or not	Presence of loose slabs on sidewalls	Water seeping from the sidewalls or not	Sidewalls support required or not

3.3 Face preparation and drilling accuracy data

Proper face preparation and accurate marking of blast holes positions on the face has an influence on the drilling accuracy. Face preparation involves barring of face, marking of centre lines both on the face and hangingwall to ensure that mining is kept within the required mining directions. Drilling direction lines are marked on the sidewalls and hanging wall based on the survey notes issued by the survey department and it includes the required dip and excavation direction.

Table 4 shows the different parameters measured during face preparation. The parameters are recorded based on the percentage off from the correct position.

Table 4. Face preparation and drilling accuracy

	Percentages (%)				
	Face centre line not straight	Face horizontal lines not straight	Face vertical lines not straight	Blast holes drilled off marked position	Blast holes less than 1m apart
Bord 8 Split 15 South	0	5	5	0	0
Bord 10 South	10	10	15	10	25
Bord 12 South	15	10	5	5	10
Bord 12 Split 18 South	20	10	10	15	15
Bord 14 South	10	15	15	20	15
Bord 14 Split 18 South	0	5	5	5	0
Bord 16 South	0	0	5	5	5
Bord 20 South	15	15	10	10	10
Bord 20 Split 17 South	5	5	10	15	10
Bord 24 South	10	10	10	15	15
Bord 24 Split 15 North	0	5	5	0	5
Bord 26 North	5	5	5	5	5
Bord 26 Split 11 North	10	5	5	0	5

3.4 Excavation Dimensions Data

The excavation dimensions data was categories according to pillar, bords and splits dimensions. The excavation dimensions are an indication of the extent of the stoping overbreak/underbreak and they are also an indication of how pillars are affected due to the stoping overbreak/underbreak. Table 5 shows the different excavation parameters that were recorded during data capturing.

Table 5. Excavation dimensions

	Mining Height (m)	Bord Width (m)	Pillar width (m)	Depth of reef (m)
Bord 8 Split 15 South	6.8	5.9	8.2	480
Bord 10 South	5.6	7	7.9	480
Bord 12 South	4.8	6.4	8.0	480
Bord 12 Split 18 South	5.8	6.8	8.1	480
Bord 14 South	6.6	7	7.6	480
Bord 14 Split 18 South	5.2	6.4	8.1	480
Bord 16 South	6.3	6.4	8.2	480
Bord 20 South	7.4	6.2	7.8	480
Bord 20 Split 17 South	6.5	7.2	8.0	480
Bord 24 South	5.2	7	8.0	480
Bord 24 Split 15 North	6.1	6.3	8.1	480
Bord 26 North	5.2	7.5	8.2	480
Bord 26 Split 11 North	5.2	6.5	8.0	480

4 SUPPORT SYSTEMS DATA

4.1 Support Installation Data

For each of the mining area studies, the support properties necessary for evaluating support effectiveness were collected. The properties for bolts included: Bolt type, Bolt length (m), Bolt diameter (mm), Hole diameter (mm), Annulus (mm) and Washer type as well as the resin properties where applicable.

It is essential that support is installed according to the standard operating procedure to ensure effectiveness and efficiency of the support systems.

4.2 Roof Bolter Evaluation Data

The use of effective and efficient support installation equipment is also an important factor in effective support systems. Evaluation of the roof bolter was used to determine its effectiveness in the installation of support. The following are the parameters recorded during the evolution of the roof bolter: Roof bolter boom type, Cycle time (bolts per hours/shift), Drill bit type, Drill bit diameter (mm), Bolt type, Type of pin/nut, Drilling method, Free Rotation speed (rpm), Drill speed (rpm), Resin spinning speed (rpm), Torque (Nm) and Thrust (kN).

5 STOPING OVERBREAK/UNDERBREAK DATA ANALYSIS

5.1 Stoping Overbreak/ Underbreak Challenges

There are a number of challenges which are encountered due to stoping overbreak/underbreak. These challenges have been identified and categories into three groups, namely, production challenges, safety challenges and financial challenges. Each of the challenges was analysed and its practical implications on day to day mining operation expressed.

5.1.1 Production challenges

- Due to stoping underbreak, the required tonnages expected per blast are reduced. The reduction in tonnages coupled with loss in tonnage combines to affect the overall production figures.
- Due to stoping overbreak, ore dilution tends to occur in places were the excavations are advancing close to waste material. The dilution of the ore material reduces the ore tonnage expected from the blast and effect the processing of the ore.

5.1.2 Safety challenges

- Due to stoping overbreak, pillar dimensions are reduced resulting in pillar robbing. Pillar robbing is a safety challenge as it affects pillar strength which in turn affects the interaction

between adjacent pillars thereby reducing pillar stability. Pillar robbing also causes pillar failure due to the weight of the overburden as the pillar sizes are reduced below design dimensions which results in reduced pillar strength.
- Stoping overbreak/underbreak damages the hanging wall, sidewalls and face and results in uneven surfaces which increase the likelihood of scaling and can result in FOG. FOG is regarded as the major contributing factor in most fatalities in underground mines in South Africa.

5.1.3 Financial challenges

- The loss in production is financially challenging as production generates revenue and if production figure are not met, the mine operates at a loss.
- Stoping underbreak results in fewer tonnages produced which affects daily production figures which in turn affects cost per ton figures.
- Stoping overbreak results in larger excavation dimensions which require additional support which means more money than necessary has to be spent on support.

5.2 Geological Condition Analysis

Geological structures intersected by excavations cause major stability problem to underground excavations. These geological structures have the potential to cause blocks and wedges around the excavation. The following analyses was done:

- Fault/Shear Zones

From the 13 panels that were inspected, 9 panels intersected either a fault or a shear zone. This is a total of 69% of the panels inspected.

- Dykes/Sills

From the 13 panels that were inspected, none of them intersected a dyke or a sill.

- Joints

From the 13 panels that were inspected, all of the panels intersected joints. This means that 100% of all the panels intersected joints. Joints have different effects on the stability of an excavation based on the number of factors such as, the joint set number, the joint roughness number, the joint alteration number and the joint water reduction factor.

- Blast Induced Damage

From the 13 panels that were inspected, 1 panel showed blast induced damage. This is 7 % of the total panels and it can be concluded that blast induced damage does not have that much of an effect on the geological structures.

- Weathered

From the 13 panels that were inspected, none of the panels showed signs of being weathered which reduces the effects of joint water reduction factor from the joints intersected by the excavations.

From the geological condition analysis, it can be observed that most of the panels are being intersected either by a fault or a shear zone. The high percentage of panels intersecting either a fault or shear zone means that the underground excavations are prone to stability problems if not properly supported.

There is minimal number of dykes and sills intersected based on the data. The reason for this may be due to the fact that dykes and sills are rare geological structures in the geological complex in which the mine is situated but they have an effect on the stability of an excavation which is why they must be captured if encountered.

5.3 General Excavation Condition Analysis

The general excavation conditions were used to identify the factors that influence stability of the excavation and hence safety of the miners. The general conditions were categorised according to face condition, hangingwall condition and sidewalls conditions. Table 6 shows aspect conditions and the investigated parameters and results for 13 panels.

Table 6. Investigated parameters and results for the 13 panels considering different aspects

Aspect	Investigated parameters and results for the 13 panels			
Face conditions	Face barred or not	Presence of loose slabs on the face	Presence of sockets on the face	Water seeping on the face or not
	3 (23%) not	4 (31%) had	none	none
Hangingwall conditions	Hangingwall barred or not	Presence of loose slabs on hangingwall	Support installed to face or not	Adequacy of support
	5 (38%) not	2 (15%) had	7 (54%) not	6 (46%) not
Sidewall conditions	Sidewalls barred or not	Presence of loose slabs on sidewalls	Water seeping from the sidewalls or not	Sidewalls support required or not
	5 (38%) not	4 (31%) had	1 (7%) had	2 (15%) required

Figure 1 shows analysis results for face preparation and drilling accuracy of the panels inspected. From the 13 panels that were inspected, the average face centre line drawn not straight was 7.7%. The average horizontal lines drawn not straight were also 7.7%. The average face vertical lines drawn not straight were 8.1%. The average blast holes drilled off marked position were 8.1% and the average blast holes less than 1m apart was 9.2%. The number of centre lines, horizontal lines and vertical lines not drawn straight during face preparation affects the blast hole position which affects the holes interaction. The blast hole interaction is essential to ensure that the correct panel dimension are kept after each blast hence reducing stoping overbreak/underbreak.

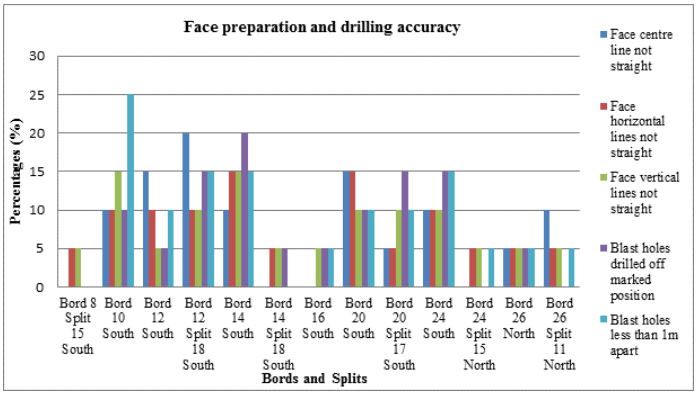

Figure 1. Face preparation and drilling.

Table 5 shows excavation dimensions of the panels inspected and from the table the following analysis in figure 2 was done. Figure 2 shows that 43% of the panels inspected had mining height greater than the designed mining height and 57% of the panels had mining height less than the designed mining height.

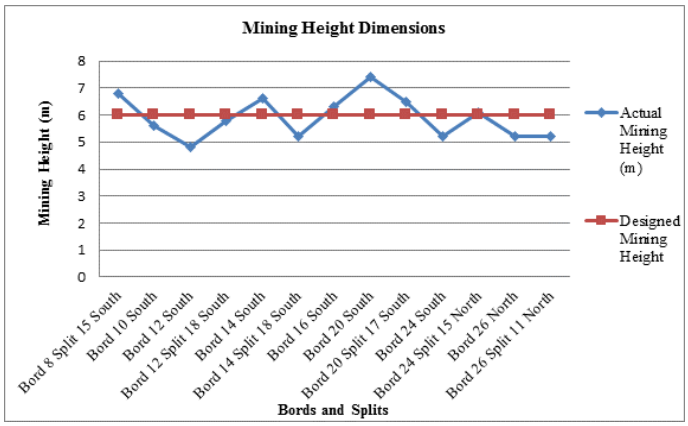

Figure 2. Mining height dimensions

Figure 3 shows 62% of the panels inspected had bord width less than the designed bord width. 23% had the same bord with as the designed bord width while 15% had bord width above the designed bord with dimensions.

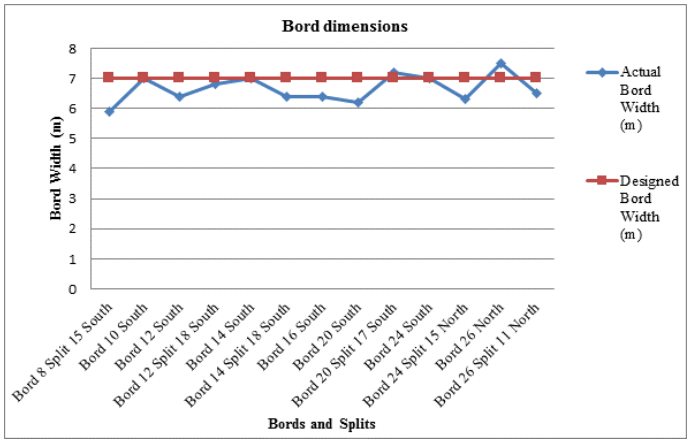

Figure 3. Bord width dimensions

Pillar design calculations were done to analyse the influence of stoping overbreak/underbreak on pillar stability. Figure 4 shows that 23% of the pillar widths were less than the designed pillar width. 31% of the pillar widths were approximately the same as the designed pillar width while 46% were above the designed pillar width. From the pillar strength formula, pillar width is an important design parameter. If the pillar width is less than the required width there is a chance that the pillar will not be able to provide the required stability hence reducing the effectiveness of the support provided by the pillar.

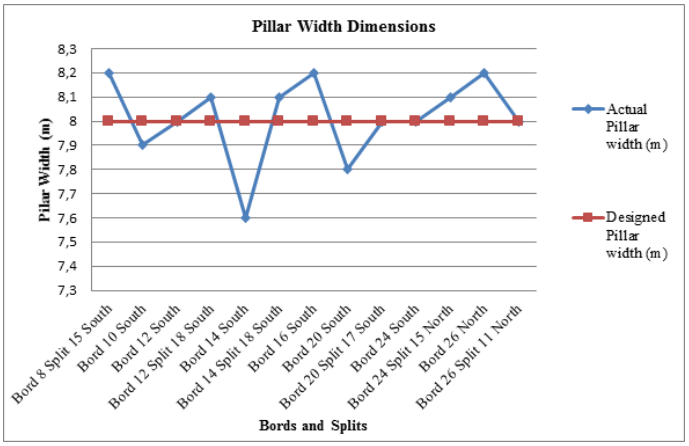

Figure 4. Pillar width dimensions

The rock engineering department monitors all the pillars. In cases where there is a robbed pillar, the adjacent pillar dimensions were increase to provide support for the robbed pillar. Pillar bolting is also done as a precaution to keep the robbed pillar safe.

6 SUPPORT SYSTEMS DATA ANALYSIS

6.1 Support Systems Challenges

Underground support systems encounter a lot of challenges depending on the rock conditions and on the installation of the support. Underground hard rock mining has a number of challenges relating to primary and secondary support. These challenges have been identified and categories into three groups, namely, production challenges, safety challenges and financial challenges. These challenges are discussed as follows:

6.1.1 Production challenges

- Incorrect installation of support leads to additional support which affects the mining cycle and hence production.
- Failing pillars, this requires the section to be closed until the pillars are supported. Production is affected, especially if most of the production is planned from that particular section.

6.1.2 Safety challenges

- Incorrect installation of roof bolts creates unsafe working conditions increasing the likelihood of scaling and FOG.
- Robbed pillars are a safety hazard as the pillars are likely to fail overtime causing the roof to collapse.

6.1.3 Financial challenges

- Re-support requires additional roof bolts which require additional cost outside of the budget.
- Any support concerns which lead to temporal closing of a section is a financial loss as no production will be achieved during the closing off period.

6.2 Support System Installation Analysis

The support systems parameters of the panels inspected were analysed and some of the results are as presented in figure 5. According to safe support standards, the last row of rockbolts must not be more than 1.5m from the face. Figure 5 shows 50% of the last row of rockbolts is more than 1.5m away from the face.

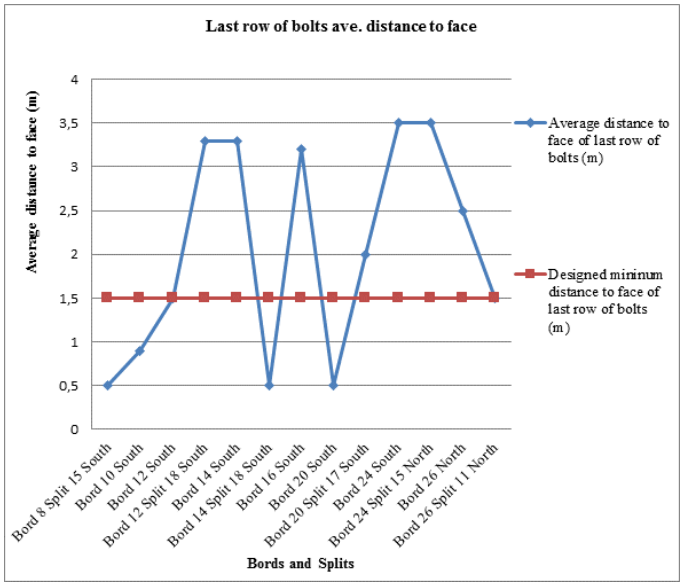

Figure 5. Distance of last row of bolts

From figure 6, it can be noted that 23% of the installed bolts had bolt spacing greater than the designed bolt spacing and 15% of the row spacing was greater than the designed row spacing.

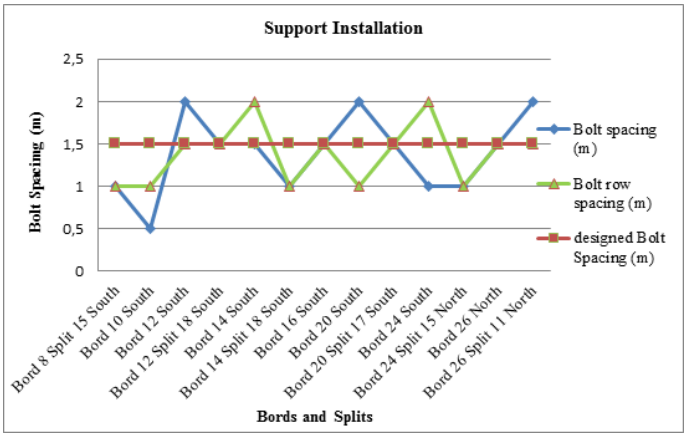

Figure 6. Support installation

The greater bolt and row spacing affects the total area required to be covered by a roof bolt hence affecting the effectiveness of the rockbolts. The optimum ratio of bolt length to bolt spacing is 1.5 (Canbulat, 2008). The mine uses 2.2m long bolts and the minimum spacing that satisfies the optimum ratio is 1.5m and less. In cases were the spacing exceed 1.5m there are chances that the rockbolts are not providing the sufficient stability.

The effectiveness of the roof bolt system is dependent on the density of the bolt pattern. The density of the rockbolts pattern depends on the number of bolts per row and the spacing between rows (Mark, et al., n.d.). This means that if the bolt pattern is not maintained there is a chance that the rockbolts will not be as effective. The number of rockbolts/row less than the required number suggests that at certain locations the support system is not as effective as it should be.

6.3 Roofbolter Analysis

The quality of installation of a support system is directly related to the performance of the equipment that is used to install the support. The relationship between support holes profile, speed, torque and thrust must be inspected as part of quality control and quality assurance of the roofbolter. The recommended roofbolter parameters for optimally producing rough walled holes in South African underground mines are as given in table 7.

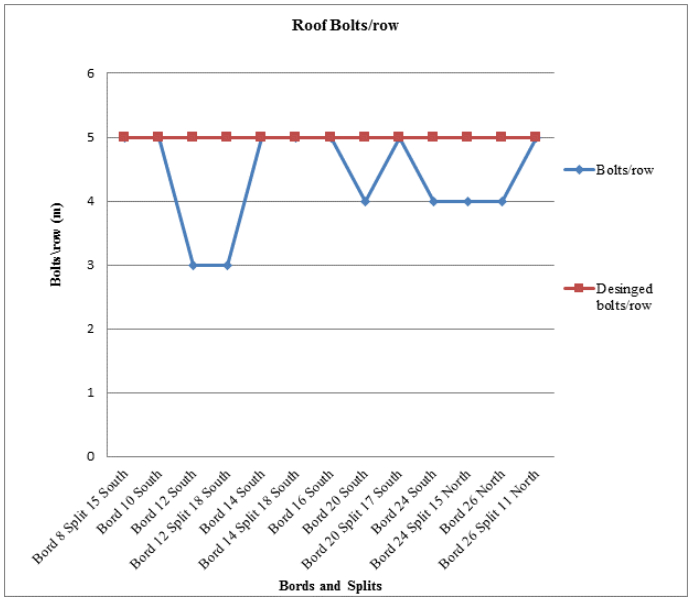

Figure 7. Roof bolts/row.

Table 7. Roofbolter parameters (Canbulat, 2008)

Spinning speed	450 rpm
Torque	240 Nm
Thrust	15 kN

Form table 7, the following observations were noted:

- The free rotation speed, drill speed and resin spinning speed of the roofbolter evaluated exceed the recommended rotation speed of 450 rpm.
- The thrust of the roofbolter far exceeds the recommended thrust of 15 kN.
- The torque of the roofbolter also exceeds the recommended torque of 240 Nm.

7 CONCLUSION AND RECOMMENDATIONS

Safety of underground excavations depends on proper excavation techniques and on proper and adequate support systems including installation. One of the research objectives was to establish and understand all factors that contribute to stoping overbreak/underbreak using the underground hard rock mining data. It is evident that geological features play a major role in stoping overbreak/underbreak. Apart from geological features, the general excavation

conditions prior to face preparation and drilling also contribute to stoping overbreak/underbreak.

Determining the actual impact of stoping overbreak/underbreak on pillar support and support systems was also crucial in this study. The data analysed show that only a few pillars dimensions were not up to the required dimensions. The impact of the reduced pillar dimensions was determined to be minimal as the pillars investigated were not in close proximity to each other and their surrounding pillars were able to maintain the overall stability around the robbed pillars. The FOS of the most robbed pillars was determined to be within the set safe standards due to initial overdesign. Support is considered to be adequate based on the analysed data and on the roof bolter analysis.

The research noted that stoping overbreak/underbreak does play a role in the overall stability but there are numerous factors that have to be combined in order for the effect of stoping overbreak/underbreak to be reliably accounted for.

This research noted that the practice of the following aspects increase stability by minimising stopping overbreak/underbreak:

- accurate marking and drilling of the panel
- accurate barring and marking of the hangingwall so that support installation is done correctly.
- accurate drilling and charging leading to accurate implementation of stoping dimensions design.
- incorporation of smooth wall blasting minimising excavation damage.

Behavior of FPZ and Pre-existing Cracks in an Intact Rock Specimen Subjected to Uniaxial Loading

F. Küçüköztaş, N. Erarslan
Adana Science and Technology University, Department of Mining Engineering and Mineral Processing, Adana, Turkey

ABSTRACT Rock fracture mechanics is concerned with the initiation and growth of fractures in the Earth's crust, rock mass and intact rock at scales ranging from microns to kilometers. This includes the initiation of new cracks from the heterogeneous rock fabric; the opening, closing, sliding, and growth of pre-existing cracks under tension and compression. In rocks, the crack tip non-linear process zone is caused by the initiation and propagation of the microcracks in the immediate vicinity of a crack tip and it is described as the crack tip microcracking zone or Fracture Process Zone (FPZ).This research is a numerical study and focuses on behavior of crack tips in a cylindrical intact rock sample under triaxial stress conditions. All simulations are done by using FRANC2D fracture mechanics program. Results obtained with this study show the behavior of FPZ and fracturing of the pre-existing cracks are found dependent on geometry and position of cracks in the specimen. Some fracture mechanics principles such as fracturing modes mode I (tensile) and mixed mode (tensile-shear) were considered in this research as well.

Keywords: Rock fracture mechanics, Fracture Process Zone (FPZ), FRANC2D, pre-existing crack, mode I, mixed mode

1 INTRODUCTION

Fracture mechanics is the study of propagation of cracks in materials. In general, materials can be classified into two classes, brittle or ductile (Whittaker et al., 1992). The classification can be easily described on the stress-strain curve where the elastic and plastic region could be identified. For brittle materials, plastic deformation areas are significantly smaller than those of materials of high ductility. In simple terms, brittle materials display little deformation followed by a catastrophic failure while ductile materials strains significantly before failure. This paper primarily considers the crack initiation, propagation and coalescence in brittle materials such as rocks and concrete. According to the researches, the brittle materials always have an ultimate fracture point of much greater in compression than in tension as an example of that of concrete which has four times in difference in strength (Whittaker et al., 1992 Erarslan 2011)

In numerical models, all simulations are done by using FRANC2D fracture mechanics program by considering ductility and brittleness and the geometry of the sample has been assumed as a continuous, isotropic and homogeneous elastic body with the cylindrical shape concrete block with two internal flaws are used. The simulations are modelled with the flaw angle of 30°. Since the flaw angle is constant, the simulations are done by increasing ligament length by every 6 mm in both c and s direction.

The critical issue in this research is that once the crack is started in specimen, stress distribution near the crack tip changes very much. In most cases, the crack started from the internal flaw tip due to tension stress concentration but in some cases some stress-induced cracks start around Fracture Process Zone (FPZ). According to this fact, the assumption is made to predict the crack propagation and its orientation.

According to the Linear Elastic Fracture Mechanics (LEFM), crack propagation will start when stress intensity reaches a critical

value, which is called fracture toughness. Therefore, stress intensity factor is having great role in the crack propagation and mainly depends on the fracture displacement modes and crack geometry (Whittaker, et al., 1992).

1.1 Background

When a rock sample is under an increasing load, a dominant internal stress is also increased until it reaches a critical stress level, so called rock strength. Similarly, when a cracked rock sample is under an increasing load with the effect of opening or shearing the crack, a dominant internal stress across the crack tip forms causing an increase in the crack length until it reaches an ultimate crack resistance state, called fracture toughness. Inglis (Inglis, 1913) provided a mathematical solution to the stress magnitudes around an elliptical hole in a stressed thin plate. Based on Inlis's (Inglis, 1913) stress analysis, Griffith (Griffith, 1924) established a relation between the fracture causing stress and the crack size.Griffith states that "brittle solids fail by incremental propagation of a multitude of randomly oriented, small pre-existing cracks." (Griffith 1924) The theory not only applies to microscopic fractures but also macroscopic cracks existing in brittle materials such as concrete. Griffith's theory also states that the total energy on a crack plate is equal to the summation of the boundary applied work, strain potential energy and free surface energy in the free faces of Griffith's crack and facture occurs when the tensile stress at some crack tip exceeds theoretical cohesive strength of the material (Griffith 1924).

1.2 Linear Elastic Fracture Mechanics

Linear Elastic Fracture Mechanics (LEFM) is used to determine the initiation and propagation of cracks in brittle materials. The assumptions of this method assumes material is isotropic and linear elastic. Given this, the stress field around the tip of crack can be analyzed with the theory of elasticity. The fundamentals of LEFM are generally derived from plane strains which are all associated with the three modes of failure: Mode I (tensile), Mode II (shear) and Mode III (tearing). To note, LEFM can only be used when the plastic deformation are small compared to the size of the crack known as the small-scale yielding (Whittakker et al., 1992).

Three basics fracture displacement modes in fracture mechanics are tensile (Mode I), shearing (Mode II) and tearing (Mode III). In opening mode (Mode I), the tensile stress is applied normal to the plane of crack which causes the two crack surfaces to open up and separate from each other. In sliding mode (Mode II), shear stress acting parallel to the plane of the crack which is perpendicular to the crack front. Therefore, the one crack surface slides relative to the other parallel to the crack extension direction. In tearing mode (Mode III), a shear stress acting parallel to the plane of the crack and parallel to the crack front. Figure 1 provides a visual diagram of what the types of fracture displacement modes are.

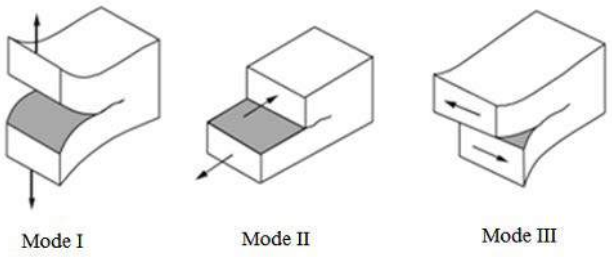

Figure 1. Fracture Displacement Modes

1.2.1 Stress Intensity Factor (SIF)

LEFM states that a crack will propagate when its stress intensity factor (KI) reaches a critical value (KIC). KI is the driving force for fracture and KIC is a measure of material resistance. Additionally, crack initiation started when the value of KI is equal to KIC. Additionally, it is corresponding to the critical state of the stress intensity factor and it is also required for crack initiation and subsequent propagation (Eraslan & Williams 2011)

In numerical modelling, it is expected to evaluate the K value (stress intensity factor)

versus new crack lengths and they are recalculated for each step of the crack length. During each crack length increment, an accurate evaluation of mode I and mode II are foreseeable for the prediction of load and angle change necessary for the corresponding length configuration for the next iteration (Whittaker et al., 1992). The following equation is used to determine the stress intensity factor

The mode I (tensile) stress intensity factor K_I itself is dependent on the crack length, C, the applied stress, σ_A, and a geometry factor, ψ (Whittaker et all. 1992).

$$K_I = \psi \sigma_A \sqrt{\pi C} \quad (1)$$

1.3 Crack Initiation under Compression

Crack initiation under compressive loading forms a much more complicated issue than in tension. Griffith (1924) postulated that crack forms under compression are a direct result from the crack tip of local tensile stresses. Significant differences in failure crack pattern can be observed for both tension and compression. (Whittaker, et al., 1992, Nasser 1995). The equations given by the linear elastic fracture mechanics (LEFM) to calculate stresses and stress intensity factors (SIF) for a crack under tensile loading, are also applicable for a crack under compressive loading, but using opposite signs, i.e. signs of KI and KII become negative. A negative KI means compressive stress acting at the crack tip and a negative KII just indicates an opposite direction of the shear stress acting parallel to the crack plane. As shown in Figure 2, inclination angle (θ) of a compressively loaded crack is such that the crack extension occurs parallel to the major principal compressive stress (Figure 2a), while it is parallel to the minor principal tensile stress in the case of a crack loaded by a tensile load (Figure 2b).

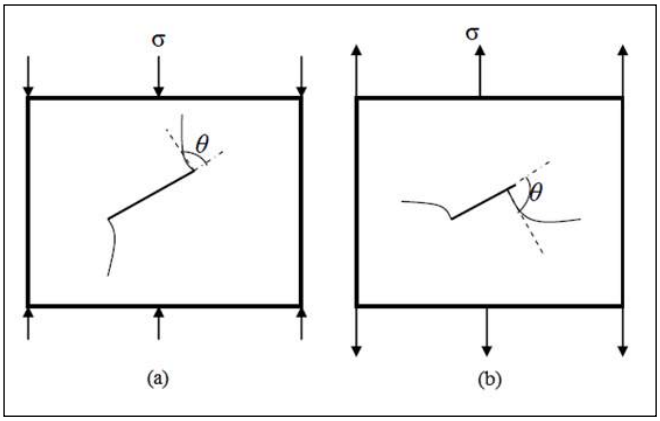

Figure 2. Crack propagation paths under compression (a) and tension (b)

1.4 Maximum Tensile Stress Criterion

The maximum circumferential tensile stress governs the crack initiation and propagation. The theory states:

- Crack propagation will initiate in a radial direction at the crack tip.
- The plane of propagation is normal to the direction of maximum tensile stress.
- Crack propagation occurs if the circumferential tensile stress reaches a critical value which is material dependent.

$$\cos\frac{\theta_0}{2}[K_1 \sin\theta_0 + K_{II}(3\cos\theta_0 - 1)] = 0 \quad (2)$$

The above equation forms a fracture initiation locus. To check whether or not a crack propagates the KI and KII factors, corresponding to the present geometry and given load configuration is substituted into equation to find the direction of probable crack propagation, θ. Then these three parameters KI, KII and θ are substituted into the left hand side of equation. If the less hand side of the equation is in unity, then the crack is stable, otherwise it will propagate Whittaker et al., 1992).

2 METHODOLOGY

The objective of this research is to investigate the relationship between ligament length (a) and stress distribution of the modelled specimen. The three main parameters flaw angle (β), 'c' (continuity) and 's' (spacing) are the main geometrical

parameters in the numerical simulations (Figure 3). Series of finite element modellings were conducted to model notch crack initiation and propagation under monotonic diametral loading. The stress distribution and crack propagation analysis in the specimens were conducted using the finite element program, FRANC2D (FRacture ANalysis Code). The right hand side of Figure 3 shows that, the internal flaws are parallel to each other and they have the length of '2a' or 12 mm. Therefore, 'a' has a value of 6 mm. And the internal flaws have 1mm in width. The ligament length are defined by two directions which include 'c' and's' direction. As shown in Figure 3, this block has the cross-section of 30 mm x 96mm with the height of the 156 mm.

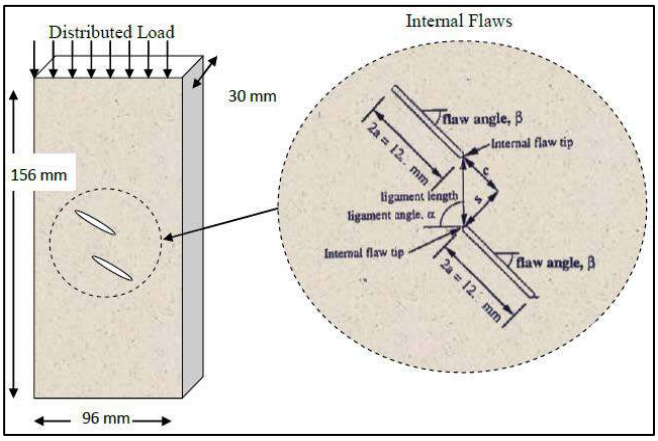

Figure 3. Specimen model and simulation parameters

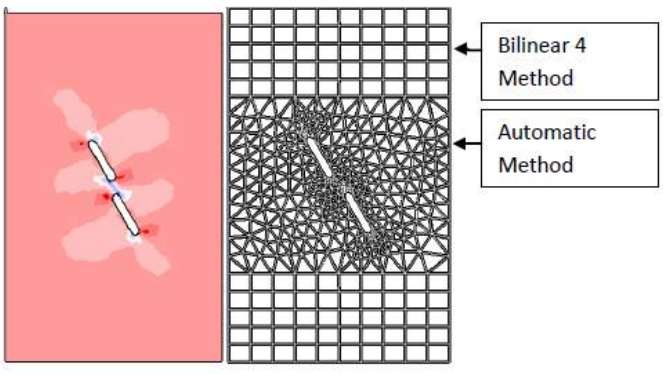
The first step in modelling was to predetermine the specifications of the models that were to be created on Casca. Casca was the meshing software used to construct every mesh and is relatively simple to use, consisting of three main steps to complete a mesh: 1. Outline the shape with the geometry tools, 2. Add nodes along the boundaries of the constructed shape and 3.Mesh the parts of the constructed shape that were meant to be solid.

Before the completed mesh was imported into the testing software, called Franc2D, specifications were devised for the numerous other factors required for the pre-process.

In simulations, the rock has a Young's modulus of 59, 000 MPa and a Poisson's ratio of 0.15. Load is expressed as traction pressure, which corresponds to a projected width of the loaded section of the rectangular surface and distributed load of 2000, 000 N were applied from the top of block. In all simulations, the bottom of the surface was fixed in both x and y directions. It should be noted that the loading traction of this specimen block is not point load because the load was applied as distributed load even very small area is considered. Subsequently Franc2D can display the normal and shear stress distributions in the modelled specimen; these were observed to identify possible crack locations.

After the stress distributions had been observed and the possible crack locations identified initial cracks were made into the specimen. This was followed by a defined automatic propagation of them and an analysis of the stress intensity factors history.

Since the middle part is the most critical section, higher numbers of segments are used Sub Divide function, whereas lower numbers of segments are used for top and bottom parts of the concrete model. Therefore, in final step of meshing, Bilinear 4 method is used for top and bottom part of the concrete block whereas the middle part used Automatic meshing method. In addition, Automatic meshing method give better mesh generation then Bilinear 4 method and this will give the more exact contour data than Bilinear 4 method. The main objective of using both Bilinear 4 method for top and bottom part is to safe time from model simulation by reducing the number of mesh. After using mesh designing, FRANC2D is used for crack propagation (Figure 4).



Figuıre 4. Meshing configuration

3 RESULTS

3.1 Simulations for θ=30°

In general, it was found that the full range of mixed mode loading conditions, including pure Mode I and pure Mode II loading, could be created using an inclined crack with inclination angles (β) between 0° and 90°. Figures 5 and 6 show the coloured contour diagrams for maximum principal stress (Tensile) distribution and shear stress distribution respectively with different parameters for 'c' and 's' values. There are two different sections in these figures and the top four diagrams are the stress distribution due to the variance of 's' parameter with the constant value of 'c' whereas the bottom diagrams are the stress distribution results from varying 'c' parameter with the constant value of 's'. The diagram in the top right corner of the figure shows the colour legend of the stress distribution. Pozitive numbers represent tension and negatives are for the compression.

The loading situations for various inclination angles were simulated properly without any new crack initiation or propagation. In general, the region of tensile stress distribution extended closer to the centre of the chevron notch crack, with increasing crack inclination angles. The maximum tensile stress was obtained along the crack plane at the tip of the β = 0° inclined chevron notch. Increment of 's' and 'c' value was found decreasing the maximum principal stress and shear stress for both before and after crack propagation. Additionally, there are more significant decreases on maximum principal stresses than shear stresses when the ligament length was increased. And also the increment of 's' value have greater impact on decreasing maximum principal stresses than increment of 'c' value.

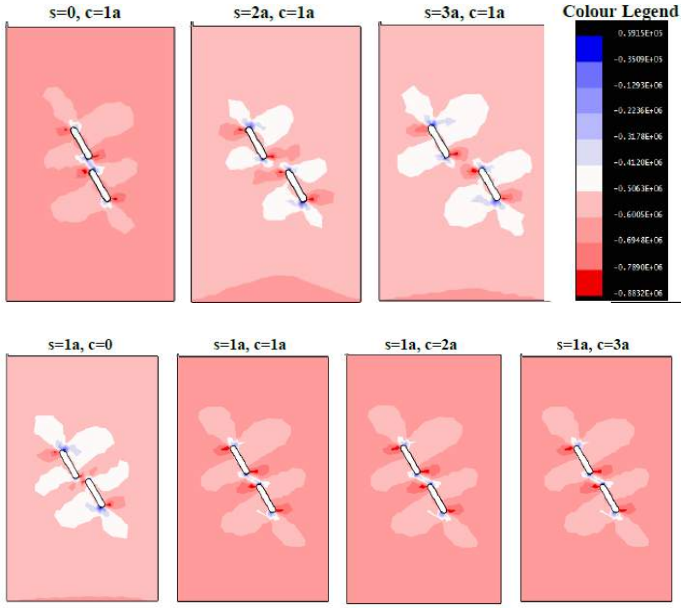


Figure 5. Maximum Principal Stress Distribution before crack initiation

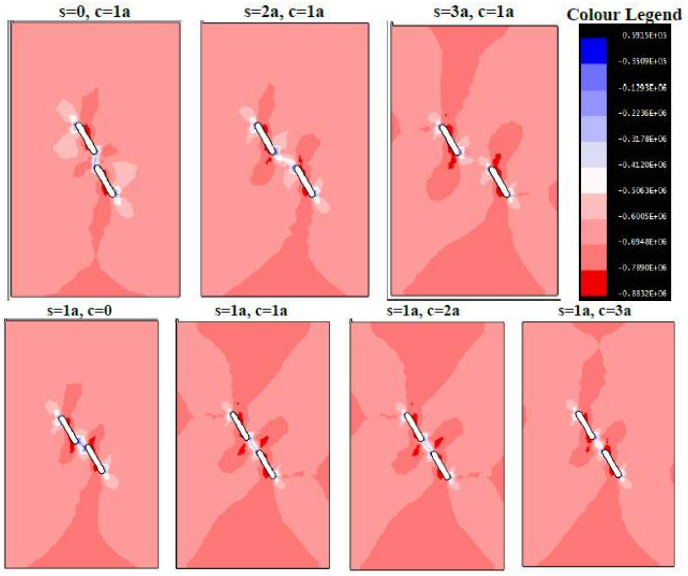

Figure 6. Shear Stress Distribution before crack initiation

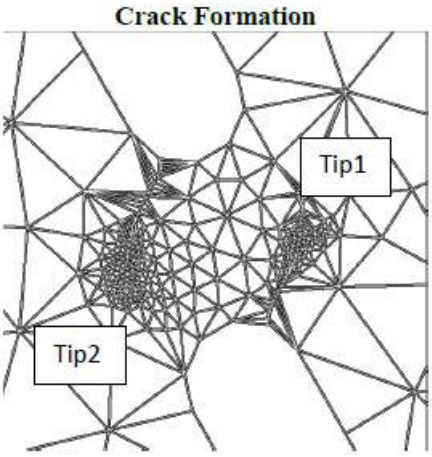
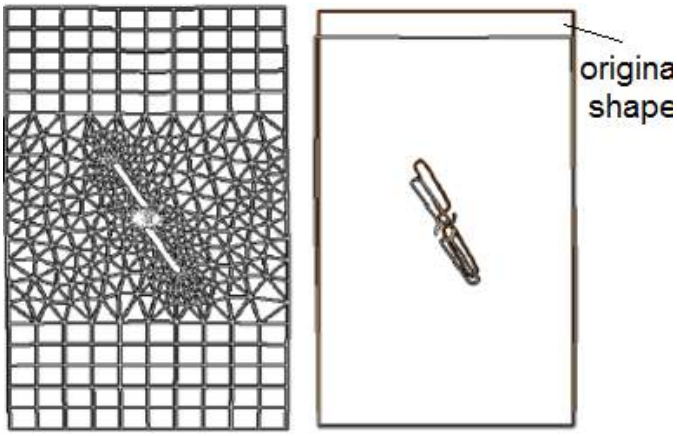
After the stress distribution analysis, crack propagation analyses were conducted to investigate the crack displacements depending on the crack inclination angles. The automatic re-meshing strategy adopted in FRANC2D was to delete the elements in the vicinity of the crack tip, move the crack tip and then insert a trial mesh to connect the new crack to the existing mesh (Figure 7a). The crack propagation simulation results are shown in Figure 7. It was found that the crack initiation angle was strongly dependent on the notch crack inclination angle. Moreover, the direction of crack propagation

was found to be parallel to the loading direction and was in good agreement with experimental findings (Figure 7b). The problem type for crack simulations was plain stress and the crack propagation was conducted using the 'automatic noncohesive crack propagation' option of FRANC2D. However, the cohesive crack model implemented in FRANC2D is for Mode I fracturing only. Hence, noncohesive crack propagation was used in our models for the sake of accuracy of the inclined crack propagation simulations.



(a)



(b)

Figure 7. Crack initiation and propagation simulations (a) re-meshing at the tip (b) stress-induced crack coalescence

Figure 8 shows the stress tracks around the pre-existing cracks. As shown in Figure 8 (left), the compressive stress is quite high around the tip of cracks, it means there are possible FPZ zones around the tips of pre-existing cracks. Although the compressive zone is effective at the tips, there are also effective tensile stresses around the tips for stress-induced crack initiation and propagation.

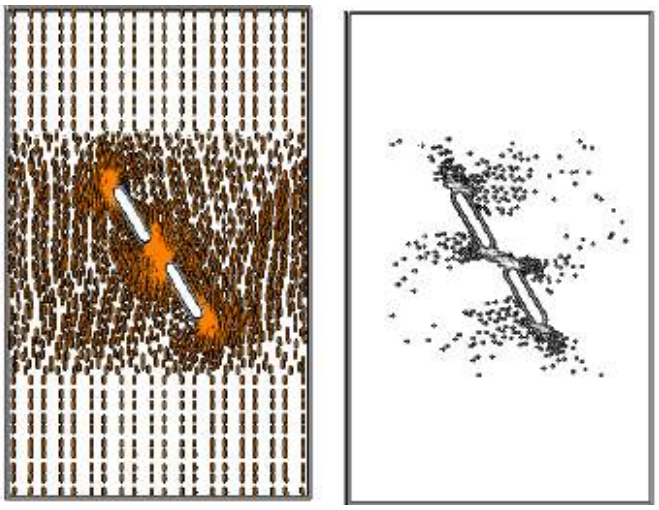


Figure 8. Stress tractions around pre-existing cracks (a) compressive (b) tension

Both the experimental and numerical results were in agreement with the findings in literature (Ingraffea 1981; Al-Shayea 2005; Lin et al. 2009).

4 CONCLUSIONS

In general, the results of the numerical stress distribution analyses showed that it was not possible to obtain pure Mode I and pure Mode II fracturing modes with uniform diametral compressive loading on to the specimen geometry. Both tensile stress and shear stress were found to be effective with all inclination angles and 's' and 'c' values.

In order to check the validity of our numerical modelling, a comparison of numerical results and experimental findings regarding crack extension (θ), crack inclination (β) angle and spacing between pre-existing cracks was made. A good agreement was found between numerical and experimental findings regarding crack extension (θ) and crack inclination (β) angles. The crack initiation angle was found to increase with increasing crack inclination angles and spacing. As the high tensile stress zone extended along the centre of the notch crack instead of the tip, with an increasing inclination angle in the stress distribution analysis in the previous section, crack

initiation in crack simulations started from a region closer to the centre of the notch crack when the β increased.

Although all crack propagations were mixed mode I-II, maximum KI value was always found higher than KII value which means that all these cracks are mainly initiated due to the tensile stress. The KI value also decreased with the increase of 's' and 'c' whereas there were no significance changes for KIIC values.

Comparison of Mechanical Behaviour of G Class Cements for different Curing Time

G Sınıfı Çimentoların Mekanik Davranışlarının Farklı Kür Süresine Göre Karşılaştırılması

D. Guner, H. Ozturk
Middle East Technical University, Mining Engineering Department, Ankara, Turkey

ABSTRACT Since 1900's, well cementing is one of the most substantial method in casing application of oil, gas and geothermal. The American Petroleum Institute (API) identifies well cements in 8 classes with respect to pressure, temperature and the depth of the well. G class cement is the most commonly used cement type for well casing purpose due to its sulphate resistance ability. High sulphate-resistant (HSR) G class cements are often used in well cementing industry. API Standards mainly focus on uniaxial compressive strength (UCS) value of cements cured for 8 and 24 hours. There is no any available research on the long term (14 days) properties of G class cement in the literature. This study presents the comparison of UCS and Elastic modulus (E) growth of 3 different G class cements (2 domestic, 1 foreign products) over 14 days curing time. During the laboratory studies, samples prepared in the laboratory conditions with different curing times (2, 7 and 14 days) are tested based on ASTM standards. It is concluded that the increase in the curing time improves the UCS and E of cements 2-3 times. Logarithmic relationships exist between curing time and UCS, E. Moreover, mechanical properties of these products show significant differences between each other. The UCS and E values of G class cement produced in Turkey have values incontrovertibly lower than that of an equivalent foreign product.

Keywords: G class cement, curing time, uniaxial compressive strength, elastic modulus, high sulphate resistant (HSR), cement mechanical properties, casing

ÖZET 1900'lü yıllardan beri kuyu çimentolaması petrol, doğalgaz ve jeotermal kuyuların muhafazalanmasında kullanılan önemli bir yöntemdir. Amerikan Petrol enstitüsü (API) kuyu çimentolarını kullanılabildikleri basınç, sıcaklık ve kuyu derinliklerini esas alarak 8 farklı sınıfa ayırmıştır. G sınıfı çimento yüksek sülfat direnci nedeniyle bu çimentolar arasında kuyu muhafazası amacıyla yaygın olarak kullanılan bir çimento türüdür. API standartlarında bu çimentolar için genel olarak 8 ve 24 saatlik kür sürelerine bağlı tek eksenli basma dayanımı (TEBD) ve Elastik Modül (E) değerleri üzerinde durulmuştur. Literatürde bu çimentoların uzun vadede (14 gün) ulaştıkları TEBD değerleri bulunmamaktadır. Bu çalışmada 3 farklı firmanın ürettiği (2 yerli 1 yabancı) G sınıfı çimentoların kür süresine bağlı olarak TEBD ve E değerlerindeki artışlar sunulmuştur. Laboratuvar çalışmalarında, numuneler belirli standartlar ölçüsünde hazırlanıp farklı kür süreleri (2, 7 ve 14 gün) için deformabilite testine tabii tutulmuştur. Sonuç olarak çimentoların kür süresindeki artışın TEBD ve E değerlerini 2-3 kat arttırdığı görülmüş ve bu ilişki logaritmik eşitliklerle açıklanmıştır. Ayrıca tüm deney koşulları sabit tutulmasına karşın test edilen 3 ürünün mekanik özellikleri arasında önemli farklar gözlemlenmiştir. Yerli ürünlerin TEBD ve E değerleri eşdeğer yabancı ürüne göre yadsınamayacak şekilde düşüktür bulunmuştur.

Anahtar Kelimeler: G sınıfı çimento, kür süresi, tek eksenli basma dayanımı, elastik modül, yüksek sülfat direnci, çimento mekanik özellik, kuyu muhafazalama.

1 INTRODUCTION

Well casing has always been primary concerns for various different drilling purposes. Although generally the petroleum industry is well known for its casing system applications, there are many other fields; such as geothermal, natural gas and solution mining industries also use well casing applications. The primary purpose of cementing is to keep the casing in place, to provide stability and zonal isolation of the well, to prevent corrosion and to avoid the influx of fluids or gases into the annular space of the well.

American Petroleum Institute (API) is the only authorized standardization committee in this area. This institute classifies eight categories of cements depending of the well condition and use of well cementing purposes (API, 2005). These categories are listed in Table.1 for different depth and temperature ranges.

Table 1. API Well Cement Classification

Class	Depth Range (m)	Temperature Range (ºC)
A	0-1830	0-77
B	0-1830	0-77
C	0-1830	0-77
D	1830-3050	77-127
E	3050-4270	77-127
F	3050-4880	110-160
G	0-2440	0-93
H	3660-4880	0-93

Among these cement classes, more than 80% of the companies prefer class H & G cements for well cementing in the United States. On the other hand, the rest of the world (more than 95%) uses class G cement (SPE, 2009).
The general properties of class G cements are;

- Obtained by grinding Portland cement clinker,
- Consist of hydraulic Ca_2SiO_4,
- Generally contains one or more forms of $CaSO_4$ as an interground additive,
- No more additives other than $CaSO_4$ and H_2O.

Two different forms of class G cements are available on the market, namely medium and high sulphate-resistant (MSR, HSR). HSR type cement is more commonly used cement type in petroleum, natural gas and solution mining industry.

Although API standards give fine details of specification of class G cements, according to these standards there is no any requirement of minimum uniaxial compressive strength (UCS) value at the end of 24hours curing time. However, early or late UCS and Elastic Modulus (E) of casing might be very crucial for preventing influx of fluids or gases from neighbour rock to a well or from well to the neighbour rock.

There are many different class G suppliers in the world. In this study, three different HSR class G cements are tested (two are from local, one is from international) in accordance with test standards and the relationships between UCS, E vs. curing time is found.

2 PREVIOUS TESTS

Although the long term performance of the stated cement is not indicated in production standards, some researchers performed laboratory test with different conditions; such as different curing temperature and pressure to investigate the performances of them. In the last decade, various research studies were performed UCS and E tests on the performance of cements. The obtained results are tabulated in Table 2.

In the literature, there is only one study about the investigation of long term performance of class G cements: Teodouri et.al. (2013) performed UCS test with 5cm length cubic specimens. They stated that one day cured UCS of the specimen is about 6MPa, and this value increased substantially to 56MPa for 20 day curing. In this study, Class G cement composition had a water cement (w/c) ratio of 0.45 without any additives and the density of the slurry was given as 1.89 g/cm^3.

Table 2. UCS & E Values of Class G Cements from the Literature

Ref.	UCS (MPa)	E (GPa)	Test Conditions
Le Roy et al. (2000)	37	6.6	Cured at 77°C, 27 MPa p. for 3 days
Morris et al. (2003)	40	5.4	Cured at 84°C, 27 MPa p. for 2 days.
Wehling (2008)	49	8.7	Cured ambient temperature and p. 3 days
Teodouri et al. (2012)	48	12.0	Cured ambient temperature and p. 3 days.
Nasvi et al. (2013)	53	-	Cured at 60°C, for 3 days
Nasvi et al. (2013)	27	-	Cured ambient temperature and p. 3 days

3 LABORATORY STUDIES

Three different Class G cement products are tested in the laboratory for UCS and E determination.

3.1 Sample Preparation

Sample preparation is the most laborsome part of the laboratory testing. In order to obtain homogenous test specimens, all test specimens for each product were prepared in a single mixing process.

In mixing process, electric mixer is used at 120rpm level for all products. The samples are prepared at a constant water - cement (w/c) ratio of 0.5 (Figure 1.)

Figure 1. Slurry Agitation Stage

At the end of the mixing, density of the each slurry was measured as 1.81g/cm^3. After mixing of cement and water, slurry is poured into cylindrical 50mm diameter PVC moulds. Sometimes, it is hard to remove test specimen from the moulds, to prevent this problem and not to damage the specimen, releasing agent is sprayed into mould before casting. Prepared moulds are presented in Figure 2. PVC moulds were prepared 2-3cm longer than the aimed sample length to account for shrinkage in length during curing.

Figure 2. Moulded Test Specimens

After moulding progress PVC moulded concrete samples are submerged into water bath during curing at 25-29ºC ambient room temperature and 30-40% humidity of laboratory environment. At the end of curing time, test specimens were removed by using special removing device (Figure 3.). Finally, top and bottom surface of the specimen was smoothed out by a chainsaw for the standardized length to diameter ratio of 2.

Figure 3. Removing of Test Specimen

3.2 Testing Apparatus

Laboratory tests are carried out with a displacement controlled with a universal testing machine which has a 500kN load capacity. Since MTS machine does not enable to visualize load displacement curve during tests, a data acquisition system is attached to the test set up. Moreover, this system can record eight data reading per second; it helps to obtain more sensitive test results.

In order to record axial displacement on the specimen, two strain gauge based transducer are attached to the rigid plate and for lateral displacement recording, circumferential extensometer is attached to the middle of the specimen as shown in Figure 4.

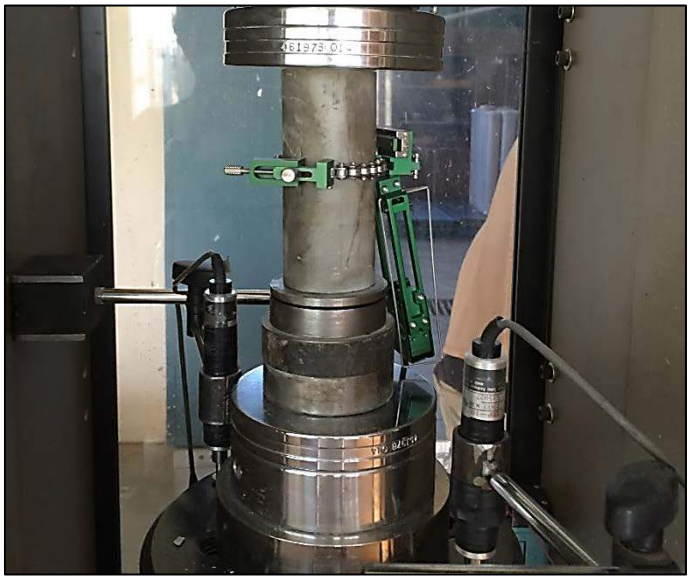

Figure 4. Laboratory Test Apparatus

3.3 Laboratory Testing

Deformability tests are conducted for 2, 7 and 14 days of curing time. Three valid test results of 2 and 7 days cured specimens for each product are obtained. For 14 day curing time, since expected UCS and E values are much higher than 2 and 7 days, six valid tests are conducted. Table 3 presents the number of tests for each curing time and the product type.

Table 3. Conducted Test Numbers in Laboratory Studies

Product Code	Curing Time (Days)		
	2	7	14
D1	3	3	6
D2	3	3	6
F	3	3	6

Product names were used as for the local products 1 and 2, international product as D1, D2 and F respectively. A total number of 36 valid tests are conducted.

Laboratory studies are carried out in accordance with the standards suggested by International Society for Rock Mechanics (ISRM) and (ASTM D7012). During laboratory studies, test are conducted under constant strain rate of 0.50 mm/min. and the specimens failed in 4 to 6 minutes.

4 TEST RESULTS

At the end of laboratory tests, stress vs. axial strain curves are plotted. Figure 5 shows a representative stress-axial strain curves of 2 days cured for three products.

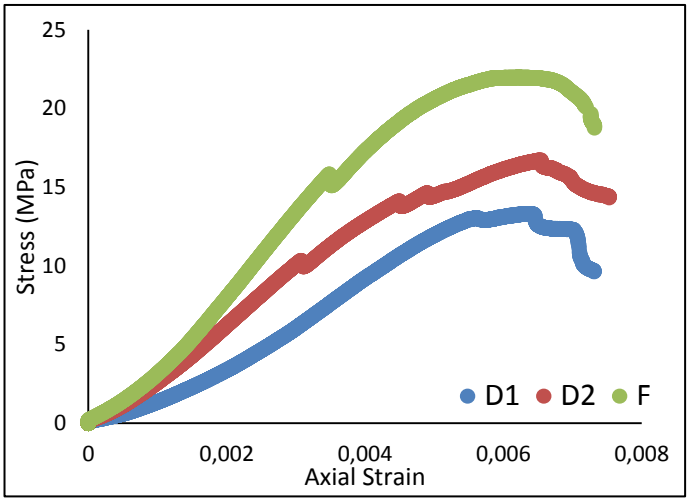

Figure 5. 2 Days Cured Representative Stress-strain Curves

According to the given curves, product F is stronger and stiffer than the other two products. At the end of the test evaluation part, UCS and E values are calculated. Figure 6 shows the relationship between UCS and curing time. The UCS values strongly depend on the curing time for the cement samples, the relationships can be expressed using a logarithmic trend line.

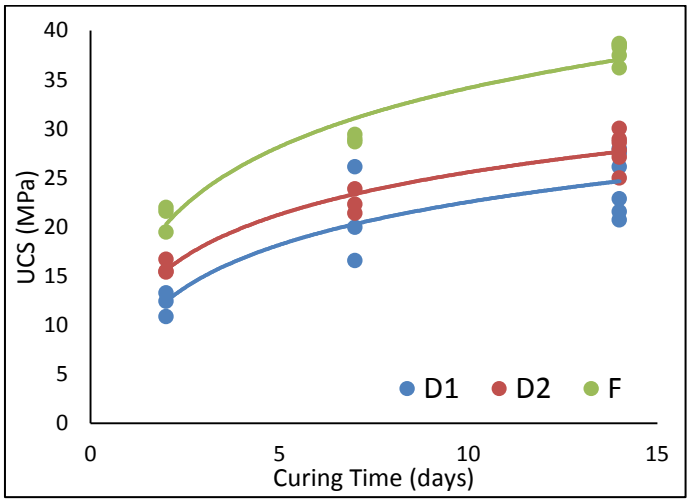

Figure 6. UCS versus Curing Time Relationships of Three Products

It should be noted that all the testing and curing conditions are kept constant for all products. Relationship between the UCS and curing time is very similar for D1 and D2 products. UCS test results, the related logarithmic relationships and correlation coefficients are presented in Table 4.

Table 4. UCS Test Results

Sample D1			
Curing Time	2 Days	7 Days	14 Days
UCS (MPa)	12.20 ± 1.23	20.89 ± 4.85	24.47 ± 3.15
Logarithmic Relationship	UCS = 6.2933ln(Days) + 8.0528		
R^2	0.75		
Sample D2			
Curing Time	2 Days	7 Days	14 Days
UCS (MPa)	15.88 ± 0.72	22.54 ± 1.27	27.92 ± 1.74
Logarithmic Relationship	UCS= 6.2035ln(Days) + 11.287		
R^2	0.93		
Sample F			
Curing Time	2 Days	7 Days	14 Days
UCS (MPa)	21.01 ± 1.35	29.02 ± 0.38	37.49 ± 1.02
Logarithmic Relationship	UCS = 8.6195ln(Days) + 14.305		
R^2	0.95		

The compressive strength increased substantially with increase in curing time from 2 to 14 days for all products. At the end of 2 weeks, Product F has more than 37MPa UCS, on the other hand corresponding UCS value for the given time of the product D2 is less than 25MPa.

Similar growth is also observed on Elastic modulus values for the three products. Figure 7 shows the relationship between elastic modulus and curing time.

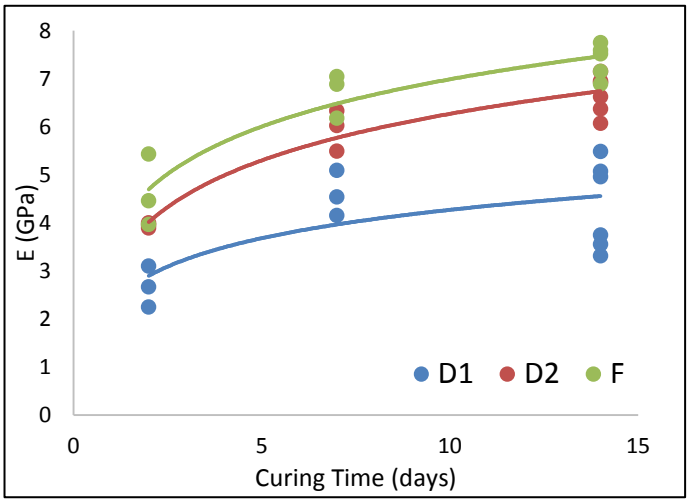

Figure 7. Elastic Modulus versus Curing Time Relationships of Three Products

As a result of the deformability tests, notable difference is observed for three different products as seen in UCS test results. Obtained Elastic modulus values, the related logarithmic relationships and correlation coefficients are presented in Table 5.

Elastic modulus values are almost doubled between the 2nd and 14th days curing time tests. At the end of the 2 weeks curing time, product F has more than 7GPa Elastic modulus value. Although similar Elastic modulus growths are observed in the other products, notable difference is obtained.

As expected, the uniaxial compressive strength and elastic modulus for three products are directly related with curing time.

Table 5. Elastic Modulus Results

Sample D1			
Curing Time	2 Days	7 Days	14Days
E (GPa)	2.25 ± 0.43	4.60 ± 0.47	4.36 ± 0.92
Logarithmic Relationship	E = 0.8528ln(Days) + 2.307		
R^2	0.45		
Sample D2			
Curing Time	2 Days	7 Days	14Days
E (GPa)	3.95 ± 0.05	5.95 ± 0.43	6.68 ± 0.41
Logarithmic Relationship	E = 1.4017ln(Days) + 3.0423		
R^2	0.92		
Sample F			
Curing Time	2 Days	7 Days	14Days
E (GPa)	4.62 ± 0.74	6.70 ± 0.46	7.38 ± 0.35
Logarithmic Relationship	E = 1.4227ln(Days) + 3.7129		
R^2	0.87		

5 CONCLUSIONS & RECOMMENDATIONS

In this study, uniaxial compressive strength and the elastic modulus of the 3 different class G cements are investigated based on the curing time. For this purpose two local and one international class G cements were tested in accordance with related test standards.

Main conclusions of this study is as follows;

- As expected, the uniaxial compressive strength and elastic modulus for class G cements are directly related with curing time. As curing time increased UCS and E values also increased. A logarithmic relationship exists between the curing time and UCS or between E and the curing time.
- Elastic modulus and UCS values almost doubled between the 2nd and 14th days. Although all the test parameters and laboratory conditions were kept constant, notably differences were observed for each product.
- The UCS and E values of G class cement produced in Turkey had values incontrovertibly lower than that of an equivalent international product.

According to the given conclusions, suggested recommendations and future works are listed as follows;

- in order to investigate the long term performance of class G cements, it may better to carry out longer curing time tests, like 28 days.
- different water-cement ratio tests might be useful.
- curing temperature, pressure and humidity are also significant parameters for cements, detailed tests considering these parameters may give important results.
- domestic class G cement suppliers may review their products by considering these obtained results.

Correlation of Linear and Volumetric Fracture Densities in Jointed Rock Mass

H. Mirzaei
Faculty of Mining, Petroleum and Geophysics, Shahrood University, Iran

ABSTRACT In this paper the relation between linear and volumetric fracture densities is investigated with the use of synthetic discrete fracture networks. A synthetic rock mass containing one joint set with known geometrical parameters is considered and various discrete fracture network models for different amount of volumetric fracture densities were generated. For each fracture network, a set of boreholes were simulated to determine linear fracture density. Then correlation of known volumetric densities and corresponding calculated linear densities is studied. Results show that the currently used relation to obtain volumetric density is not valid.

Keywords: Linear fracture density, volumetric fracture density, Monte Carlo simulation

1 INTRODUCTION

In different mining and civil engineering activities such as stability analysis of underground mining spaces (Fekete & Diederichs 2013), slope stability in open pit mines, prediction of dilution potential in block caving method (Katherine et al. 2008), hydraulic behavior of rock mass (Lee & Moon 2004), hot dry rock geothermal energy systems (Tran & Rahman 2007) etc., geometrical modeling of jointed rock mass is essential task.

In general, in these applications, extensive sampling is difficult or expensive and the data available at the time of decision-making are scarce. For these reasons, the only feasible approach is via stochastic models based on the limited available data (Dowd et al. 2007).

The Discrete Fracture Network (DFN) analysis is a widely applied modeling approach to stochastic simulation of rock fracture network. The DFN approach relies on stochastic realizations of fracture systems using Monte Carlo simulations (Jing & Stephansson 2007).

Density is a parameter which describes the amount of fracturing of rock mass. Linear, areal and volumetric fracture densities are defined as Number of fractures per unit length, Number of fractures per unit area and Number of fractures per unit volume, respectively.

Volumetric fracture density (D_3) is one of key parameters required to simulate the geometry of jointed rock mass. Since dismantle of rock mass is not imaginable, direct measurement of D_3 is not possible. In practice, D_3 is estimated from calculated linear (D_1) or areal (D_2) fracture densities obtained from scanline, borehole or window sampling methods (Priest 1993).

In this paper the relation between linear and volumetric densities is investigated with the use of synthetic discrete fracture network models.

2 DISCRETE FRACTURE NETWORK MODELS

A large degree of uncertainty is associated with the geometric properties of fractures, especially their locations, shapes and sizes. These uncertainties are the reasons for using stochastic distributions as their mathematical representations, rather than explicit and deterministic representations.

For rock mass characterization, the field mapping data from scanlines, windows or boreholes are processed to identify the fracture sets. After identification of the sets, the fractures should be regrouped into their

corresponding sets for further statistical analysis to determine the mean values for dip direction and dip angle and their probabilistic density functions. One of the common types of distribution functions for orientation is the Fisher distribution (Jing & Stephansson 2007). With the identification of the sets complete, the rest of the parameters, i.e., the density, spacing, fracture size (trace length) and aperture are analyzed to produce the respective probability density functions (PDFs). According to the literature the negative exponential, log normal and power law probability distribution functions govern on trace length and therefore fracture size (Jing & Stephansson 2007).

To take into account the uncertainties associated with rock fracture geometrical properties, discrete fracture network concept is employed to model rock mass geometry which is based on the Monte Carlo simulation technique.

2.1 Monte Carlo Simulation

Monte Carlo simulation is a stochastic process which addresses the 'randomness' of the fracture network geometry, by representing the fracture properties of location, size, orientation and aperture as random variables following their own specific PDFs, after assuming the shapes of fractures (commonly disk shape) and calculating the volumetric densities of all sets of fractures. The aim of the simulation is to generate a large number of realizations of a fracture system, each of which corresponds to a particular set of individual random variables for the locations (of fracture geometric centers), orientations, size and apertures, generated according to their specific PDFs. In this process the number of simulated fractures in each realization is depend on volumetric density and model volume.

The procedure of Monte Carlo technique to stochastic simulation of rock fracture system is illustrated schematically in Figure 1.

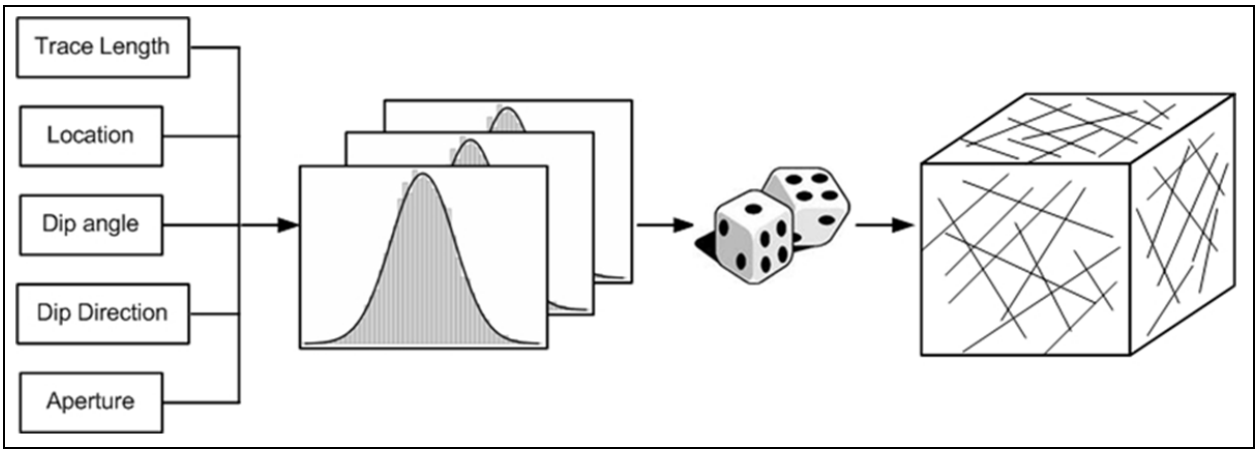

Figure 1. Monte Carlo simulation to generate rock fracture system.

2.2 Discrete Fracture Network Generation

Generation of a realization of a fracture network system can be achieved by different methods. The one described below is one of the simple cases (Jing & Stephansson 2007). It involves the following multiple steps:

a) Choosing a generation domain in 2D or 3D space within which a realization of a fracture network system is to be generated;

b) Starting from fracture set 1, calculating the number, N, of fractures to be generated according to the density values (D_2 or D_3) and spacing;

c) Generating the locations of N fracture centers as a Poisson process;

d) At each fracture center, generate two random numbers representing its values of dip direction and dip angle according to its Fisher PDF;

e) Generating a random number representing its size, according to its fracture size PDF, and generating a string of vertex coordinates defining its outer boundaries according to the shape assumptions (circular disks or rectangles, etc.);

f) Generating a random number representing its aperture according to the respective PDF;

g) Repeat steps (a) to (f) for all sets of fractures;

The above steps can establish one fracture network realization. They must be repeated to generate the desired number of fracture network realizations for a proper stochastic simulation, usually by using different seed numbers (used for initializing the random number generation process).

The probability distribution functions assumed in this sturdy for geometrical parameters are summarized in Table 1.

Table 1. Assumed probability distribution function for fracture geometrical properties.

Parameter	Probability density function
Location	Poisson process
Orientation	Fisher distribution
Size	Negative exponential

3 RESEARCH PROCEDURE

To investigate the relation between linear and volumetric fracture densities, a synthetic rock mass containing one joint set with known geometrical parameters were considered.

For various amounts of volumetric fracture density (D_3) with same geometrical properties, different DFN models were simulated. For each amount of D_3, various realizations are generated.

To calculate linear fracture density (D_1) of simulated DFN models, a set of boreholes with regular pattern were used for sampling the fractures (intersected fractures).

D_1 is dependent on the orientations of the boreholes, and is therefore termed apparent fracture density (Jing & Stephansson 2007). The apparent linear density is calculated as follow:

$$D_1 = \frac{N}{L} \quad (1)$$

where N is number of intersected fractures by borehole and L is length of borehole. To remove the orientation bias and obtain true linear density, the calculated apparent density must be corrected by the cosine of the acute angle θ of the fracture set normal and borehole direction (Zeeb et al. 2013, Lacazette 1991):

$$D_1^* = \frac{N}{L\cos\theta} \quad (2)$$

The mean of linear densities determined from different boreholes is calculated as corresponding linear density for known volumetric fracture density of current synthetic DFN model.

Once the linear densities related to different known volumetric densities were calculated from various synthetic DFN models, the relation between D_1 and D_3 could be investigated.

To produce synthetic DFN models, carry out the explained simulations and perform the above mentioned procedure, a set of computer programs were prepared in MATLAB software and used in this study.

4 CORRELATION OF LINEAR AND VOLUMETRIC DENSITIES

To investigate the relation between linear and volumetric fracture densities based on described procedure, a synthetic rock mass containing one joint set with known geometrical parameters as presented in Table 2 was considered.

Table 2. Parameters for simulation of rock mass.

Model Volume (m^3)	$10\times10\times10$
Joint set orientation (Dip/Dip Direction)	$60^\circ/180^\circ$
Fisher constant	100
Mean fracture size (m)	1

A realization of the synthetic rock mass (sample DFN model) with volumetric density of 1 ($1/m^3$) is shown in Figure 2.

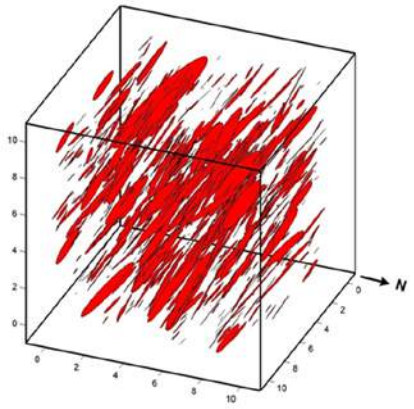

Figure 2. A realization of synthetic rock mass.

For various amounts of D_3 from interval [0.2-2.4] with same geometrical properties of Table 1, different DFN models were simulated. For each amount of D_3, five realizations of rock mass were generated.

To calculate linear fracture density (D_1) a set of boreholes (16 boreholes) with 10 m length and with regular pattern as shown in Figure 3 were used for sampling the fractures (intersected fractures).

For each borehole the number of intersected fractures was counted and apparent and corrected linear density was calculated using relations 1 and 2.

For instance for known D_3 of 1 ($1/m^3$), the values of corrected amount of D_1 determined from five boreholes for three realizations are given in Table 3.

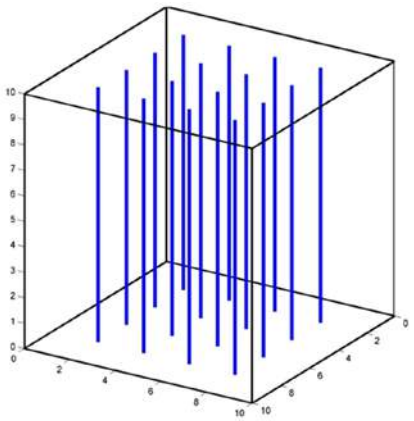

Figure 3. Pattern of simulated boreholes.

Table 3. Values of D_1 correspond to D_3 = 1 ($1/m^3$).

Borehole	Realization		
	1	2	3
1	2.2	1.6	1.4
2	1	1.4	1
3	1.4	1.2	0.8
4	1.6	0.8	1.2
5	1.4	1.4	1.2

The mean of apparent and corrected D_1 determined from 16 boreholes for five realizations of simulated rock mass are plotted with respect to D_3 in Figures 4 and 5 respectively.

Then the average of apparent and corrected D_1 values for various realizations of rock mass are determined and plotted with respect to D_3 in Figures 6 and 7 respectively.

According to Figures 6 and 7, D_3 and D_1 show linear relation. Therefore a line was fitted to these data as shown in Figures 6 and 7. Fitted line equations indicate that volumetric density is approximately equal to 0.7 of corrected linear density and 1.4 of apparent linear density.

The obtained results were compared with the relation argued in (Jing & Stephansson 2007) in Figures 6 and 7. According to this reference, D_1 and D_3 relate with together as follow:

$$D_3 = 2 D_1 \qquad (3)$$

The results of this study indicate that the currently used relation (3) is not valid.

As discussed the number of fractures to be generated during DFN construction process is depend on volumetric fracture density amount. Therefore incorrect D_3 value led to production of improper rock mass geometrical model which is the fundamental of further mechanical and hydraulic studies.

Consequently based on the results of this study, to model geometry of rock mass, first the corrected or true linear density must be calculated from borehole data or scanline method and then volumetric density must be assumed 0.7 of corrected linear density.

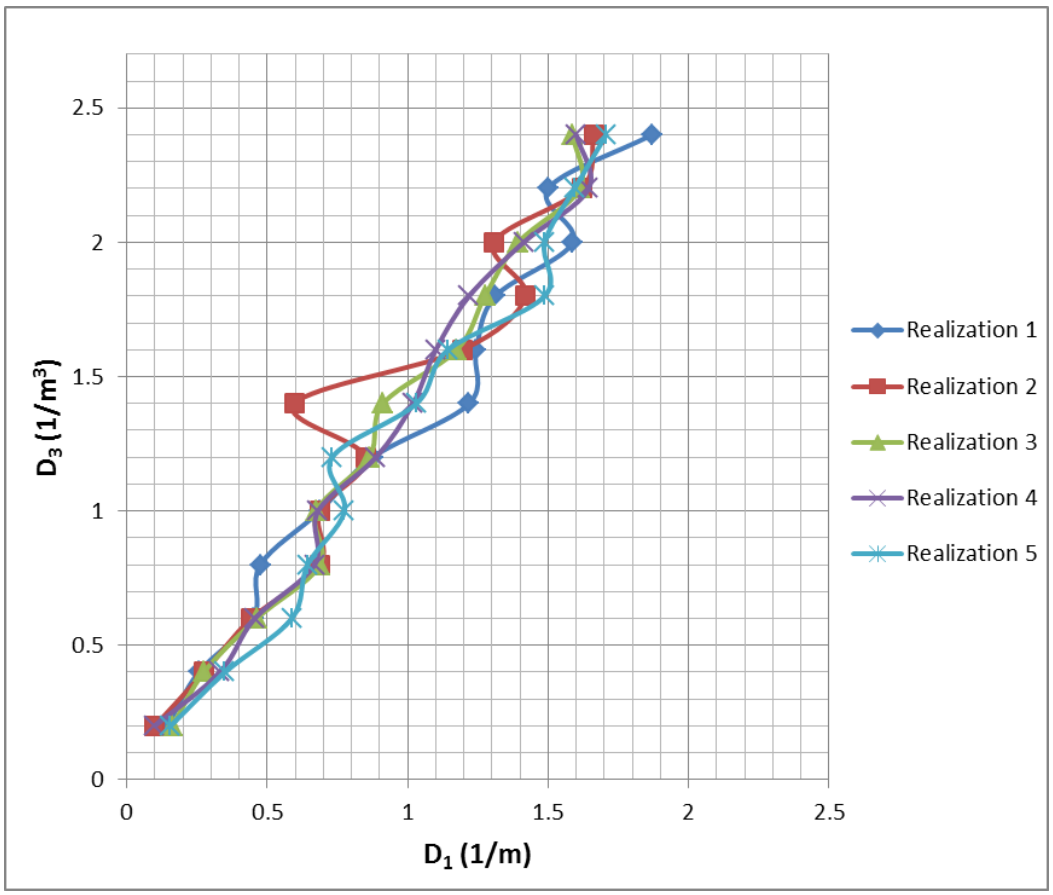

Figure 4. Apparent linear density versus volumetric density for various realizations.

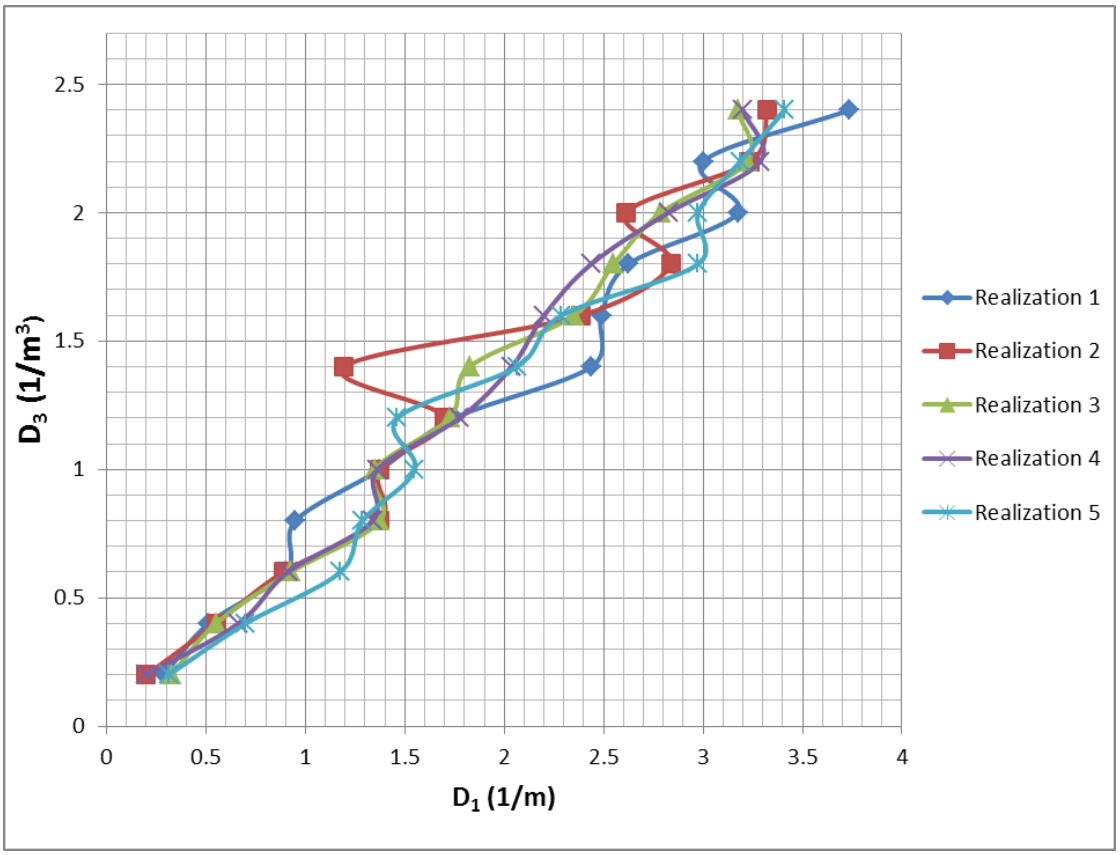

Figure 5. Corrected linear density versus volumetric density for various realizations.

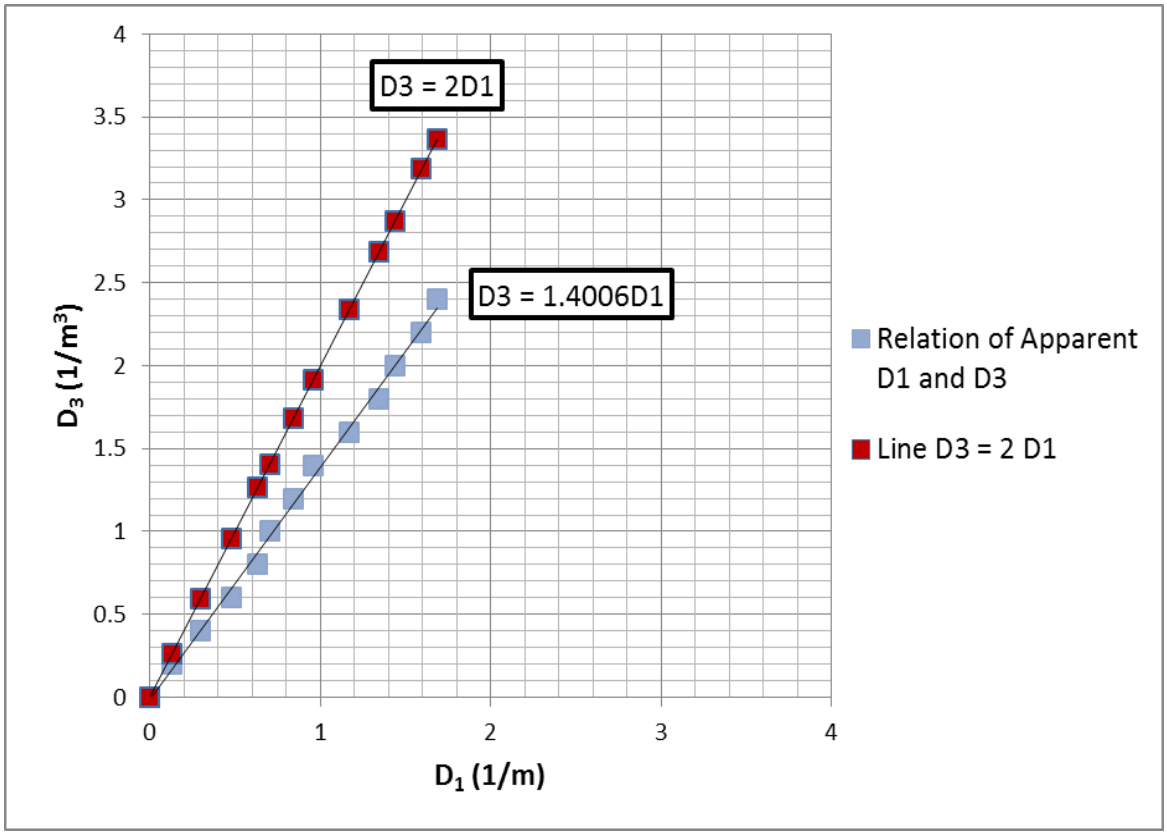

Figure 6. Relation of average apparent linear and volumetric densities in comparison with the relation $D_3 = 2\ D_1$.

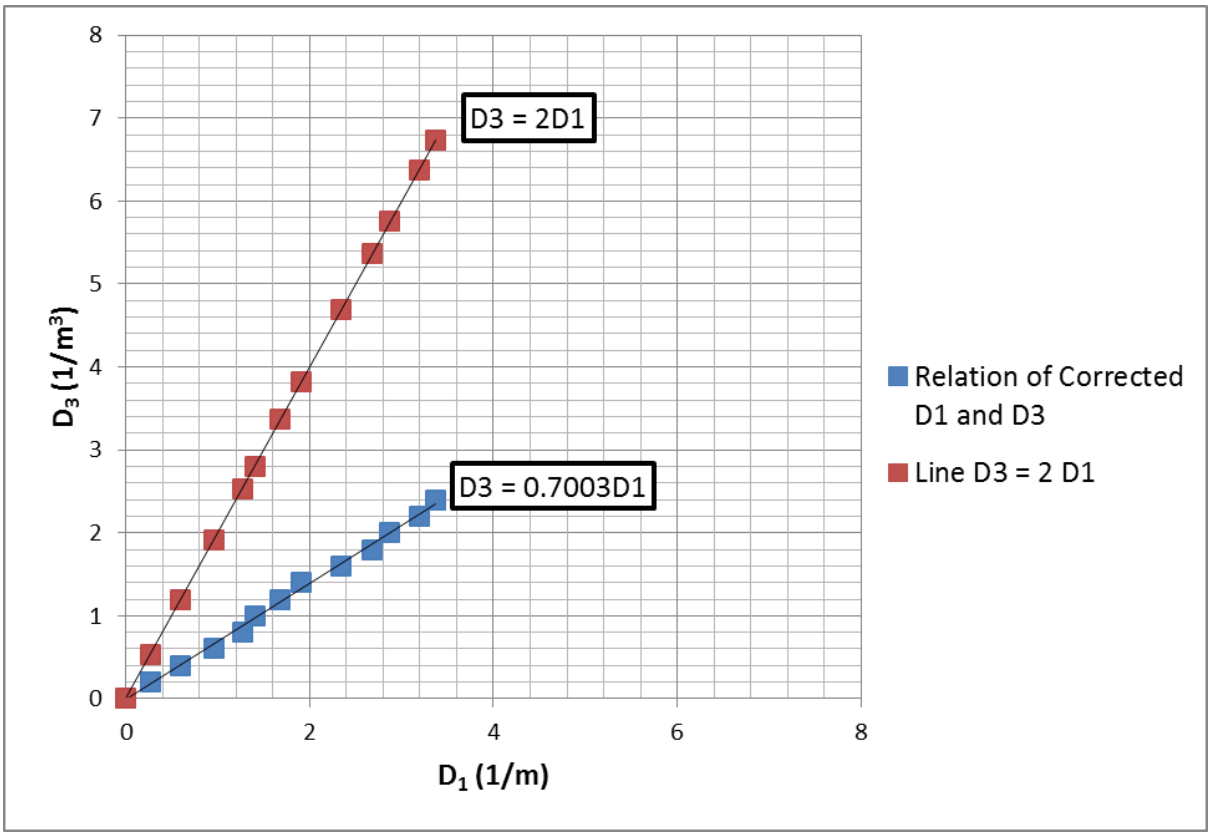

Figure 7. Relation of average Corrected linear and volumetric densities in comparison with the relation $D_3 = 2\ D_1$.

5 CONCLUSION

In this study a synthetic rock mass containing one joint set with known geometrical parameters is considered and various DFN models for different amounts of volumetric fracture densities were generated to investigate the relation between linear and volumetric densities. For each fracture network, a set of boreholes were simulated to determine linear fracture density correspond to known volumetric density. Obtained results show the currently used relation between linear and volumetric densities is not valid.

Finally this study propose that to model the geometry of rock mass, first the corrected or true linear density must be calculated from borehole or scanline data and then volumetric density must be considered equal to 0.7 of corrected linear density.

Earthzyme – Paving a New Way for Haul Road Construction

T. Burns
Cypher Environmental Ltd. 1149 St Matthews Ave Winnipeg, Canada R3G 0J8

ABSTRACT - The following is a technical summary of some examples of the past 15 years of Cypher Environmental Ltd.'s work with EarthZyme soil stabilizer.

The use of environmentally friendly EarthZyme soil stabilizer can dramatically reduce costs associated with the construction and maintenance of new haul roads and the stabilization of existing haul roads. EarthZyme is a concentrated blend of enzymes, electrolytes and surfactants that produce fantastic results on suitable soils. After an application of EarthZyme, treated soils have shown to yield higher densities, increase California bearing ratio (CBR) values, and reduce permeability and swell. EarthZyme works on clay based soils, stabilizing them to comparable strengths of traditional aggregate haul roads. This results in a significant cost savings in expensive raw material inputs such as coarse sand and gravel, which are not required when a soil is stabilized with EarthZyme. EarthZyme soil stabilization has been successfully used in a variety of road construction projects. Specifically in a thoroughly studied project in Ecuador, EarthZyme treated soils were determined to yield a significant reduction in swell (170 %) and an increase in CBR (51 %). These modifications in soil properties, due to stabilization with EarthZyme, are consistently reported and long-lasting even though the product biodegrades (> 90 %) within 28 days. This report will go into greater detail regarding the advantages that EarthZyme can provide when introduced to any mine site. Further to the cost savings in raw materials, emphasis will be placed on the reduced maintenance requirements and costs that introducing EarthZyme to a road construction project exhibits through the long term stabilization and improved engineering characteristics of a stabilized soil. EarthZyme has a diverse application history; from humid climates like Southern China, and tropical Latin America to the arid Gobi Desert of Mongolia, or the extreme climates of West Africa, and Northern Alberta, Canada. The most challenging of these, in terms of climate and road requirements, has been the Athabasca oil deposits of Northern Alberta, Canada. The consistently low temperatures and high levels of precipitation combined with the extreme weight of haul trucks, 400-700 tonne loaded weights, required to mine the deposit was put to Cypher Environmental Ltd. as a challenge in 2009. Cypher Environmental Ltd. eagerly met this challenge and together with our Western Canadian distributor, Frontline Integrated Services Limited, and our other industry partners, have successfully reduced the cost of all-weather haul road construction while exceeding industry standards in the Athabasca Oil Sands and around the world.

Keywords: EarthZyme, road construction, stabilized road

1 INTRODUCTION

Cypher Environmental Ltd. has been developing and applying EarthZyme liquid soil stabilizer for over a decade. In our extended time applying and developing EarthZyme we have successfully utilized the product in diverse projects and global settings. For the past 5 years Cypher Environmental Ltd. has been working closely with the mining industry in the Athabasca oil sands to construct haul roads that outperform dated and costly aggregate construction methods. These EarthZyme stabilized road s have displayed both short and long term cost savings. Due to the competitive nature of the mining industry this summation of works completed will not specifically reference our

clients or their projects. Differentiation will be made between road type a project location

2 ECONOMIC BENEFITS OF EARTHZYME CONSTRUCTION PROJECTS

Currently aggregate material is becoming scarce on many mine sites, particularly in the Athabasca oil sands. Typically haul road construction requires a well graded aggregate to achieve desired characteristics: high load bearing capacity, wear resistance, and weather resistance. Constructing haul roads with EarthZyme utilizes fine grain clayey soils and standard equipment. These clayey soils are traditionally considered mine waste or over burden. EarthZyme haul roads in the Athabasca oil sands have been studied in comparison to aggregate all-weather haul roads and have consistently produced comparative, if not superior results. These haul roads have shown to be faster to build, exhibit reduced rolling resistance and rack events, and cost less to construct.

EarthZyme road construction methods, whether for heavy mining trucks or municipal traffic, are quite similar. The difference between constructing a haul road (40 metre width) or a municipal road (7 metre width) is equipment selection. For haul road construction Cypher Environmental Ltd. recommends utilizing 1-2 large haul trucks (ex. Caterpillar 793) or steel drum rollers (ex. Caterpillar CS64) depending on availability, to compact the soil, 1-2 large water trucks (40-100 tonnes), a large grader (ex. Caterpillar 16M or 24M), and 2 reclaimers (ex. Caterpillar RM500 Reclaimer). For municipal road construction Cypher Environmental Ltd. recommends utilizing 1 steel drum vibratory compactor and a pneumatic roller (ex. Caterpillar CS64, Caterpillar PS360C), 1-2 graders (ex. Caterpillar 14M) or 1 grader and 1 reclaimer (ex. Caterpillar RM300), and a 10-20 tonne water truck. A major similarity between EarthZyme road construction projects in different industry settings is the associated short and long term cost savings.

As a result of the similarities in construction techniques and effort, and the competitive nature of the mining industry, a well-studied comparative municipal construction project will be utilized to display the short term cost saving nature of EarthZyme road construction.

2.1 Short Term Economic Benefits of EarthZyme

An empirical review of a municipal road construction project in Ecuador was conducted by Eco-Road Solutions, Quito, Ecuador (Helberth, 2012, June). This review encompassed several aspects of the project, including a cost comparison between two equal sections of road; one constructed with standard aggregates, the other using clayey soil and EarthZyme. This study determined that the EarthZyme stabilized road was completed more efficiently on all measurement criteria (Table I).

Table I - Economic savings of EarthZyme municipal road construction, Quito Ecuador

Action	Savings with EarthZyme
Material transported	95 %
Use of machinery	59 %
Material	27 %
Labour	33 %
Total Project Savings	**47 %**

The largest saving resulting from this study was in material transportation. Material and transportation cost savings result from EarthZyme projects because raw material inputs for EarthZyme road construction are considered waste by many industries and therefore inexpensive to acquire. It is worth noting that prior to this project the contractor had not previously worked with EarthZyme, but they had received mandatory training from a Cypher Environmental Ltd. representative. Also, constructing roads with EarthZyme reduces machine hours and labour, which results in increased contractor capacity.

2.2 Long Term Economic Benefits of EarthZyme

2.2.1 Reduced rolling resistance

Reducing the rolling resistance of a haul road directly results in reduced fuel cost and increases haul fleet productivity of a road segment (Regensburg & Tannant, 2001). Using EarthZyme to construct fine grain clayey haul roads has shown to reduce rolling resistance. A rolling resistance study conducted in the Athabasca oil sands determined the average rolling resistance of an EarthZyme treated haul road constructed with Clearwater Clay Shale overburden of medium to high plasticity. This study determined that the average rolling resistance was 2.7 % with a standard deviation of 0.5 %. This is well within the boundary requirements of many Athabasca oil sands companies, 3-5 % for permanent road surfaces (Regensburg & Tannant, 2001).

Haul roads constructed with similar material and not stabilized with EarthZyme exhibit considerably different characteristics than an EarthZyme stabilized haul road. Common rolling resistance values for similar material, in-situ benonitic clay shale of medium to high plasticity, range from 7-13 % with an addition of 1.5 % for every inch (2.54 cm) of penetration (Dionne 1987). Increased rolling resistance directly relates to increased fuel consumption and reduced haul fleet productivity (Figure I).

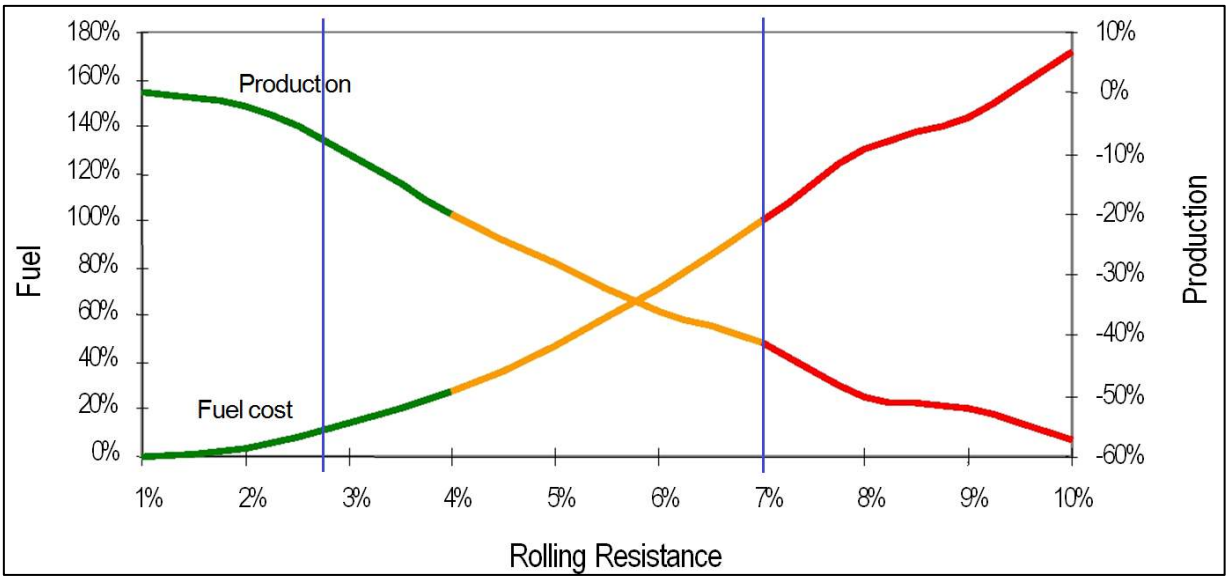

Figure I - Relationship between rolling resistance and increased fuel consumption and decreased haul fleet productivity (Holman, 2006)

Figure I was used to forecast potential economic benefit of reducing rolling resistance on a mine site. It was determined that reducing rolling resistance of a haul road from 7 % to 2.7 %, 1 deviation above average was determined to be 3.2, will increase haul fleet productivity by 35 % and decrease fuel cost by 90 % percent (Table II).

Table II - Potential savings resulting from reduced rolling resistance

Rolling Resistance (%)	Production (%)	Fuel Cost (%)
Clay Shale; 7.0	- 47	100
Clay Shale + EarthZyme 3.2	- 7	10
Savings (%)	**35**	**90**

From Table II and Figure I it is evident that reducing rolling resistance on haul roads using EarthZyme can yield extensive savings in fuel consumption and significantly

increase the productivity of a mining operation.

2.2.2 Reduced/eliminated racking events

To date the cost reductions associated with the reduced maintenance and racking events on EarthZyme haul roads has not been quantified. This is an area Cypher Environmental Ltd. plans to focus on in the future to further display the economic benefits of EarthZyme haul roads. The study previously referred to with respect to rolling resistance also determined that no trucks passing over the EarthZyme stabilized haul roads exhibited racking events. RAC events as defined by Caterpillar Inc. (2012), "RAC measures the frame's rack and pitch. Rack is the lateral twisting of the frame due to uneven loading on the diagonal tires. Pitch is the force on the frame from front to rear which occurs when the truck crosses a bump or dip perpendicular to the line of travel, hard braking or turns." (para. 2). These trucks were monitored daily. Traffic was considered high for an average mine in the Athabasca oil sands and travel speeds were consistently greater than 40 km/hr.

Although not quantified, reduced maintenance requirements have been consistently reported on EarthZyme soil stabilization projects in diverse work site application settings. The cohesive nature of the fine particles, and the improved binding and strengthened clay bonds facilitated by EarthZyme makes possible the reduced maintenance of the haul roads. To ensure that the wear surface of an EarthZyme haul road achieves the required level of water and wear resistance, a slurry coat is applied to the final lift during construction. A slurry coat is applied using approximately 1:1000 ratio of EarthZyme to water, with an application rate of 1 litre of EarthZyme to 1000 square metres of compacted surface. Contractors apply this mixture topically to the road and allow it to soak into the compacted surface. Once the moistened surface is no longer tacky, fully loaded haul truck(s) compact the surface. They make several passes until the road dries and requires rewetting or until the surface seals. This process forces the larger granular particles down and the cohesive fines to the surface, creating a tightly sealed road that effectively repels and sheds water (Figure II, A., B.).

2.2.3 Reduced maintenance

Quantifying reductions in maintenance of roads is a costly task, in both time and funds. Further complicating this task is the competitive nature of the mining industry. Through experience in road construction, Cypher Environmental Ltd. determined that reduced maintenance on haul roads can be objectively measured in grading requirements. To date EarthZyme haul roads require minimal grading, generally only to clear spillage from haul trucks. Furthermore, the high volume of traffic and loading subjected to EarthZyme treated haul roads enables the roads to maintain the high levels of density achieved during the initial compaction process carried out during construction. Due to the homogeneous nature of the soil structure, EarthZyme haul roads exhibit negligible rutting and remarkable reductions in common maintenance issues. These issues frequently result from imperfections in road surfaces or bearing layers: wash boarding, rutting, potholing.

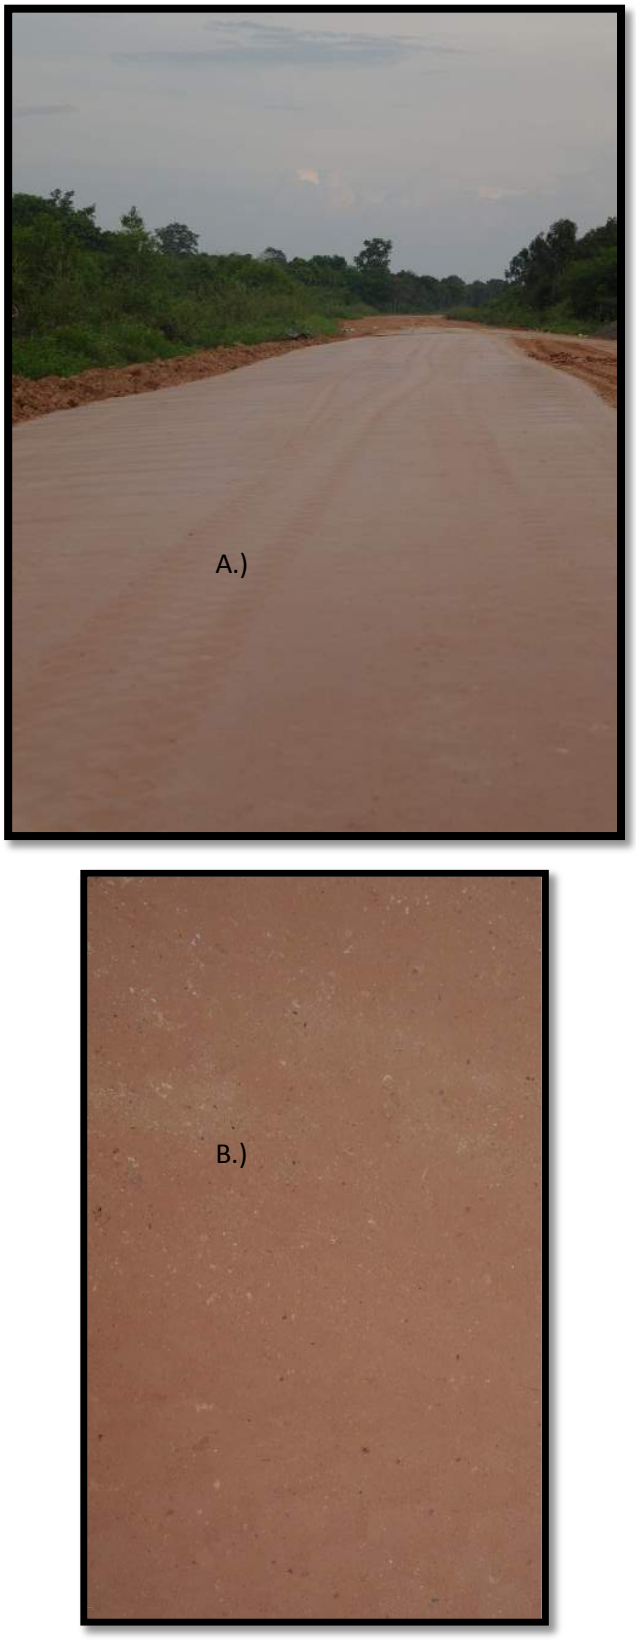

Figure II - Coal mine haul road; Indonesia

A. Sealed surface after slurry coat is finished

B. Close-up of haul road surface

It should be noted that tightly bound surface of EarthZyme treated haul roads have significantly reduced dust production. Reduced fugitive dust is of high value to mine sites as increased dust levels can result in reduced haul fleet productivity. The reduced productivity results from reduced visibility due to fugitive dust. Reduced visibility by dust is a safety hazard and requires haul trucks to slow down and in some cases stop to prevent accidents. Reducing dust caused by haul truck traffic on EarthZyme treated haul roads can allow for faster operating speed and increased efficiencies of haul fleet operations. Reducing dust can also help to reduce wear caused by dust particulates to the moving parts of haul trucks, extending part life. The overall reduction in dust also provides cleaner air for workers.

These reductions in common maintenance issues directly result from an increased homogeneity of a bearing layer and surface with increased strength and durability. These reductions in overall maintenance have been reported as a result of EarthZyme stabilization in a diverse climate setting from Northern Alberta, Canada to Columbia and Indonesia. Other examples of diverse climates that achieve similar results include: West Africa, Southern China, Dominican Republic, Ecuador, Mongolia, Peru, Romania, South Korea, Turkey, and the Southern United States.

To achieve these desirable cost savings, a client must first test the soil for compatibility with EarthZyme.

3 SOIL REQUIREMENTS

EarthZyme is not effective at stabilizing all soils. Before treating a soil with EarthZyme, Cypher Environmental Ltd. recommends several standard soil tests be conducted: Particle Size Distribution-ASTM D422, Atterberg Limits liquid and plastic-ASTM D4318.

This testing verifies that the soil contains fines in excess of 20 % by weight passing the 75 micron sieve (# 200 sieve), and a plasticity index above 8. The A-line on the Casagrande Chart determines soil acceptability for treatment. A soil that plots on or above the A-line is considered acceptable and exhibits the short and long-

term gains in engineering properties associated with EarthZyme stabilization. A soil that plots below the A-line can still be treated with EarthZyme, but will exhibit only short term gains in engineering properties. The difference in the length of effective treatment relates to the non-organic clay content and chemistry of the soil. The long-lasting stabilization of EarthZyme directly relates to the use of clay as the binding agent. This is because the clay is indigenous to the soil and not an additive that will leach out of the soil or degrade through soil microbes and soil chemistry. This combined with the increased cohesive nature of the treated clay and the permanent alteration of the chemistry of the soil, results in haul roads that exhibit minimal maintenance and increased load carrying capacity for many years.

4 EARTHZYME

4.1 What it is

EarthZyme is added to clay-mineral soils to increase compactability and decrease the mobility of water in the compacted soil matrix. EarthZyme consists of these three primary elements:

1. An ionic solution that interacts with the clay minerals in the fill to reduce the proportion of water that is weakly bonded to the clay particles. The ionic solutions serve to reduce the diffuse double-layer, which allows greater densities to be achieved under a constant compaction force.
2. A strong surfactant that serves to reduce the viscosity of the water, increasing the lubricating effect of the water during compaction. This ultimately achieves greater densities at lower moisture contents while enhancing alignment of the clay particles, which reduces the permeability of the compacted mass. The surfactant also serves as a carrier fluid for the enzymes and ionic solution.
3. A combination of enzymes that facilitate ion exchange between clay particles and the ionic solution.

These three compounds work in harmony during haul road construction enabling conventional construction equipment to achieve higher densities than with untreated compacted clay fill. The higher densities, in turn, create a compacted mass with greater clay particle alignment and binding. This results in significantly higher strength, durability, and bearing resistance. The combined affect renders the treated compacted fill hard, improving water replant characteristics, making it suitable for road surface and base construction.

4.2 How it works

Clay minerals are negatively charged. As a result, the positively charged portions of the polar water molecules are attracted to the negatively charged surfaces of the clay particles, forming weak ionic bonds between the clay minerals and the polar water. Soil scientists referred to this as the diffuse double layer, and is the mechanism that causes clay soils to swell and lose strength in the presence of free water (Das, 2008, Ch. 4). The thickness of the diffuse double layer depends on the chemistry of the clay minerals and the pore water (Michael & Soga, 2005, P. 158). The diffuse double layer thickness can be reduced by altering the clay and pore water chemistry (Michael & Soga, 2005, P. 158). EarthZyme utilizes an enormous ionic exchange potential to shrink the diffuse double layer, which reduces the soils ability to adsorb water, reducing the optimum moisture content of the treated clay soil, and allowing higher compaction densities. Surfactants enhance this ion exchange by increasing the penetration of the ion solution into the capillary structure of the soil. The surfactants also serve as a carrier fluid for the enzymes. These enzymes facilitate increased ion exchange between different clay mineralogy; enabling EarthZyme to be diversely effective. These combined effects permanently reduce the clays affinity to water.

The EarthZyme surfactants have a dual purpose during the soil stabilization process.

The EarthZyme surfactants have the temporary effect of decreasing surface tension and water viscosity, acting to encourage compaction. This lubrication results in achieving a dispersed soil structure and reduced pore spacing. This reduction in surface tension further reduces the moisture requirements of the soil for optimal compaction. The combined effect of the shrunken diffuse double layer and reduction in surface tension reduces the optimum moisture content of the soil in combination by approximately 1-2 %. This process creates a fine grained soil structure with significantly reduced pore space and increased platelet to platelet contact.

The combination of the high degree of compaction (reduced pore space and capillary structure) and dispersed (parallel) soil structure vastly reduces the permeability of the soil and vastly increases the strength (bearing capacity). As EarthZyme biodegrades the surfactants breakdown, and re-establish the surface tension of the water. This triggers the bound water (liquid bridges) to tighten, creating greater internal compression forces. These results in increased suction and skeletal forces in the soil matrix, further reducing space between cohesive clay particles, and increasing covalent and ionic bonding. Ultimately, this causes the hardening or curing of the compacted clay fill, resulting in the completed surface exhibiting increasing strength overtime. The majority of this process happens in the first 5-7 days, continuing until day 28.

The reduced void ratio also facilitates increased natural binding via chemical bonding, and Van Der Waals bonding between clay structures (Michael & Soga, 2005, Ch. 7). The increased density and subsequent increased bonding of clay fabric in combination with their parallel orientation works to create a bearing surface that exhibits not only increased strength properties, but, increased homogeneity. Combined, the effect is to resist re-adsorption of water that would otherwise reduce strength. The dispersed nature of the soil matrix further increases this effect. This dispersed soil structure also assists to reduce permeability, a result of a reduction in interconnected pores that otherwise aid in water transmission and a reduced inclination for the compacted soil to exhibit brittle failures (Bowles, 1992). This creates a strong more durable road, with a reduced inclination to water and increased uniformity of strength gains.

5 PAST PROJECTS

The diversely applicable design of EarthZyme enabled Cypher Environmental Ltd. to effectively stabilize road construction projects around the world and across the industrial/municipal sectors. EarthZyme's highly concentrated design, 1 liter of EarthZyme required to treat 33 cubic metres of compacted soil, makes EarthZyme cost effective on a global scale. Common links between all of these projects include increased bearing capacities and reduced susceptibility to water permeation and degradation. Cypher Environmental Ltd. developed alterations to the CBR test to predict the effectiveness of EarthZyme on particular soil types. Traditionally determining road design requirements utilizes the CBR test (Bowles, 1992). The CBR test is a well-known test that can be conducted in the majority of soils laboratories in both developed and developing countries. Because of this Cypher Environmental Ltd. utilized the CBR test for years to predict the strength gains and stability of foundations stabilized with EarthZyme. Reduced infiltration of and affinity to water is an important aspect of road construction with fine grained, traditionally highly expansive soils. EarthZyme effectively reduces the expansive characteristic of normally expansive soils yielding a low cost, stable construction material (Table III).

Table III - Swell reduction of fine grain soils treated with EarthZyme; 96 hour test

Project Type	Location	EarthZyme*	Untreated*	Swell (% Reduction)
Municipal Paved Road	Caupicho Quito Ecuador	0.3	0.81	**63%**
Secondary Unpaved Road	Hainan Province China	0.08	0.26	**69%**
Primary Unpaved Road	Hainan Province China	0.06	0.28	**79%**
Municipal Paved Road	Metropolitan District of Quito Ecuador	0.01	0.32	**97%**
Highway	Cajamarca Peru	0.88	1.8	**51%**

*(percentage; vertical deflection divided by initial thickness/height of compacted soil)

The significant strength gains exhibited as a result of compacting soils with EarthZyme is an important added benefit of constructing haul roads with EarthZyme and fine grained soils (Table IV).

Table IV - Increased bearing capacity of fine grained soils compacted with EarthZyme

Project Type	Location	CBR No EZ	CBR With EZ	Increase in CBR (Avg. % Change)
Primary Unpaved Road	Puerto Plata Dominican Republic	43	196	**353%**
Primary Unpaved Road	Peru	12	37	**208%**

These strength gains are a result of EarthZyme's unique ability to increase the bonding of the parallel oriented clay platelets while reducing the void ratio in fine grained soil at a moisture content below optimum (OMC). This is important in both increasing the overall strength of the soil and the uniformity of the engineering properties of a haul road. This bound particle orientation causes the soil to behave in a consolidated, sheet like elastic fashion; enabling the fine grained soils to tolerate higher loads with minimal breakdown of the consolidated soil structures. Generally, a haul road behaving in an elastic fashion is not beneficial to mine economics because it results in increased rolling resistance. The constant deflection of the haul road causes this increased rolling resistance resulting in a constant up-hill effect. This increased rolling resistance is due to the constant deflection of the haul road, which produces the constant up-hill effect previously mentioned (Regensburg & Tannant, 2001). This constant up-hill effect is not exhibited on fine grain EarthZyme stabilized haul roads because of large increases in CBR number. The combined strength gains and dispersed particle orientation of EarthZyme stabilized soils greatly increases their durability and bearing capacities. This creates a superior haul road using economical material inputs that can withstand repeated substantial loading with minimal maintenance or resurfacing.

5.1 Results from a recent Mining Haul Road Project in Mali, Africa (November 2013):

A stabilization project was carried out at the Randgold Somilo site on the haul road connecting the Gounkoto and Loulo mines. EarthZyme was used to stabilize the road to a 20 cm depth, treating the in-situ soil. On an

average month, 4200 trucks weighing 65 tons each use the haul road and after one month of operation, Randgold reported the following test results. CBR data from the road was collected before and after treatment with EarthZyme (Table V and Figure III). Samples were taken from both lanes of the road, lane "A" being the lane the empty trucks travel on and lane "B" the one the loaded trucks travel on. As shown below there was a combined CBR improvement of 159.91%.

Table V – CBR Data from EZ treated mining road in Mali, Africa

6 SUMMARY OF BENEFITS

As a result of Cypher Environmental Ltd.'s commitment to providing the most cost effective, highly functional and environmentally friendly solution, Cypher Environmental Ltd. has been able to reduce the industrial foot print of road construction, while simultaneously reducing project costs. These reductions in cost are seen not only as a result of reduced costly raw material inputs, labour and machine hours, but throughout the extended life of the road. In the past 5 years EarthZyme has been integrated more and more into the mining industry as an effective additive to all-weather road construction projects. Studies of these all-weather haul roads have determined that EarthZyme stabilized haul roads exhibit reduced rolling resistance, racking events, and reduced grading requirements. This results in increased productivity and reduced fixed costs of road networks, increasing overall efficiencies at mine sites utilizing the EarthZyme product

Effect of Placement Configurations on Strength Behaviour of Cemented Paste Backfill

E. Yilmaz
University of Quebec in Abitibi-Témiscamingue (UQAT), Department of Applied Sciences, 445 Boul. de l'Université, Rouyn-Noranda (Québec) J9X 5E4 Canada

ABSTRACT This paper presents the effects of placement conditions on strength properties of cemented paste backfill CPB cast in different size moulds ($D \times H$ = 10 × 20 cm, 7.5 × 15 cm, and 5 × 10 cm) and prepared at binder contents of 3 wt%, 4.5 wt%, and 7 wt%. CPB samples were subjected to four placement conditions: capped-drained C-D; uncapped-drained U-D; capped-undrained C-U; and uncapped-undrained U-U. Results show that the highest strengths were obtained from C-D samples, followed by U-D, C-U and U-U samples, respectively. This may be explained by the drainage of free water within CPB at early ages, which offers higher strengths. The CPB's strength increased with a decrease in mould size in all cases for all the samples. The moulds 5 × 10 cm gave the best strengths due to a more homogenous matrix and the decreased number of micro-cracks in grains.

Keywords: Cemented paste backfill, strength parameters, placement conditions

1 INTRODUCTION

Cemented paste backfill (CPB) is a relatively high density (typically with more than 70% solids) engineered material which is made up of mill tailings mixed with hydraulic binders, and process water. CPB is being increasingly used underground as a result of increasingly stringent environmental regulations. Its main benefits include lower operating costs and a reduction of the amount of water sent to the tailings impoundments for surface disposal. The decrease of the amount of mine tailings reduces the environmental impact and offers major cost benefits for most modern mines (Benzaazoua et al., 2004; Bussière, 2007; Yilmaz, 2011; Yilmaz et al., 2014a).

The CPB mix ingredients (tailings, binder and water) greatly affect the performance of the backfill during its transportation, delivery and strength development. Mix designs must be considered for both placement and curing properties of in situ paste backfill materials. As mining operations go ever deeper, CPB is placed into stopes to provide a stable stage for miners to work on and ground support for the walls of the adjacent adits. Depending on its specific application, CPB must encompass desirable strength properties to better endure underground stresses. Overall, a sufficient unconfined compressive strength (UCS) for a CPB with binder contents of 3-7 wt% varies between 700 and 2000 kPa (Brackebusch, 1994). However, the condition for minimum strength acquisition should be determined from the design loads to which the material may be subjected. For example, when CPB is employed for underground disposal, a UCS between 150 and 300 kPa is required to remove the liquefaction at early ages (Bloss, 2002). In open stoping operations, when free-standing wall faces are exposed during pillar recovery, strengths higher than 1 MPa after curing of 28 days are desired to retain the strength and durability of CPB (Belem and Benzaazoua, 2008). When CPB is used for roof support, a UCS of higher than 4 MPa is required essentially (Grice, 1998).

Most experimental works have been done so far on CPB' intrinsic and extrinsic factors (Kesimal et al., 2004, 2005; Fall et al., 2010; Ercikdi et al., 2009, 2010; Yilmaz et al., 2009, 2011, 2014b, 2015; Benzaazoua et al., 2010; Cihangir et al., 2012; Ghirian and Fall, 2013, 2014; Belem et al., 2013). To assess the CPB's strength, unconsolidated backfills with dimensions of 10 cm in diameter and 20

cm in height are typically utilised in the laboratory studies. Handling huge volumes of tailings to be used during testing is time-consuming and costly. To end this, a number of researchers (Benzaazoua et al., 2004; Yilmaz, 2010; Pokharel and Fall, 2013) have used 5 × 10 cm plastic moulds for UCS tests. Additionally, these moulds do not often have drainage holes at the bottom and are used as their top is capped. Although the final CPB design is based on the strength properties derived from lab-prepared CPB samples using these plastic moulds, these lab studies are not mostly representative of the in situ placement and curing properties. There are in fact some problems with scaling up lab-prepared CPB samples' strength results to determine the field strength properties. The difficulties often lie in the selection of suitable specimen size and shape for lab tests (Consoli et al. 2006; Fourie et al., 2006; Hassani et al., 2007; Belem et al., 2007; Darlington et al., 2011; Thomson et al., 2012; Festugato et al., 2013; Ercikdi et al., 2014; Snyman et al., 2014). There is no standard specimen size and shape for the UCS testing of CPBs. Revell (2004) has shown that specimen size plays a key role on strength behaviour of CPB. The researcher found that, based on a height-to-diameter ratio of 2, small size cylinders (4 cm in diameter) gave 6-10% higher strengths than large size ones (10 cm in diameter).

In this paper, an investigation was done to assess the effect of placement conditions on CPB's strength. CPBs were cast in different mould sizes and subjected to four placement conditions: capped-drained C-D; uncapped-drained U-D; capped-undrained C-U; and uncapped-undrained U-U. A tool (CUAPS: curing under applied pressure system) was used for tests (Benzaazoua et al, 2006).

2 MATERIALS AND METHODS

2.1 Materials

Paste tailings were sampled as representative from the discharge of the rotary vacuum disc filter at the LaRonde Mine's paste fill plant (Quebec, Canada). To avoid any oxidation and prevent evaporation, tailings samples were stored in sealed plastic containers until their utilization for tests. The following lab tests were conducted according to American Society of Testing Materials standard testing procedures. Tests were done in triplicate and their average values are reported. Further details on material properties can be found in more detail in Yilmaz (2010).

2.1.1 Physical properties

Grain size distribution (GSD) of the tailings was analyzed using a Malvern Mastersizer laser diffraction particle size analyzer and the obtained GSD curve was compared fairly well with those of the tailings used in Canadian mines (Fig. 1). Table 1 lists the physical properties of the tailings. Tailings were found to have a 44 wt% fraction finer than 20 µm, hence classifying as a medium size tailings. The sample was well-graded with a coefficient of uniformity, C_u, of 7.9 and a coefficient of curvature, C_c, of 1.1. Based on the Unified Soil Classification System (ASTM D2487, 2011), the tailings sample was identified as low plasticity silt.

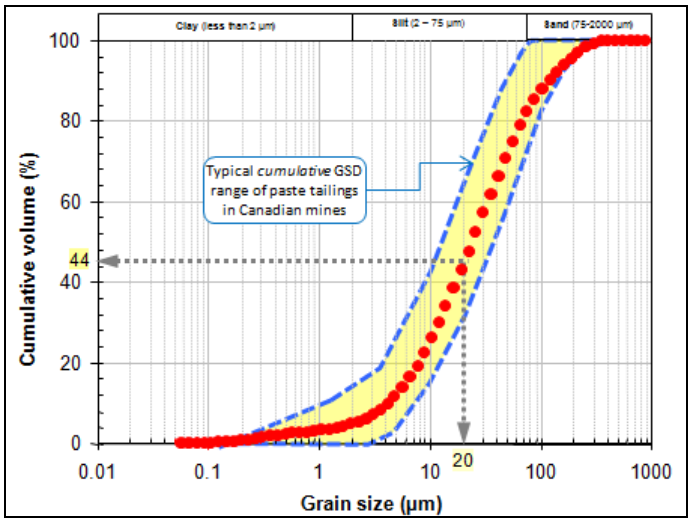

Figure 1. Grain size distribution curve of the paste tailings studied

Table 1. Physical properties of tailings

	Tailings
Specific gravity G_s	3.7
Specific surface area S_s (m^2/g)	2.2
Fines content (< 20 μm; %)	44
D_{10} (effective particle size; μm)	4.3
D_{30} (μm)	12.2
D_{50} (average particle size; μm)	24.3
D_{60} (μm)	33.6
D_{90} (μm)	119.2
Coefficient of uniformity $C_u = D_{60}/D_{10}$	7.9
Coefficient of curvature $C_c = D_{30}^2/(D_{60}xD_{10})$	1.1
Uniformity of graduation $U = (D_{90}-D_{60})/D_{50}$	4.7
Maximum dry unit weight γ_d (kN/m^3)	24.9
Optimum water content w_{opt} (%)	12.5
Void ratio at optimum condition e_{opt}	0.5

The compaction tests, based on the ASTM standard (ASTM D1557, 2012), were also performed in the laboratory as shown in Fig. 2. This method covers laboratory compaction methods used to determine the relationship between molding water content and dry unit weight of soils compacted in a 102- or 152-mm) diameter mold with a 44.48-N rammer dropped from a height of 457 mm producing a compactive effort of 2700 kN-m/m^3. The main parameters were also tabulated in Table 1. For the tailings sample, the optimum water content, w_{opt}, for the modified Proctor test was about 12.5 wt%. The corresponding dry unit weight was 24.9 kN/m^3. The calculated void ratio for the optimum condition was nearly close to 0.5.

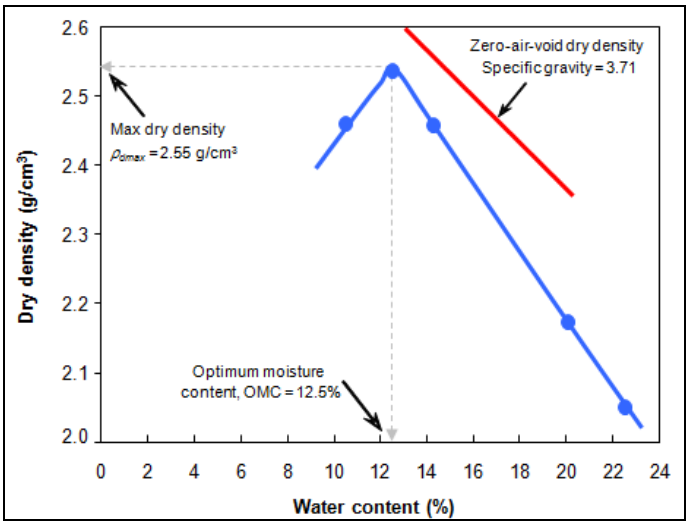

Figure 2. Moisture-dry density curve of paste tailings

2.1.2 Chemical composition

Chemical composition of the samples was determined by a Perkin–Elmer Optima 3100 RL ICP–AES (inductively coupled plasma–atomic emission spectroscopy) after sample digestion (Table 2). The tested mine tailings contained 39.2% Fe_2O_3 and 51.3% total sulfur as determined by major oxide and elemental analysis, respectively. Samples' hydraulic index ratio of unhydrated cement product ($[SiO_2+Al_2O_3]/[CaO+MgO]$) was calculated to be 0.8.

Table 2. Chemical composition of tailings, mixing waters and binders

	Tailings (wt %)	Water (mg/L)	Binder (%)
Al_2O_3	5.29	0.40	8.39
B_2O_3	0.61	0.14	0.13
BaO	0.01	0.05	0.03
CaO	0.79	782.16	42.82
Fe_2O_3	39.20	0.02	0.64
K_2O	0.24	2.77	0.55
MgO	0.16	3.03	6.19
MnO	0.02	0.01	0.18
Na_2O	0.40	455.61	2.03
S*	51.34	4069.88	3.35
SiO_2	1.07	1.91	30.91
TiO_2	0.07	n/a	0.48
ZnO	0.44	0.13	n/a

*Total sulfur was assumed expressed exclusively as SO_4^{2-} (= 2.9956 × S, based on stochiometric conversion)

2.1.3 Mineralogical properties

The Bruker AXS D8 Advance X-ray diffractometer equipped with a Co anticathode was also used to determine the mineralogy of the mine tailings tested in this study. The quantitative mineralogical analysis was also evaluated using Rietveld full-pattern fitting method equipped with the TOPAS software. The X-ray diffraction and semi-quantitative analyses revealed that the most abundant mineral within the mine tailings studied was pyrite (47%), followed by quartz (32%), chlorite (9%), paragonite (7%), muscovite (3%), talc (1%) and gypsum (1%). More information on the complete characterization of mine tailings, hydraulic binder and mixing water used in the experiments can be found in more detail in Yilmaz (2010).

2.2 Methods

2.2.1 Sample preparation

A total of 216 CPB samples were prepared by blending homogenously tailings, binder and water in an electrical Hobart D300-1 mixer until a flat consistency was achieved. Depending on the viscosity of matrix, additional water was added to set the resulting CPB solid concentration percentage to 78 wt%. Paste material was tested using the Abrams cone (ASTM C143, 2013) to achieve 7" slump for all samples (Fig. 4). To study the effect of placement conditions in the lab, samples were poured into different size moulds ($D \times H$ = 10 × 20 cm, 7.5 × 15 cm, and 5 × 10 cm) and different placement conditions (capped-drained C-D, uncapped–drained U-D, capped-undrained C-U, and uncapped–undrained U-U) for UCS testing. The capped-drained condition represents the placement of sample into the mould, which has drainage holes at the bottom and a cover on the top while the uncapped-drained condition refers to the placement of sample in the bottom-perforated mould without cover on the top. The capped-undrained placement condition, frequently used for quality control tests at both laboratory and mine sites, represents the capped mould with no drainage holes at the bottom. The uncapped-undrained placement condition represents the open-top mould with drainage holes at the bottom (Fig. 3).

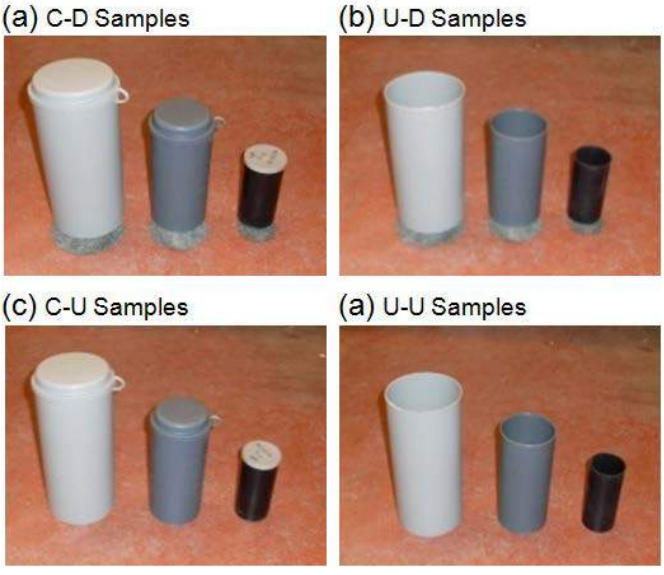

Figure 3. The drainage scenarios of paste fill

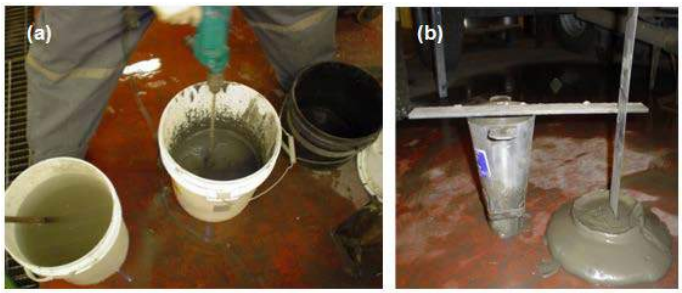

Figure 4. Photos of (a) a driller with a mixer bit in a 20-L pail, and (b) the slump test

In comparison with the unconsolidated samples a total of 108 CUAPS-consolidated samples were prepared for the prescribed curing times of 7, 14, and 28 days and binder contents of 3, 4.5, and 7 wt% (Fig. 5). For the drained scenarios, 2-mm diameter holes were drilled at the bottom of each mould, 31 holes for the 10 × 20 cm mould, 9 holes for the 7.5 × 15 cm mould, and 2 holes for the 5 × 10 cm. The geotextile filter was placed at the bottom to allow bleed water drainage. Paste samples were cast into the moulds in one-third increments. After the mould was filled, the paste was rammed in 25 blows using a small steel rod in order to eliminate any large trapped air bubbles within CPB, as described in the ASTM C143 standard. After sealing, the moulds were stored in a foggy room set at 80% relative humidity and 25°C temperature (replicates underground mine conditions) over the desired curing times.

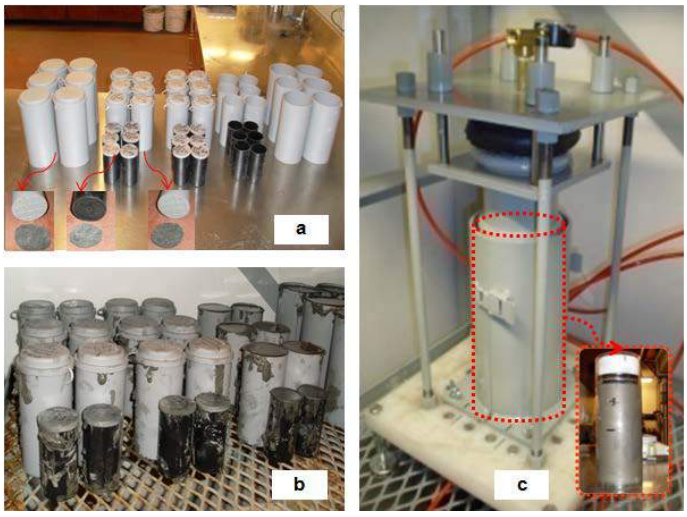

Figure 5. Photos illustrating the different size plastic moulds and test conditions: (a) empty moulds, (b) CPB-filled moulds, (c) capped-drained sample cured within CUAPS

2.2.2 Mechanical strength tests

Following the curing periods of up to 28 days, the unconsolidated paste backfills were well extracted from the drained-, undrained-, capped-, and uncapped plastic moulds using compressed air while CUAPS-consolidated paste backfill samples were extruded from the Perspex mould using an enough manual push sample extruder (Fig. 6).

Figure 6. The sample extraction methods

To determine the strength properties, the extracted CPB samples were subjected to unconfined compression tests (ASTM C39, 2012). A full automatic press (MTS Sintech 10/GL) having a loading capacity of 50 kN and a loading rate of 1 mm/min was used. Axial deformations were digitally recorded by a real-time data acquisition system. The observed UCS corresponds to the highest stress reached during the compression test. Prior to UCS testing, the samples' two ends were rectified using cutter (Fig. 7). The mean values from triplicate tests were presented in the results.

Figure 7. Photos of (a) a sample rectification and (B) CPB samples under MTS Sintech 10/GL mechanical press

2.2.3 Geotechnical index parameter tests

Some physical properties such as gravimetric water content w_g, degree of saturation S_r, dry density γ_d and void ratio e were also determined on representative CPB samples after UCS testing. A required portion of each specimen was oven-dried for about 3 days at 45 ºC in order to determine the water content of the CPB sample. Solids' specific gravity was determined by a Micromeritics AccuPyc 1330 helium pycnometer. Using these data (e.g. w_g, γ_d and G_s), the remaining physical parameters, including void ratio and degree of saturation were calculated from the mass-volume relationships. Physical properties were evaluated only on the specimen size which gave the highest mechanical strengths.

2.2.4 Mercury intrusion porosimeter tests

The CPB's microstructural properties was determined using a Micromeritics Autopore III 9420), which allows measurement of a minimum accessible radius of 0.003 µm (Fig. 8). After UCS tests, representative CPB samples ($D \times H$: 12 × 24 mm) were taken from the middle part of CPB specimen which avoids stress concentration effects. Samples were oven-dried at 45ºC for at least 96 h and then stored in a desiccator over silica gel to minimize pore alteration due to hydration product destruction and moisture ingress. For each sample, at least two MIP analyses were performed to obtain an average value.

Figure 8. Micromeritics Autopore III Model 9420 mercury intrusion porosimetry

3 RESULTS AND DISCUSSION

3.1 Effects of Placement Conditions on Strength Development of CPB

Fig. 9 shows the development of UCS with time for different CPB samples cast in a mould size of $D \times H$ = 10 × 20 cm, 7.5 × 15 cm, and 5 × 10 cm, and prepared at 3, 4.5 and 7 wt% binder dosages. These different drainage configurations appeared to affect the strength and stability, but the specimen size also played a key role in the strength development of CPB.

It can be seen from Fig. 9 that drained paste backfills generate better strengths than undrained paste backfills for a given CPB recipe and curing time. This is due the fact that the drained backfills have less water-to-cement *w/c* ratios, which favour the acceleration of cement hydration reactions with higher strengths. The results indicated are also confirmed for paste backfill samples cast in the mould sizes $D \times H$ = 7.5 × 15 cm and $D \times H$ = 10 × 20 cm (Fig. 9). It is fairly apparent that the highest strengths were obtained from the C–D samples. These samples are compared in percent with the other samples. It can be inferred from these findings that the drained CPB samples have a lesser amount of porosity. This is most often due to the fact that the water loss by drainage gives rise to the settling of the backfill and the resultant reduction of the CPB void ratio. Consequently, higher strengths are achieved when compared with the undrained paste backfills.

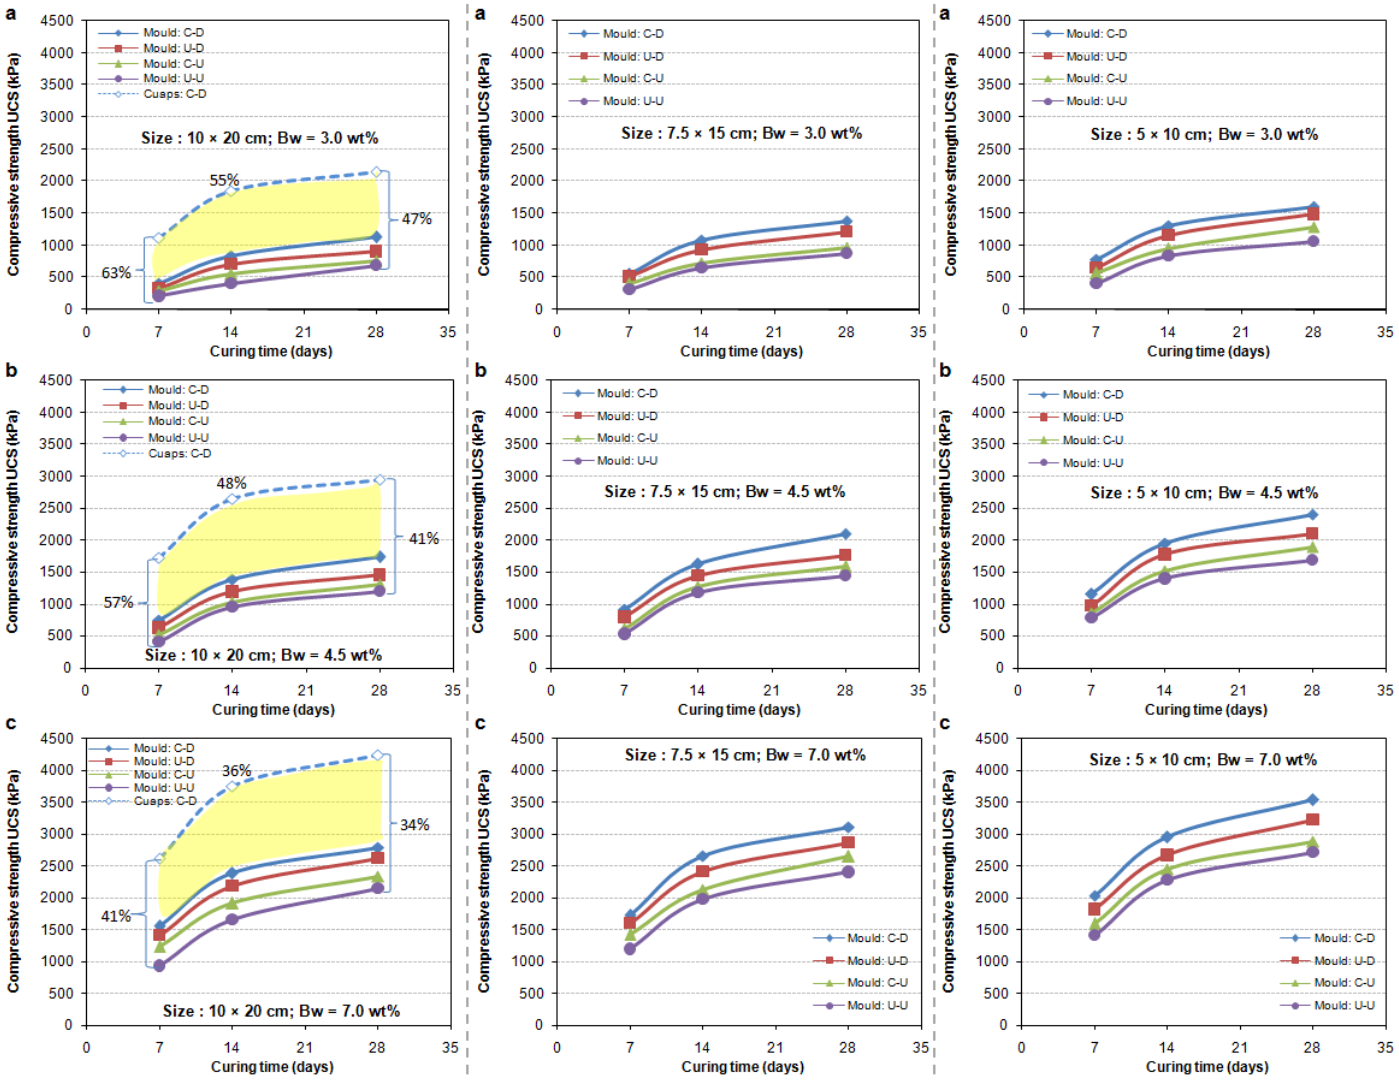

Figure 9. Change in compressive strength with curing time for different CPB samples cast in a mould size of $D \times H$ = 10 × 20 cm, 7.5 × 15 cm, and 5 × 10 cm, and prepared at binder contents of (a) 3 wt%, (b) 4.5 wt%, and (c) 7 wt%

Fig. 10 presents the evolution of the mechanical strengths of CPB prepared with 4.5 wt% of the binder type GU-Slag@20:80wt% for different curing times. It should be noted that the curing condition used in most laboratories is the C–U condition. From Fig. 7, it can be seen that the higher mechanical strengths were obtained from the small size specimen (d = 5 cm), regardless of curing condition, binder content and curing time. These findings clearly suggest the existence of specimen size effect on the resultant strength gain of CPB samples.

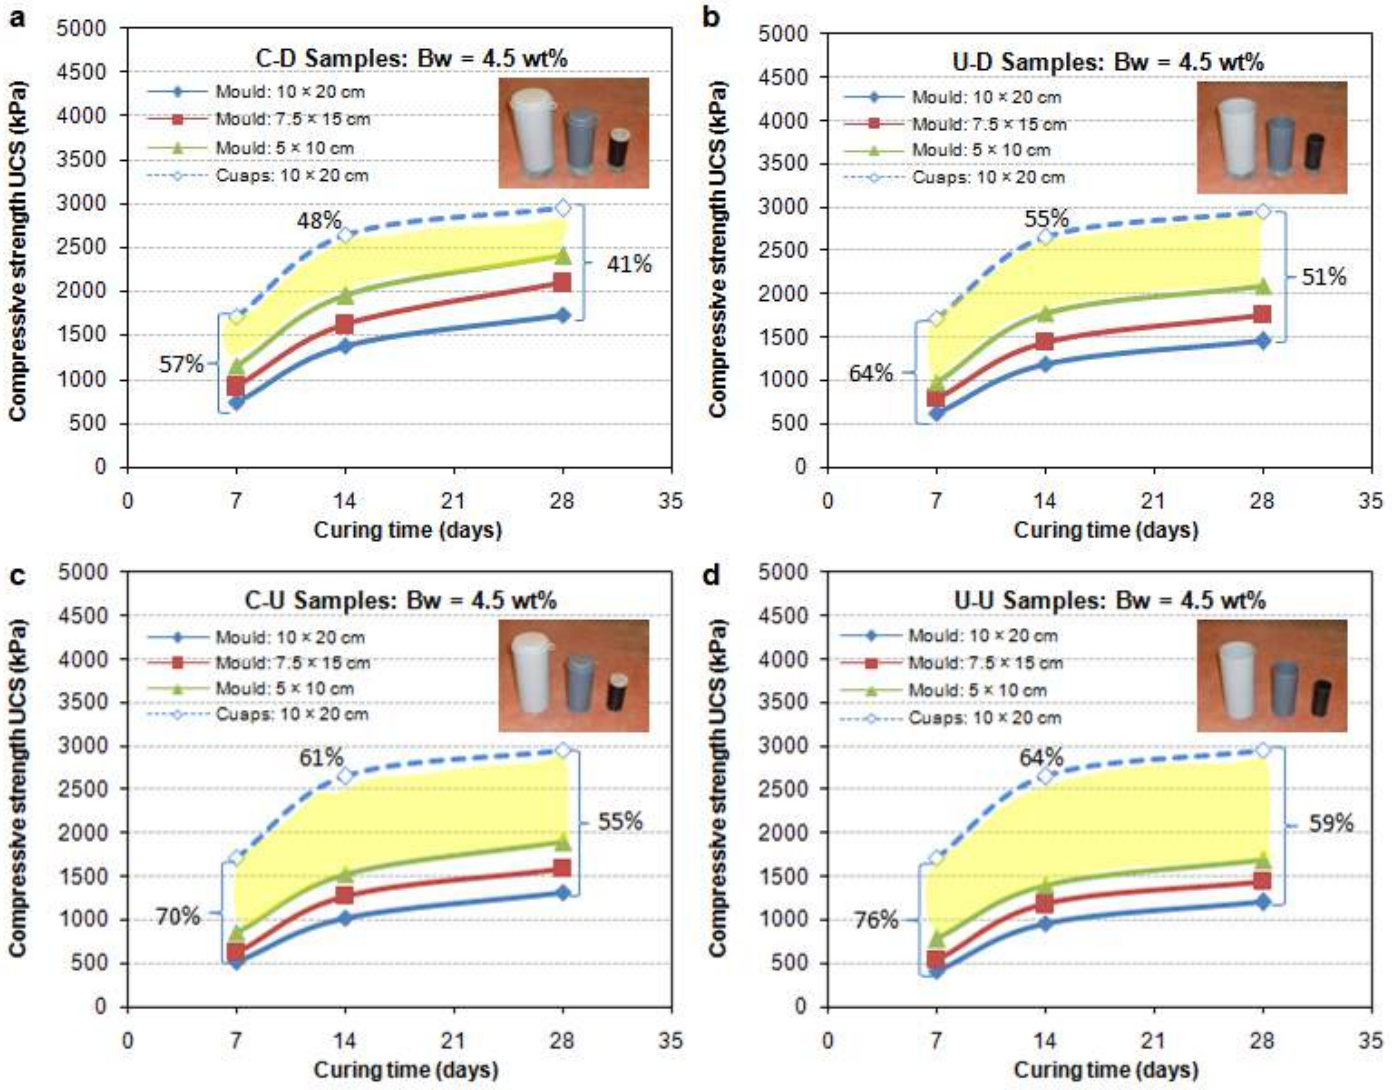

Figure 10. Specimen size effect on the UCS of CPB prepared with 4.5% of GU-Slag@20:80 wt% cured in four different placement conditions: a) capped and drained C–D; b) uncapped and drained U–D; c) capped and undrained C–U; d) uncapped and undrained U–U

3.2 Assessment of Geotechnical Index Parameters of Optimal CPB recipe

The mechanical strength properties of any CPB material are affected by its geotechnical index parameters, such as water content, void ratio, wet unit weight or specific gravity, and degree of saturation. It is well known that the physical properties that develop within CPB are greatly affected by a combination of *i*) the physical, chemical, mineralogical and micro-structural properties of paste backfill ingredients; *ii*) binder type and content; *iii*) curing conditions (with or without effective stress) including curing temperature and time; *iv*) paste mixing and placement techniques; and *v*) the internal stresses occurred in the CPB based on self-weight or time-dependent consolidation loadings.

In this study, the evaluation of physical property is made only on the most ideal CPB recipe cast in the mould 5 × 10 cm, which always gives higher strengths than other mould sizes. Fig. 11 shows the change in gravimetric water content w_g of CPB. The overall observation is that the water contents of the drained backfills is slightly lower than the undrained ones. When the binder dosage increased from 3 to 7 wt%, the water content was reduced mainly due to the initial *w/c* ratios and amounts of water required for cement hydration. This suggests that, the higher the cement content, the lower the water content is.

Fig. 11 shows the change in the void ratio *e* of different CPB samples as a function of binder content and curing time. The drained CPB samples showed smaller void ratios than the undrained ones because the water loss by drainage would give rise to the settling of paste backfill and the resulting reduction of the void ratio within backfill. Moreover, Fig. 11 illustrates that the drained CPB samples were less saturated than the undrained ones at a given binder content and/or curing time. The range of variation of degree of saturation S_r for the undrained backfills was relatively low (99.5 – 94% for the U–U samples and 99 – 92.5% for the C–U samples). After curing of 28 days, the S_r of backfill samples at 3, 4.5 and 7 wt% binder contents was determined to be 96.5%, 94.5% and 90.5%, respectively, demonstrating the decrease in the degree-of-saturation with increasing the binder content.

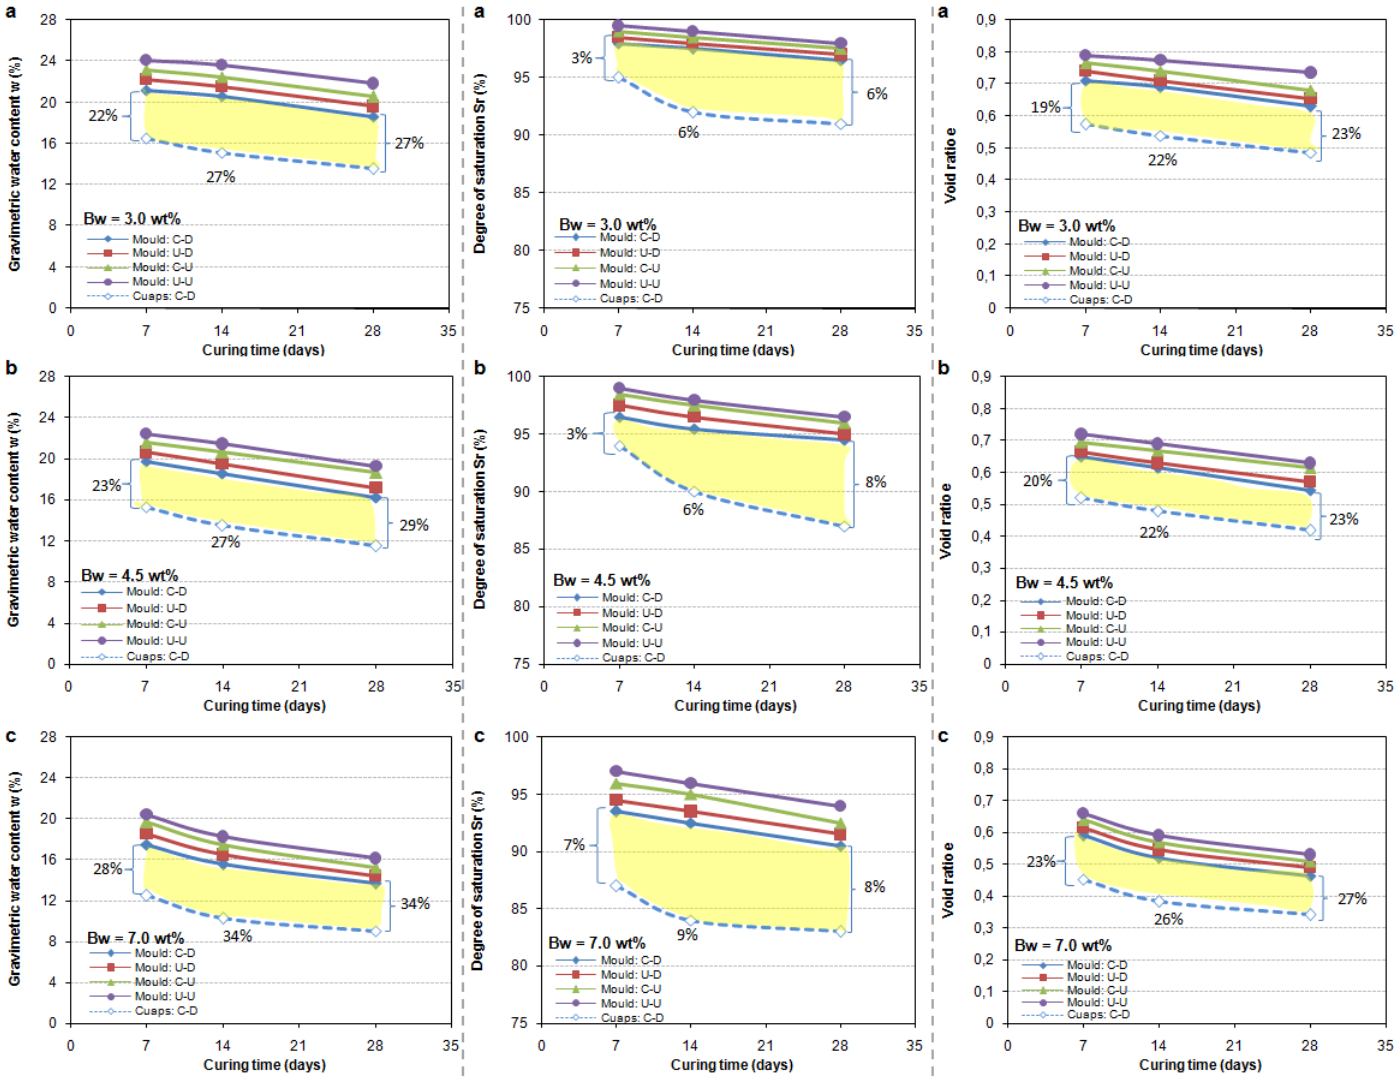

Figure 11. Change in gravimetric water content, void ratio, and degree of saturation with curing time for CPB samples cast in a mould size of $D \times H$ = 5 × 10 cm and prepared at binder contents of (a) 3 wt%, (b) 4.5 wt%, and (c) 7 wt%

Fig. 12 demonstrates the cumulative and incremental pore size distribution of the 28-day cured CPB samples prepared with the 4.5 wt% binder. The mercury intrusion porosity of CUAPS-consolidated backfills was lower (38.2%) than that of the samples consolidated in any other plastic moulds (44.8% for C-D samples, 45.8% for U-D samples, 46.2% for C-U samples, and 47.4% for U-U samples). Mercury porosimeter results indicate that the total porosity of the undrained paste backfills was greater than that of the CPB samples consolidated under effective stress due to the fact that the hydration-precipitation appears to occur to a lesser extent in the undrained samples. Application of effective stress during curing improves CPB's pore structure, and causes lower porosities in comparison with other unconsolidated samples.

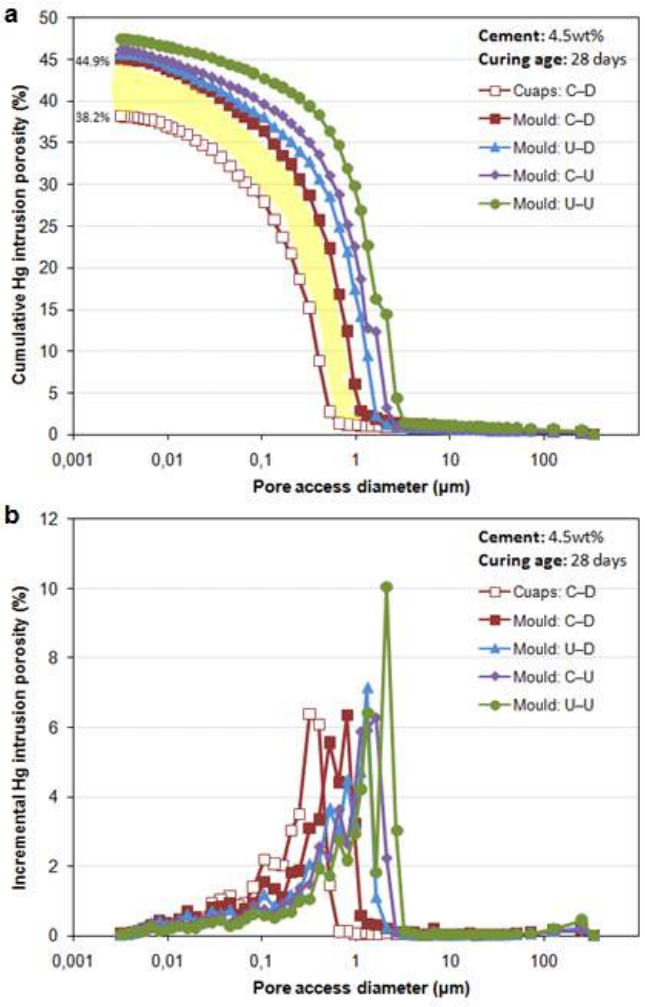

Figure 12. Cumulative (a) and incremental (b) pore size distribution of 28-day cured samples with cement content of 4.5wt%

4 CONCLUSIONS

This paper presents the results of an experimental study aimed at examining the effects of specimen sizes and placement conditions on mechanical (i.e. unconfined compressive strength) and physical (i.e. water content, degree of saturation and void ratio) properties of the CPB materials prepared using a slag blend binder consisting of 20 wt% general use Portland cement and 80 wt% blast furnace slag. A total of 432 CPB samples were produced at a binder content of 3, 4.5 and 7 wt% in different placement conditions: capped-drained C-D; uncapped-drained U-D; capped-undrained C-U; and uncapped-undrained U-U, and cast in three different size plastic moulds ($D \times H$: 5 × 10 cm, 7.5 × 15 cm, and 10 × 20 cm) over three curing times (7, 14 and 28 days).

The results from the experiments have shown that the diameter of the specimen greatly affects the overall mechanical strength for a constant height-to-diameter ratio. The most suitable specimen size with regards to the rate of strength development and the ultimate strengths was found to be $D \times H$ = 5×10 cm, which constantly provided higher strength, regardless of the placement conditions, compared to the other specimen sizes 7.5 × 10 cm and 10 × 20 cm. This is expected owing to the small volume of specimen which provides the decreased number of micro-cracks and pores in the homogenous matrix as compared with the larger specimen sizes. One of the major factors affecting the strength and stability of CPB is the placement and curing conditions entreated right after pouring the paste into the moulds. The test work has confirmed that the drained paste backfills always produce higher strengths than the undrained ones as a result of the removal of excess water within CPB, which helps accelerating binder hydration. Since in situ backfill conditions are different from those of lab-prepared backfills, the best placement condition out of different placement regimes (e.g., C-D, U-D, C-U and U-U conditions) can be determined consistent with the achieved UCS results. It is generally expected from a paste-backfilled stope condition that the porosity decreases

and the strength increases with increasing depth into the placed paste backfills. This is principally due to drainage and consolidation occurred during backfilling. The acquisition of strength for paste backfills becomes lower under the conditions of no drainage than drainage, as shown by the test results.

There is no standard backfill recipe and specimen size for the determination of the UCS of paste backfills. This work shows the prime importance of both specimen size and placement conditions for the mechanical strength development of paste backfill and hence for designing the most ideal paste backfill mixtures in the laboratory and operating a paste backfill plant in the field. Notwithstanding this, further testing is still required in order to acquire more consistent results for specimen size for determination of unconfined compressive strength of paste backfill samples, principally on the paste cored samples from paste-filled stopes. This experimental work will provide evaluation of the in situ mechanical strengths on which the field paste backfill samples are based.

ACKNOWLEDGEMENTS

The author would like to express his sincere thanks to the Natural Sciences and Engineering Research Council of Canada NSERC Discovery Grant Program, Industrial NSERC-Poly-UQAT Chair on the Environment and Mine Wastes Management and Canadian Research Chair on Integrated Management of Mine Wastes for their generous financial support. Special thanks are extended to Denis Bois, Tikou Belem, Bruno Bussière, Mostafa Benzaazoua, Nil Gaudet, David Bouchard, Yvan Poirier and Alain Perreault of the URSTM (Unité de Recherche et de Service en Technologie Minérale) Laboratory for their technical support in conducting several physical, mechanical and microstructural tests, to Nathan Mutch of Lafarge North America Inc. for providing the cement materials.

ABSTRACT The influence of Poisson's ratio (ν) on stress and strain concentration factors of plate contains a circular notch and subjects to biaxial loading have been systematically analyzed by using three dimensional finite element (3DFE) method. It is necessary to determine stress and strain concentration factors around the circular notch in order to determine the site of crack initiation. The numerical results of the stress and strain concentration factors are traced through the plate thickness. A plate under elastic state has been used in the present work. Four values of Poisson's ratio (ν) were studied numerically, varied from 0.1 to 0.4.

It is found that the maximum stress and strain concentration factors increase with increasing the Poisson's ratio (ν). The stress and strain concentration factors increase with decrease the biaxial ratio. Furthermore, the effect of Poisson's ratio (ν) on stress and strain concentration factor decreases with increasing the biaxial ratio.

Keywords: Stress concentration factor, SCF, strain concentration factor, circular notch, biaxial load, three dimension finite element

1 INTRODUCTION

Structures with circular holes have been widely used in engineering designs. This circular notch will create stress or strain concentrations. When stress concentrations exit in a structure, its strength is often different from that measured using specimens under uniaxial loading. It is necessary to determine stress or strain concentrations around the circular notch in order to determine the site of crack initiation, which can severely reduce the overall strength of the structure.

The actual 3D stress fields in the neighborhood of the notch root or circular hole are very complex (Li & Guo, 2001). The SCF or strain concentration factor in the interior of a plate with a hole or notch is significantly higher than the value on the free surface or the corresponding planar solution (Li & Guo, 2001), (Nakamura & Parks, 1990), (Wang, 2003), (Li et al., 2000), (Yang et al., 2003), (She & Gue, 2006), (Abd-Elhady, 2010). On the other hand, in engineering practice, SCF and strain concentration factor measurement are always made on the free surfaces. This may cause danger in engineering applications without proper consideration of the 3D stress distributions. She and Guo (She & Guo, 2007) show that through thickness variation of stress concentration factor, K_σ, for elliptic holes subjected to tensile stress is very slight in the thin plate and increases with increasing the plate thickness. The corresponding peak value (K_σ) max is located at the center of thickness for thinner plate but shifts to the free surface in thick

plate. Recently, She and Guo (She & Guo, 2006), (She & Guo, 2007) have already demonstrated that the SCF changes along the hole front in the thickness direction. However, the influence of Poisson's ratio has not been considered in their works.

Kotousov and Wang (Kotousov & Wang, 2002) have studied the effect of thickness and Poisson's ratio on stress concentration based on some theoretical methods which showed that the 3D stress concentration is a function of thickness and Poisson's ratio. However, these existed theoretical methods often give the SCF as a mean value view, cannot solve the distribution of SCF along the notch front in the thickness direction and so cannot obtain the maximum SCF along the notch front. Furthermore, Peishi et al. (Peishi et al., 2008) found that the thickness-dependent maximum of SCF, increases significantly with increasing the Poisson's ratio in the elliptic holes which subjected to tensile loading. Tlilan (Tlilan, 2010) studied the influences of Poisson's ratio and the geometric configuration upon the strain concentration factor, defined under triaxial stress state, of notched bars with U-notch. Tlilan show that, the Poisson's ratio has a significant effect on the strain concentration factor, especially for deep and intermediate notch depths.

The main objective of the present work is to study the influence of Poisson's ratio (ν) and biaxial ratio on the stress and strain concentration factors and their relations of elastic finite thickness plate containing a circular subjected to far end uniform biaxial loading using 3D finite element method.

2. NUMERICAL MODEL

2.1. Definitions of the geometrical parameters

The plate containing a circular hole subjected to biaxial loading is illustrated in Fig. 1. The notch diameter is 2*D* and the radius of the notch is ρ. The thickness, width and the height of the plate are 2*B*, 2*W* and 2*H*, respectively. The plane *x-y* (plane *z* = 0) is the mid plane of plate and two plate surface are *z* = *B* and *z* = -*B*, respectively. The geometrical parameters of specimens are chosen as follows:

D = 1 mm;
B/D = 2.5 ;
ν = 0.1, 0.2, 0.3 and 0.4;
The biaxial ratio, λ, = -1, -0.5, 0, 0.5 and 1;
Young's modulus *E* = 200 GPa;
W/D = *H/D* = 100;

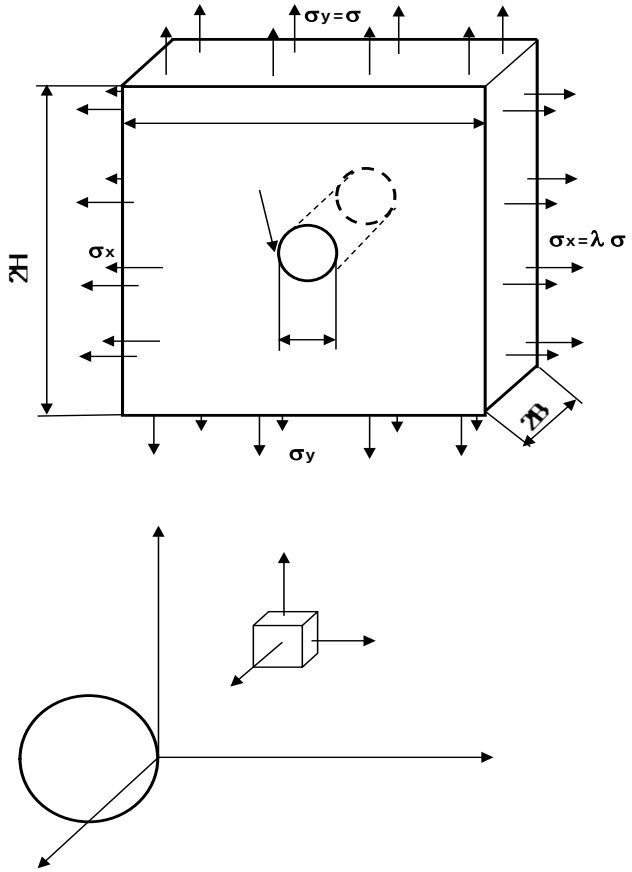

Figure 1. The geometry of the plate with circular hole under biaxial loading.

2.2. Definitions of the stress and strain concentration factor

In this paper, the stress and strain concentration factor is denoted as K_σ and K_ε respectively and the stress and strain concentration factor at the mid point of the plate is $K_{\sigma mp}$ and $K_{\varepsilon mp}$ respectively.

$$K_\sigma = \frac{\sigma_{NR}}{\sigma_{net}}; \quad (1)$$

$$K_{\sigma mp} = K_\sigma \qquad \text{at z = 0}$$

$$K_\varepsilon = \frac{\varepsilon_{NR}}{\varepsilon_{net}} \quad (2)$$

$K_{\varepsilon mp} = K_{\varepsilon}$ at z = 0

Where:

$$\sigma_{net} = \frac{\sigma_y W}{W - D} \quad (3)$$

$$\varepsilon_{net} = \frac{\sigma_y W}{E(W - D)} \quad (4)$$

Here, σ_{NR} and ε_{NR} are the longitudinal stress and strain in Y direction of plate at the notch root; σ_{net} and ε_{net} are the mean stress and strain of net section on the ligament, respectively. The K is meaning stress or strain concentration factor.

2.3. Finite Element Analysis

ABAQUS (ABAQUS, 2002) was selected to perform the numerical analysis owing to its powerful and comprehensive functions and precision. Therefore, a three-dimensional (3D) finite element model has been developed to account for geometric and material behavior of isotropic plate. A uniform, $\sigma_y = \sigma$, stress of 50 MPa is applied on the above and down boundary of the plate and $\sigma_x = \lambda\sigma$, in other hand side as shown in figure 1. The finite element meshes constructed with hexagonal structural mesh, C3D8 (An 8-node linear brick) elements, are used for a plate under Standard/static analysis.

Around 30 planar layers are divided through the thickness of the plate. The mesh refinement process is carried out to assure that results are not dependent upon the element size. So that, the size of element decreases gradually with distance from the open hole decreasing (as shown in Fig. 2). This means that the finite element (FE) meshes in the neighborhood of the hole are much denser. The plate are modeled with around 45000 elements.

2.4 Model Verification

To verify the accuracy of the present result, the values of normalized stress, $K_{\sigma}/K_{\sigma mp}$, and strain, $K_{\varepsilon}/K_{\varepsilon mp}$, concentration factor (normalized by each value of mid plane) for $\nu = 0.3$ and uniaxial loading ($\lambda = 0$) are compared with the previous numerical results using 3-D analysis found in the literature, B/D = 2.5, W/D = 100 and H/D = 100, (Zheng et al., 2008), as shown in Figures 3. Figure 3 shows An excellent agreement between present model result and data in literature (Zheng et al., 2008).

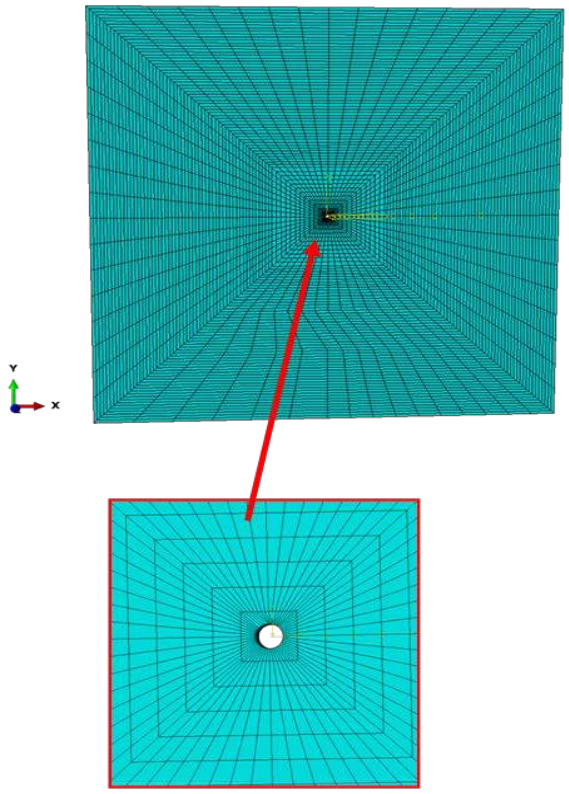

Figure 2. Finite element model mesh.

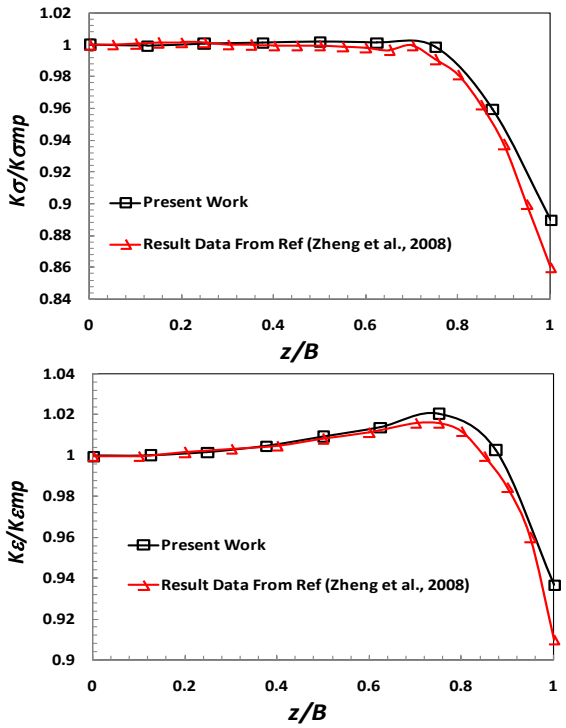

Figure 3. The distributions of the stress and strain concentration factor through-thickness of notch root for present work and numerical result in literature (Zheng et al., 2008).

3. RESULTS AND DISCUSSION

Fig. 4 illustrates the variation of normalized stress concentration factor, $K_\sigma/K_{\sigma mp}$, (the stress is normalized by each value of mid plane) versus *z/B* for different ν and λ. At different value of λ the normalized stress concentration factor has constant value equal 1 until *z/B* reach to 0.8 then decrease by increasing the dimensionless *z/B.* The obtained results for D = 1 mm, are compared with the result for D = 0.5 with the same ratio of *B/D, W/D* and *H/D* (only for $\nu = 0.1$, 0.4 and $\lambda = -0.5, 0.5$) to validate the proposed value. the values of $K_\sigma/K_{\sigma mp}$ for D = 1 is identical to this obtained for D = 0.5 with the same ratio of *B/D, W/D* and *H/D*.

Fig. 5 represents the variation of normalized strain concentration factor, $K_\varepsilon/K_{\varepsilon mp}$, (also, the strain is normalized by each value of mid plane) versus *z/B* for different ν and λ. At different value of λ the normalized stain concentration factor increase to reach to it's a peak value and then decrease by increasing the dimensionless *z/B*

The previous curves represent the variation of either the normalized $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp,}$ for $\lambda \neq 1$, can be divided to three regions. In the first region $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp}$ increased with increasing *z/B* to reach its peak value. In this region, the $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp}$ increase with increasing ν for the same *z/B.* in the second region, all values of $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp}$ decrease with increasing *z/B* by different values of decrement to intersect at one point ($z/B \approx 0.8$ in case of $K_\sigma/K_{\sigma mp}$ and $z/B \approx 0.9$ in case of $K_\varepsilon/K_{\varepsilon mp}$). In the third region ($K < K_{mp}$), the previous decrement continued to get opposite trend on the surfaces. The $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp}$ decreases with increasing ν for the same *z/B*. Therefore, it can be concluded that the peak value of K_σ and K_ε locate at the interior of the plate and this value increases by increasing the value of Poisson's ratio. While, the minimum values of K_σ and K_ε locate at free surface of the plate and this value decrease by increasing the Poisson's ratio. But, for $\lambda = 1$, the normalized $K_\sigma/K_{\sigma mp}$ or $K_\varepsilon/K_{\varepsilon mp}$ are not changed by increasing the values of *z/B* and are equal 1.

Figure 6 presents the variation of mid plane stress and strain concentration factor with λ for different dimensionless ν. For $\lambda \neq 1$, the stress and strain concentration factor increase by increasing ν. $K_{\sigma mp}$ and $K_{\varepsilon mp}$ decrease with an increase in λ. This may be due to increasing the compression stress in the notch root by increasing the biaxial ratio, λ. It was found also that the $K_{\sigma mp}$ and $K_{\varepsilon mp}$ is close to that given by Peterson (Peterson, 1997) when λ is equal zero. Furthermore, the effect of Poisson's ratio (ν) on stress and strain concentration factor decreases with increasing the biaxial ratio. For $\lambda = 1$, the stress and strain concentration factor are not affected by change the values of Poisson's ratio. Furthermore, the relation between stress or strain concentration factor and biaxial ration, λ is linear as shown in the figure 6 which is agreement with derived by Peterson (Peterson, 1997).

Figures 7 and 8 show the contours of the resulted Von Mises stress and longitudinal stress (σ_{yy}) around the open hole for $\nu = 0.3$. It is observed that, the values of Von Mises stress and σ_{yy} decrease by increasing the values of the biaxial ratio λ. The value of σ_{yy} around the second notch root at the upper and lower hole transform from the compression to tension by increasing the values of the biaxial ratio λ as shown in figure 8.

4. CONCLUSIONS

It can be concluded from the present numerical work that:

The maximum stress and strain concentration factors increase with increasing the Poisson's ratio (ν) inside the plate thickness while, it have the opposite trend at the free surface.

The stress and strain concentration factors increase with decrease the biaxial ratio.

The effect of ν on stress and strain concentration factor decreases with increasing the λ. Furthermore the stress and strain concentration factor are not affected by change the values of Poisson's ratio for $\lambda = 1$.

Estimating of Hoek-Brown m_i Using Internal Friction Angle

S. Mehrishal,
Amirkabir University of Technology, Tehran, Iran

M. Sharifzadeh,
Curtin University, Australia

K.Shahryar
Amirkabir University of Technology, Tehran, Iran

ABSTRACT Application of Hoek-Brown failure criterion in rock mechanics is more common and is verified well. In this criterion, the m_i is an important factor which controls trend of failure curve. Based on rock type and triaxial test data, the method of m_i estimation for different rocks is provided by Hoek-Brown. Indeed, this parameter is a frictional property and it depends on rock type, mineralogy and granular interlocking of rocks. In addition, it can be approximately predicted from the ratio between the uniaxial compressive strength and tensile strength of brittle intact rocks. But, because of tension strength estimation difficulties, this method is not applicable well. In this paper, correlation of m_i and internal friction angle (φ) of intact rocks is investigated and based on this correlation; a comprehensible physical concept is introduced for this parameter. Therefore, using this concept, a simple and exact estimation method is developed for m_i and H-B failure criterion calculation. The results predicted by new method are well verified by comparison with experimental test results.

Keywords: Internal friction angle, Hoek – Brown failure criterion, rock mechanics

1 INTRODUCTION

The Hoek-Brown failure criterion for intact rock and rock mass was developed in 1980 and modified over the years in order to meet the needs of users. Although, A great number of rock strength criteria have been proposed over the past three decades, but the Hoek-Brown failure criterion has been the most well-known and most frequently used one, because: (a) it was developed specifically for rock materials and rock masses; (b) it's input parameters can be determined from routine unconfined compression tests, mineralogical examination, and discontinuity characterization; and (c) it has been applied for over 34 years by practitioners in rock engineering, and has been applied successfully to a wide range of intact and fractured rock types (Sari 2010).

Hoek and Brown (1980) proposed a method for obtaining estimates of the strength of jointed rock masses, based upon an assessment of the interlocking of rock blocks and the condition of the surfaces between these blocks (Hoek 2007). According to Hoek-Brown (1980), incept of this concept is rooted in Griffith criterion. Consequently, the original criterion and general criterion for intact rock and rock mass were developed as follow:

$$\sigma_1' = \sigma_3' + \sigma_{ci}\left(m_b \frac{\sigma_3'}{\sigma_{ci}} + s\right)^a \quad (1)$$

$$\sigma_1' = \sigma_3' + \sigma_{ci}\left(m_i \frac{\sigma_3'}{\sigma_{ci}} + 1\right)^{0.5} \quad (2)$$

Where σ'_1 and σ'_3 are the maximum and minimum effective principal stresses at failure, m_i and m_b are the value of the Hoek-Brown constant respectively for the intact and rock mass. s and a are constants which depend upon the rock mass characteristics and σ_{ci} is the uniaxial compressive strength of the intact rock pieces.

The relationship between the principal stresses at failure for a given rock is defined by two constants, the uniaxial compressive strength σ_{ci} and m_i. Wherever possible the values of these constants should be determined by statistical analysis of the results of a set of triaxial tests on carefully prepared core samples. For this purpose, once the five or more triaxial test results have been obtained, they can be analyzed to determine the uniaxial compressive strength σ_{ci} and the Hoek-Brown constant m_i as described by Hoek and Brown (1983). In this analysis, equation (2) is re-written in the form:

$$y = m\sigma_{ci}x + s\sigma_{ci} \tag{3}$$

Where $x = \sigma'_3$ and $y = (\sigma'_1 - \sigma'_3)^2$, for n specimens the uniaxial compressive strength σ_{ci}, the constant m_i and the coefficient of determination r^2 are calculated using linear regression. In the absence of laboratory tests, a guideline table can be used to obtain estimate of mi and σ_{ci}. Of course, it should be noted that the simple relationship between mi and rock type as envisaged by Hoek & Brown has not proven to be appropriate with the benefit of a much greater data set than was available at that time. The most accurate method of assessing m_i values remains as statistical analysis of data from a full set of laboratory test results. In the absence of a full suite of laboratory tests, R, the ratio of unconfined compressive strength to tensile strength, is a useful indicator of m_i values (Richard and Read 2011).

This paper first summarizes procedures used to calculate m_i and then introduce a new m_i estimation method based on rock's internal friction angle and finally, compares the m_i results obtained from Hoek-Brown's linear regression method and new internal friction angle method.

2 CALCULATION OF m_i VALUE

In the m_i calculation using statistical analysis, method of data analyzing can mainly affect the obtained value of m_i. In order this, Hoek-Brown used Linear Regression but the nonlinear Levenberg-Marquardt Least Squares (Madsen et al. 2004) is default analyzing method in RocData and Simplex Reflection method (Shah, and Hoek 1992) and Linear Regression are also selectable. Applicability of this different analyzing method is investigated by Douglas (2002).

In the case of intact rock material where s = 1, Hoek-Brown noted that $m \approx \sigma_{ci}/|\sigma_t|$ where σ_t is the uniaxial tensile strength of the intact rock. However, for general criterion use, they preferred to estimate m simply as a statistical curve-fitting parameter because of the difficulty in adopting the uniaxial tensile strength as a fundamental rock property (Richard and Read 2011).

Hoek & Brown suggested that m for intact rock (m_i) reflects rock type and its value increase with coarser grain size. According to this, they established guideline tables to estimate the m_i. But, study shows that calculated values for m_i are different from those in guideline tables and this difference is more specific in igneous rocks (Richard and Read 2011). Mostyn and Douglas (2000) showed that usually the calculated values are smaller than guideline values. For example, of individual lithology, sandstone has the most extensive set of test data. The frequency distribution of m_i values for this rock type from the Douglas database shows that compared with the Hoek guideline range of 13 to 21, 35 out of the 55 data points lay outside the indicated range based on lithology (Richard and Read 2011).

Correlations of m_i with unconfined compressive strength and Deere - Miller modulus ratio (intact elastic modulus E_i divided by unconfined compressive strength σ_c) and other rock parameters are mostly very poor (Richard and Read 2011). The only rock material parameter with which m_i has any reasonable correlation is the ratio of the unconfined compressive strength (σ_c) to the tensile strength (σ_t). Sheorey (1997) defined this ratio as $R = \sigma_c/|\sigma_t|$.

Tensile strength usually is determined by two, direct and indirect, methods. The results of direct (pulling) tests are not more valid,

largely due to gripping techniques and alignment of the test specimen. The indirect (Brazilian) test is a simple procedure, with many practical advantages over direct tensile tests. However in both cases the testing procedures used can have a great deal of influence on the results. Pells notes that the correspondence between direct and Brazilian type tests is usually very good if similar size specimens are used (Pells 1993). Data from Inada & Kinoshota indicate that the values obtained from the Brazilian tests are about 1.1 to 1.2 times larger than those from the uniaxial tension test (Inada and Kinoshita 2001). The results of 20 direct and 40 Brazilian tensile strength tests from Gorski &Conlon show that the Brazilian tests results were about twice those of the direct tests (Gorski and Conlon 2007). However, there appear to be few comparative studies between the two techniques in the literature.

The laboratory tensile data in the Douglas database comprised results from both direct uniaxial tension and indirect (Brazilian) testing. Using these data, the intact rock parameter mi has been calculated in overall accordance with the Hoek guidelines (≥ 5 data sets with the maximum σ3′ ranging from 0.4 to 0.6 σci). The calculations have been done with the RocLab program using the Levenberg-Marquardt technique, discarding any results with obviously poor correlation. Figure 1 shows the relationship between R and mi. There is a fairly good relationship between R and mi. Although most of the data sets involve only a single uniaxial compressive and/or tensile test, the scatter of points is also fairly uniformly distributed about the 1:1 correlation line for both test types. Therefore, it can be conclude that the value of R is a good representative for mi.

Although, tensile strength is an important element of the failure criterion, but, Hoek-Brown do not include it in mi calculation guidelines. Though not clear, this may be related to the earlier-stated difficulties with the tensile tests. While the direct tensile test is not readily available as a standard procedure in many rock testing laboratories, the Brazilian test is simple with regard to both specimen preparation and testing procedure. Therefore, inclusion of tensile testing, as advocated by Sheorey (Sheorey 1997), into a full suite of testing for mi determination is straightforward, as also practiced in some of earlier testing investigations such as Read et al. (2005). It has been proven that R provides a simple basis for estimating mi. R has also been utilized by Cai (1983) in his investigation of tensile strength determination from acoustic emission during compression testing.

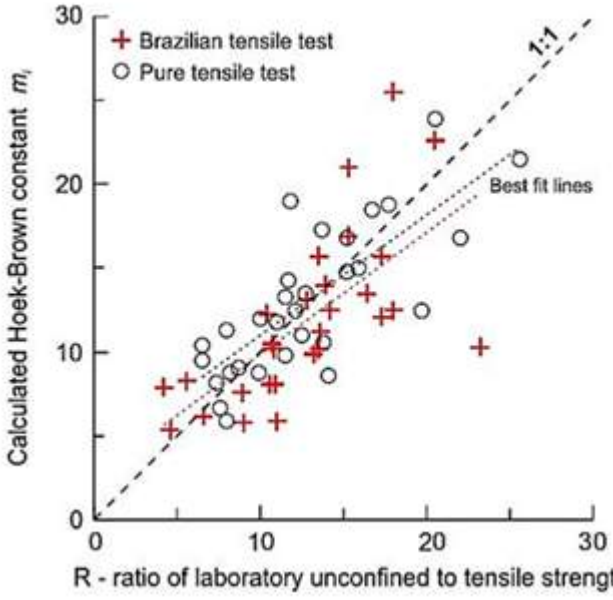

Figure 1. Plot of laboratory compressive strength to tensile strength ratio with Hoek-Brown constant m_i using data from Douglas 2002.

3 m_i ESTIMATION USING INTERNAL FRICTION ANGLE (Φ)

For each series of triaxial test data, the normal (σ_n) and shear stresses (τ) could be calculated and the Mohr circle fitting curve easily could be drawn using the equations published by Balmer (1952). Drawing Mohr fitting curve for different series of test data showed that under the low normal stress, the large and small value of m_i respectively leads to increase and decrease of instantaneous friction angles. Large values for m_i from 15 to 25 usually are associated with brittle igneous and metamorphic rocks such as andesite, gneisses and granites. And low value of m_i from 3 to 7, most are associated with ductile carbonate rocks such

as limestone and dolomite (Hoek 1983). It can be concluded that the constant m_i is related to the frictional properties of the rock and changes with the type of rock, its mineral composition, interlocking of grains, grain size and etc.

As stated previously, ratio of the unconfined compressive strength (σ_c) to the tensile strength (σ_t) has reasonable correlation with m_i and this ratio is defined as R ($R = \sigma_c/|\sigma_t|$). But, usually measuring tensile strength of rocks is difficult and the testing procedures used can have a great deal of influence on the results. In order to improve this concept, relations of Coulomb's failure theory are used in this paper. According this theory, uniaxial strength (σ_c) and tension strength (σ_t) can be written as:

$$\sigma_c = 2C \cos\varphi / (1-\sin\varphi)$$

$$\sigma_t = 2C \cos\varphi / (1+\sin\varphi)$$

Where φ is internal friction angle of intact rock and C is inherent cohesion of rock material. It is experimentally proved that rock materials usually deviate from Coulomb's failure theory in tension conditions and tension strength is about half of its theoretical value. Therefore it's assuming that:

$$\sigma_t \approx C \cos\varphi / (1+\sin\varphi)$$

Then the ratio of σ_c on σ_t (or R) is equal to:

$$\sigma_c/\sigma_t = 2(1+\sin\varphi)/(1-\sin\varphi)$$

$$R = 2(1+\sin\varphi)/(1-\sin\varphi)$$

Figure 2. Comparison of Failure criterion curves obtained from H-B linear regression and new proposed method.

Finally by replacing m_i to R and tan ψ to $(1+\sin \varphi)/(1-\sin \varphi)$, a simple equation can be obtain for m_i calculation:

$$m_i \approx 2 \, tg\psi$$

Now it is simple to understand whether the constant of m_i is related to the frictional properties of the rocks and using this equation, it is possible to introduce a simple physical concept to definition of m_i. Using this approach the values of m_i and σ_c could be estimated accurately by a simple way.

In order to investigate the validation of this approach, Hoek-Brown criterion is written for several triaxial test data using linear regression method and using new internal friction approach. Comparison the results from both methods showed that the criterion calculated from internal friction angle has a good conformity by criterion from linear regression. Figures 2 (a to e) illustrate this coincidence.

4 DISCUSSION

Researches show that the large values of m_i give steeply inclined Mohr envelopes and high instantaneous friction angles at low effective normal stress levels. Therefore it can be suggested that the constant of m_i is related to the frictional properties of the rocks. In this paper, using theoretical equations and some empirical suggestions a simple relation is introduced which make possible to estimate m_i of intact rocks using internal friction angle value. This approach introduces a simple physical concept for m_i, improves the knowledge about this parameter and makes more apparent relation between rock types and Hoek-Brown criterion. Also Calculations in this method is much simpler than other previously proposed methods.

Estimating Mechanical Properties from In-Situ Rebound Values of Some Nigerian Rocks

B. Adebayo
Department of Mining Engineering, Federal University of Technology, Akure

ABSTRACT This paper deals with the estimation of rock strength parameters using values of rebound hardness of in-situ intact rocks within South Western Nigeria basement complex. This was achieved by using L-Type hammer and the results of the rebound were obtained while holding the Schmidt hammer horizontally against the surface of the rock. The rebounds value of hardness recorded were subjected to three most accepted methods to make the data reliable. The uniaxial compressive strength and young modulus of elasticity were estimated from the equations proposed by different researchers. The result obtained showed that the compressive strength varied from 39.19 MPa to 49.38 MPa and 88.40 MPa to 101.60 MPa while the young modulus of elasticity varied from 17.55 GPa to 21.39 GPa. Strong correlation exists between uniaxial compressive strength and rebounds hardness value with multiple correlation coefficient of 0.9985.

Keywords: Schmidt hammer, rebounds, hardness, in-situ, rock

1 INTRODUCTION

The Schmidt hammer was originally designed in 1940s as an index for non-destructive testing of concrete compare to its surface rebound hardness Kahraman *et al*, (2002). The use of this instrument in rock mechanics practice was dated back to early 1960s. It has been increasingly used worldwide due to its simplicity, rapidity and portability. Also, taking the long history as well as wide spread use the standard methods of hammer rebound test by (ISRM, 1978; ASTM, 2001) might be expected to ensure consistent and reliable values for a given rock type. Aydin and Basu, (2005) in their work identified ways of reducing scatter values and thereby improving the reliability of the Schmidt hammer as a rock material characterization tool. Ayday and Goktan, (1992) found reliable correlations between L-type and N-type hammer rebounds values obtained during field testing.

Schmidt hammer models are designed at different levels of impact energy but type L and N are often use for determination of rock hardness. Type L – hammer has impact energy of 0.735 Nm while that of type N – hammer is 2.207 Nm. When the Schmidt hammer (Consist of spring-loaded piston) is pressed orthogonally against the rock surface, the piston is automatically released on to the plunger and the rebound height of the piston is considered to be an index of surface hardness (Basu and Aydin, 2004).

In the horizontal direction, energy released by the key spring is equal to the Kinetic energy of the piston with which it is released on to the plunger

$$0.5kx_1^2 = 0.5MV_1^2 \quad (1)$$

k = spring constant

x_1 = maximum stretch of the spring (when it is fully loaded)

V_1 = the velocity of the piston when it touches the plunger (while firing)

M = the mass of the piston

Similarly Basu and Adyin (2004) said that the kinetic energy of it piston at the instant of rebound starts must be equal to the energy of the key spring stretched by x_2 at maximum rebound position expressed by equation 2.

$$0.5MV_2^2 = 0.5\ k\ x_2^2 \quad (2)$$

V_2 = the initial rebound velocity of the piston

Combining Equations (1) and (2)

$$\frac{x_2}{x_1} = \frac{V_2}{V_1} \quad (3)$$

They also expressed the ratio of $\frac{x_2}{x_1}$ in percentage form called the rebound number given by equation (4)

$$R_h = \frac{x_2}{x_1} \times 100 \quad (4)$$

However, several methods of concluding Schmidt hammer test have been proposed, as described by Poole and Farmer (1978). Ayday and Goktan, (1993) statistically compared the three most accepted methods of (Hucka, 1965; Poole and Farmer, 1978; ISRM, 1981) and concluded that the ISRM method was different from other methods.

Some researchers proved that Schmidt hammer test is an important index test for rock material characterization. It was observed that during feasibility studies of mining project data on the rock properties are not readily available and the Schmidt hammer test is very cheap and quick to conduct. The objectives of this study therefore, are to estimate some rock properties from Schmidt hammer rebound values and used the data established to characterize the rock. Ultimately, this will serve as a preliminary data for investors in Solid Mineral as guide them in the selection of mine machinery as well as to be able to prepare functional feasibility studies.

1.2 Descriptions of the Study Area

The study area covers Oyo, Ogun, Osun Ondo and Ekiti State. All these states fall within the Precambrian of south western Nigeria, which is a part of Nigerian Basement Complex. Five groups of rocks could be identified in the basement complex (Rahaman, 1988). These rocks are: (i) migmatite gneiss-quartzite complex; (ii) slightly migmatised to unmigmatised meta-sediment; (iii) charnokite rocks; (iv) older granite and (v) unmetamorphosed dolerite dykes. The number of outcrops in this region varies from isolated boulders to large exfoliated domes and inserlberg. The location of the study areas are presented in Table1.

2 MATERIAL AND METHODS

2.1 Material

In-Situ hammer tests were performed on six different rock types; the test sites included operating quarries, abandoned quarries as well as natural outcrops within the South Western Nigeria Basement Complex. In addition, tests were carried out with L-type hammer having impact energy of 0.735 Nm. The tests were carried out with the hammer held horizontally against the surface of in-situ rock.

2.2 Methods

The three most accepted methods were selected among different Schmidt hammer rebound techniques and these methods are described below:

2.2.1 Test method 1

Hucka,(1965) Suggested that the peak value from ten continuous impacts at a point should be selected as presented in Table 2

2.2.2 Test method 2

ISRM, (1981) recommended that 20 rebounds values from single impacts separated by at a plunger diameter should be recorded and averaged the ten upper values as presented in Table 2.

2.2.3 Test method 3

Poole and Farmer, (1980) advised that the peak value from at least five continuous impacts at a point should be selected as presented in Table 2.

2.3 Estimating Some Rock Properties Using Mean Rebounds Values.

The uniaxial compressive strength and young Modulus of the rock samples were estimated from equation (5) and (6) proposed by Aydin and Basu, (2005) respectively and the results are presented in Table 3.

$$\sigma_{ucs} = 1.45 * e^{(0.07 \times RL)} \quad (5)$$

σ_{ucs} = estimated uniaxial compressive strength

R_L = Rebound Value of L-type hammer

$$E_t = 1.04 \times e^{0.06xRL} \quad (6)$$

Where E_t = the estimated young modulus. In addition, the limestone sample's uniaxal compressive strength and young modulus was determined from equation (7) and (8) proposed by Sachpazis, (1990).

$\sigma_{ucs} = 4.29. R_L - 67.52$ (7)

$E_t = 1.94*R_L - 33.93$ (8)

Decree and Millers, (1966) proposed equation 9 and 10 for estimation of uniaxial compressive strength these equations were used to obtained another set of values and the results are presented in Table 3

$\sigma_{ucs} = 4 (R - 25)$ (9)

For R up to 50

$\sigma_{ucs} = 20 (R - 45)$ - (10)

For R over 50

σ_{ucs} = Uniaxial Compressive strength in (MPa).

R = Hardness Rebound value

3. RESULTS AND DISCUSSION

Furthermore, the field test results of the of the rebound hardness values from six different locations are presented in Table 1. The rebounds values of hardness vary from 24 to 52, 20.6 to 50.4, 26 – 52 for test method 1, method 2 and methods 3 respectively. The sample from Ewekoro (limestone) has the least rebound value of hardness and the sample from Ikole-Ekiti (Granite) has the highest rebound value of hardness. The standard deviation of rebound values are 0.85, 1.73, 1.2 2.73 2.33 and 1.48 for samples IK0l, AW02, IB03, EW04, IG05 and OR06 respectively.

Table 1. Field Test of Rock Samples Using L- Type Hammer

Rock Code No.	Procedure Test 1	Procedure Test 2	Procedure Test 3	Standard Deviation
IK01	52.00	50.40	52.00	0.85
AW02	52.00	49.00	52.00	1.73
IB03	52.00	49.80	50.00	1.21
EW04	24.00	20.60	26.00	2.73
GA05	52.00	48.80	52.00	2.33
OR06	50.00	47.10	48.00	1.48

Table 2 presents the estimated strength parameter from equation proposed by different researchers. The Uniaxial compressive for strength and young modulus estimated from equation proposed by Aydin and Basu, (2005) ranges from 39.19 MPa to 49.38 MPa, 17.55 MPa to 21.39 MPa respectively. The uniaxial compressive strength obtained appear to be low for granite Moreso, the values of compressive strength determined from Deere and Millier, (1966) equations ranges from 88.40 MPa to 101.60 MPa these values are a bit reasonable but the equation can be used to compute rocks of low rebounds hardness values. Sachpazis, (1990) proposed equations were used to determined value of compressive strength and young modulus of elasticity for limestone of 20.85 MPa and 6.03 GPa respectively as presented in Table 2.

Table 2. Estimate of Some Mechanical Properties from In-situ Rebounds Value

Rock Code No.	Aydin and Basu,(2005)	Aydin and Basu,(2005)	Sachpazis, (1990)	Sachpazis, (1990)	Deere and Miller,(1966)	Mean Rebound Values from Test Procedure 2
	σ_{ucs} (MPa)	E_t (GPa)	σ_{ucs} (MPa)	E_t (GPa)	σ_{ucs} (MPa)	
IK01	49.38	21.39	-	-	101.60	50.40
AW02	44.77	19.67	-	-	96.00	49.00
IB03	47.34	20.63	-	-	99.20	49.80
EW04	-	-	20.85	6.03	-	20.60
GA05	44.14	19.43	-	-	95.20	48.80
OR06	39.19	17.55	-	-	88.40	47.10

Figure 1 presents the relationship between compressive strength, young modulus of elasticity and rebounds hardness values from test procedure 2, the results showed that strong linear relationship exist between the Compressive, young modulus and rebounds hardness values of test procedure 2 and these are expressed by Equation 11 and 12.

$\sigma_{ucs} = 3.076R_L - 105.82$ (11)

$E_t = 1.1597R_L - 37.113$ (12)

Where,

σ_{ucs} is the uniaxial Compressive Strength (MPa)

E_t is the young modulus of Elasticity (GPa)

R_L is the rebounds hardness value from test procedure 2

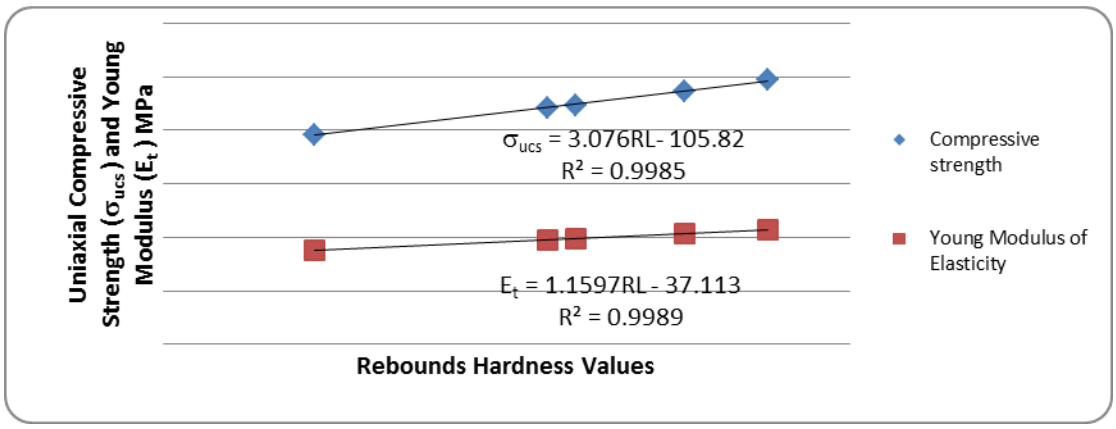

Figure 1. Compressive Strength and Young modulus of Elasticity against Rebounds Hardness Values from Test Procedure 2

4. CONCLUSION

This paper had investigated estimation of strength parameters from in-situ rebound hardness values. The result obtained showed that uniaxial compressive strength obtained from Aydin and Basu, (2005) proposed equations which ranges from 39.19 MPa to 49.38 MPa are lower than the values of strength obtained from Deere and Miller, (1966) proposed equation which ranges from 88.40 MPa –101.60 MPa. Ultimately, strong correlations exist between uniaxial compressive strength, young modulus of elasticity and rebounds hardness value from test procedure 2.

Haulage Drift Stability Analysis- A Sensitivity Approach

W. Abdellah
University of Assiut, Assiut, Egypt

ABSTRACT Haulage drifts are the primary access to the mining blocks of an ore body in a multi-level mining system of a tabular ore deposit. Drift instability could lead to serious consequences such as injuries, production delays and higher operational cost. Rockmass properties are significant geotechnical design input parameters. These parameters are never known precisely and always uncertainties associated with them.

The stability of the haulage drift is examined through parametric study of a nonlinear, elastoplastic, two-dimensional finite element model representing typical mining layout most commonly adopted in Canadian underground metal mines. The parametric study examines the influence of footwall rockmass geomechanical properties (e.g., cohesion, friction angle, dilation angle and Young's Modulus) and the mining depth (e.g., horizontal-to-vertical stress ratio). Stability indicators are defined in terms of displacement, stress and the extent of yield zones, which adopt as a basis for assessing the effect of different parameter on the stability of haulage drift.

Keywords: Stability, haulage drift, rockmass properties

1 INTRODUCTION

Drifts are the arteries of mines, e.g. they are used to transport the blasted ore (valuable minerals) out of mining zone. Drift instability causes ground caving, thus can be a serious problem e.g. injuries, production delay and increase in operation costs. As the mine haulage drifts are the only access where loaders and/or trucks travel through, they must remain stable during their service life (Abdellah et al., 2013 and 2014, Wei et al., 2012, Zhang and Mitri, 2008).

Rockmass properties are significant geotechnical design input parameters. These parameters are never known precisely. There are always uncertainties associated with them. Some of these uncertainties are due to lack of knowledge, limited collected data, errors in testing and random data collection. Therefore, a one should use a tool, such as sensitivity analysis to tackle these inherent uncertainties associated with the rockmass properties.

1.1 Problem Definition

To evaluate the stability of mine haulage drift, A two-dimensional, elastoplastic, finite element model (Phase 2D) is created as shown in Figure 1. The study zone is divided into three zones; hanging wall, orebody and footwall. The orebody consists of massive sulphide rock (MASU). The hanging wall contains Metasediments (MTSD) and the footwall comprises of Norite rock (NR). Three stopes are modelled to simulate the ore extraction with respect to mining step. The haulage drift is driven in the footwall and its dimensions are 4.5 m by 4.5 m and at a distance of 15 m from the nearest orebody (e.g., stope 3).

The physical and geomechanical properties for the different rockmass units included in this study are presented in Table 1 (Abdellah et al., 2012).

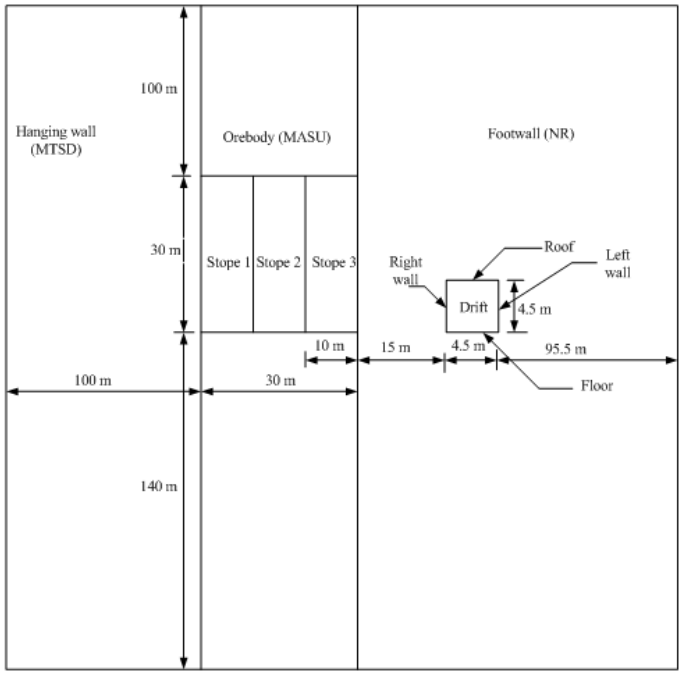

Figure 1. Model geometry and its dimensions

Table 1. Rockmass properties (Abdellah et al., 2012)

Rockmass Property	Hanging Wall	Orebody	Footwall	Backfill
Density, MN/m^3	0.027	0.030	0.029	0.023
E, GPa	40	10	24	2.5
Poisson's ratio, υ	0.18	0.22	0.15	0.35
Cohesion, C (MPa)	4.8	10.2	11.2	0.1
Tensile strength, τ (MPa)	1.52	1.80	0.99	0.075
Friction Angle, Φ (deg)	38	43	35	35
Dilation Angle, ψ (deg)	ϕ/4	ϕ/4	ϕ/4	0

1.2 Dealing with Uncertainty

As mentioned before, due to the heterogeneity of the rockmass, data from underground excavations are limited. Therefore, a great deal of uncertainty is inherent in the design of underground excavations. In order to develop a reliable design approach, one must use methods that incorporate the statistical variation of the numerical model input parameters representing the rockmass properties, i.e. mean, variance and standard deviation, as well as the design of rock failure criteria (Kwangho et al., 2005).

To quantify the uncertainty related to the model input parameters, three possible ways exist: deterministic analysis, sensitivity analysis, and simulation approach. This paper focuses on the parametric (sensitivity) analysis which will be discussed in the next section.

2 SENSITIVITY ANALYSIS

Numerical models are known to be deterministic by nature, i.e. a set of model input parameters will produce a unique set of results in terms of stress, deformation, and yield pattern. It is for this reason, model parametric study adopting sensitivity analyses is often carried out to allow for the better understanding of the problem, e.g. stability of mine openings, as a result of changing in some of critical model input parameters (e.g. Cohesion, Young's modulus, angle of internal friction, horizontal-to- vertical stress ratio) (Musunuri et al., 2009).

In a sensitivity analysis, a single parameter is systematically varied while all the other parameters are kept constant. The sensitivity analysis provides an understanding of the effect of each parameter on the overall behavior of the model. However, no distribution is obtained for the output parameters (random variables). It can be carried out by varying single parameter (random variable), at each run, based on specified coefficient of variation (COV) and monitoring the effect of this variation on the applied performance criterion. The variable, at each run, has one value of [(μ-σ), μ and (μ+σ)] while keeping all other parameters is constant (no change in their average values).

Five footwall rockmass parameters namely: cohesion, friction angle, dilation angle, Young's Modulus and horizontal-to-vertical stress ratio are varied to evaluate their effects on the stability of haulage drift with respect to mining step, as listed in Table 2.

Table 2. Footwall model input parameters at each run

Run / parameter	k	C, MPa	E, GPa	ϕ, degree	ψ, degree
Run 1	1.65	11.2	24	35	7.5
Run 2	1.98	11.2	24	35	7.5
Run 3	1.32	11.2	24	35	7.5
Run 4	1.65	13.44	24	35	7.5
Run 5	1.65	8.96	24	35	7.5
Run 6	1.65	11.2	28.8	35	7.5
Run 7	1.65	11.2	20.8	35	7.5
Run 8	1.65	11.2	24	42	7.5
Run 9	1.65	11.2	24	28	7.5
Run 10	1.65	11.2	24	35	10.5
Run 11	1.65	11.2	24	35	7

3 DRIFT STABILITY EVALUATION CRITERION

In the following section, three evaluation criteria are described, which are used as a basis for the interpretation of numerical model results for the assessment of the stability of the mine haulage drift with respect to mining step.

3.1 Extent Of Yield Zone

Yielding is the most common criterion used in numerical modelling when elastoplastic model is employed. This condition occurs when the stress state reaches the surface of the yield function, which is when the rock is loaded beyond its elastic limit. In this study, Mohr-Coulomb yield function is adopted as a measure for "drift satisfactory or /and unsatisfactory performance".

3.2 Displacement/Convergence Criteria

Displacement/convergence criteria depend on the stiffness of the rockmass properties and the purpose of underground opening. In the following, three displacement-based criteria are introduced.

3.2.1 Wall convergence ratio (WCR)

WCR is defined as the ratio of the total magnitude of the wall closure to the span of the initial drift as shown in Equation (1):

$$WCR = \left(\frac{W_0 - W_d}{W_0}\right) \times 100 \quad (1)$$

Where: W_0 is the original span of the drift and W_d: is the span of the drift after deformation.

3.2.2 Roof sag ratio (RSR)

RSR is defined as the ratio of the roof sag (ΔS) to the span of the drift as given in Equation (2):

$$RSR = \left(\frac{\Delta S}{W_0}\right) \times 100 \quad (2)$$

3.2.3 Floor heave ratio (FHR)

FHR is defined as the ratio of the floor heave (Δh) to the span of the drift, Equation (3):

$$FHR = \left(\frac{\Delta h}{W_0}\right) \times 100 \quad (3)$$

3.3 Mining-Induced Major Principal Stress (σ_1)

It defines the location of high stresses areas due to mining activity.

4 RESULT AND DISCUSSION

In the following section, the effect of each varied parameter will be demonstrated to show its effect on the stability of mine haulage drift based on the previous stability indicators.

4.1 Effect Of The Horizontal-To-Vertical Stress Ratio "K" On The Evaluation Criteria

The ratio, k, is defined as the average horizontal stress σ_h to the vertical stress σ_v as given in Equation (4):

$$K = \frac{\sigma_h}{\sigma_v} \quad (4)$$

The effect of "K" on the stability indicators is discussed below.

4.1.1 Effect of "K" on the stress

In the Canadian Shield, k varies nonlinearly with the depth. At shallow depth, k tends to be larger than it is in deeper mines. As shown in Figure 2, the increase of "K" (e.g., increase horizontal stress due to increase in depth) results in increase of major induced-mining principal stress at drift roof and floor. On the other hand decrease in the major induced-mining stress at the drift walls.

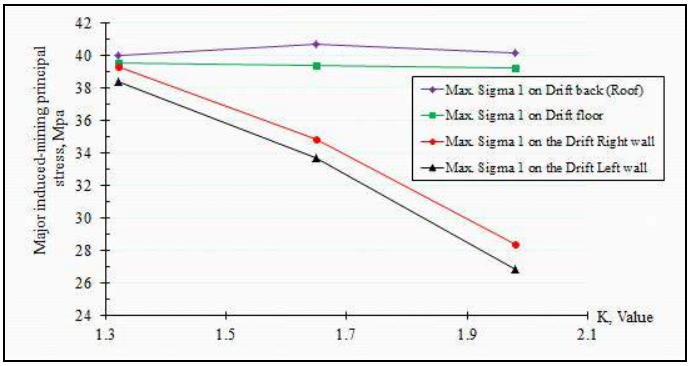

Figure. 2. K- value versus Major induced-mining principal stress.

4.1.2 Effect of "K" on the displacement

Displacement convergence criteria are generally site specific; they depend not only on the rock mass stiffness characteristics but also on the intended use of the underground opening as well as the design and code requirements. As illustrated in Figure 3, the increase of "K" value results in increase in the displacement/convergence criteria around mine haulage drift. The more effect occurs in the roof of the drift (e.g., shown by increase of the roof sag ratio "RSR") followed by right wall of the drift. The less effect appears in the drift left wall.

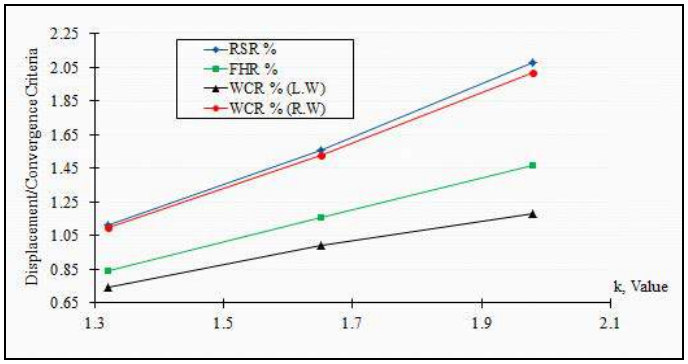

Figure. 3. K- value versus displacement/convergence criteria.

4.1.3 Effect of "K" on the extent of yielding zones

Yielding criterion is widely used in numerical modeling when elastoplastic model is adopted. Thus yielding may be considered as an important factor contributing to instability. As shown in Figure 4 below, the extent of yield zones increases as "K" increases. It can also be seen that the yielding zone extends around haulage drift as mining progresses. The maximum length of the yielding zone exceeds 15m in the left sidewall (LW) of haulage drift.

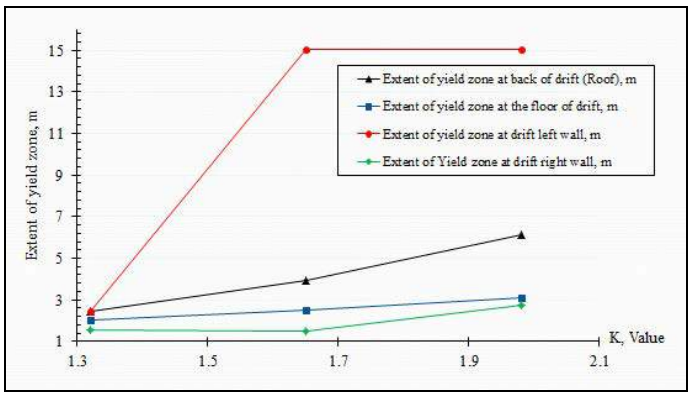

Figure. 4. K- value versus extent of yielding zones.

The development of yield zones with modelling mining steps based on Mohr-Coulomb criterion and average "K-value" of 1.65 is shown in Figure 5(a-d). It is obvious that the yielding zones increases as mining advances.

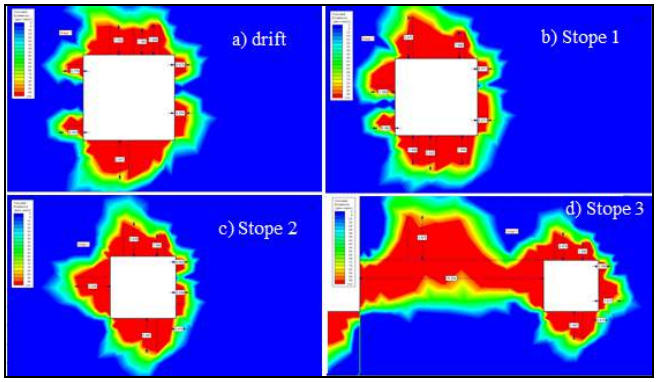

Figure 5. Development of yield zones with modelling mining steps at average "K-value" of 1.65.

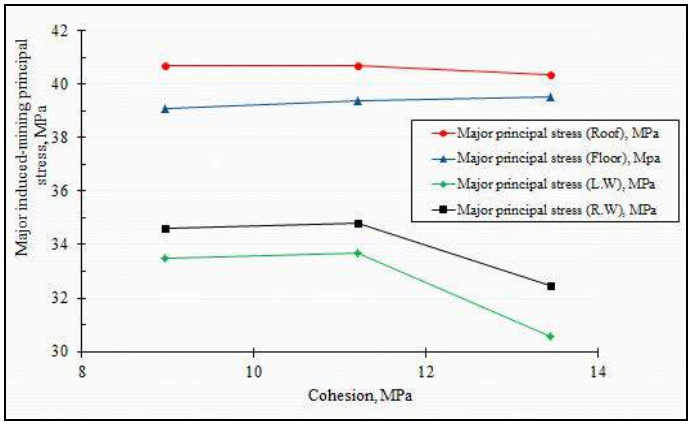

Figure 6. Cohesion versus major induced-mining principal stress

4.2 Effect Of Cohesion

Cohesion is a measure of internal bonding of the rock material. For example, if a shear force is applied to a cube of muddy soil or rock at zero normal pressure, the resulting shear deformation is accompanied by a measurable resistance. The resistance force per unit area is termed cohesion.

4.2.1 Effect of cohesion on the stress

In natural soils, cohesion results from electrostatic bonds between clay and silt particles. Thus, soils devoid of clay or silt are not cohesive except for capillary forces arising when little water forms bridges between sand grains, resulting in negative pore pressure (suction). In contrast, rocks normally exhibit much greater cohesion, thousands of times larger than soils. Figure 6 generally depicts that, as cohesion of rockmass increases the major induced-mining stress decreases. The most decrease occurs in the sidewalls of the haulage drift (e.g., left wall (LW) and right wall (RW)).

4.2.2 Effect of cohesion on the displacement/convergence criteria

Increase of cohesion results in decrease in the displacement (e.g., deformation) as shown in Figure 7.

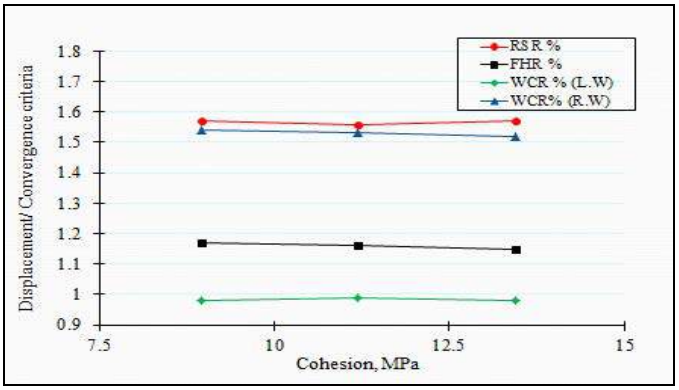

Figure 7. Cohesion versus displacement/convergence criteria.

4.2.3 Effect of cohesion on the extent of yielding zone

Figure 8 shows that, as cohesion increases, the yielding zones decreases.

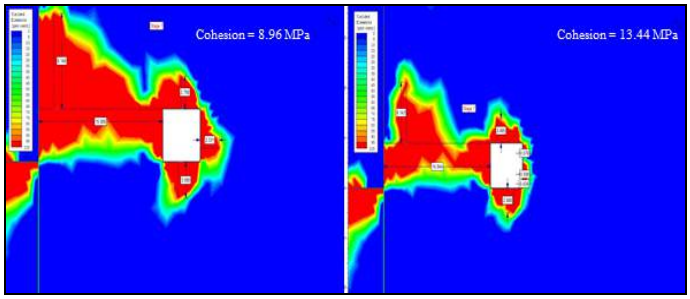

Figure 8. Extents of yield zones around haulage drift at two different cohesion values (final mining step).

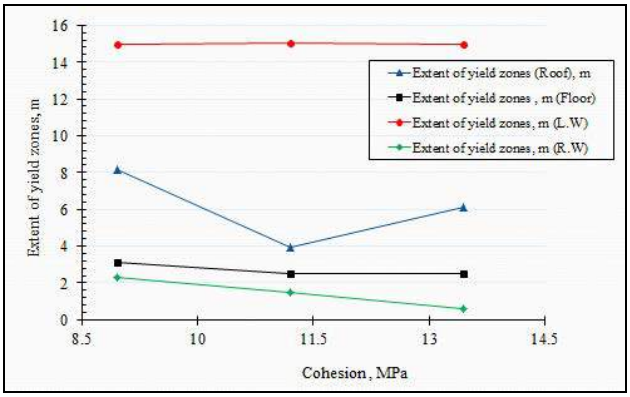

Figure 9. Cohesion versus extent of yielding zones

As shown in Figure 9 above, the increase in cohesion results in reduction in the extent of yielding or failure zones.

4.3 Effect of Young's Modulus

Young's Modulus is modulus of elasticity measuring of the stiffness of a rock material. It is defined as the ratio, for small strains, of the rate of change of stress with strain. This can be experimentally determined from the slope of a stress-strain curve obtained during compression or tensile tests conducted on a rock sample. Similar to strength, Young's Modulus of rock materials varies widely with rock type. For extremely hard and strong rocks, Young's Modulus can be as high as 100 GPa. There is some correlation between compressive strength and Young's Modulus.

4.3.1 Effect of stiffness on the stress

The increase of Young's Modulus (E) means increase the stiffness of the rockmass. The induced-mining principal stress decreases as stiffness increases, as shown in Figure 10. It can be seen that, the biggest drop in the major induced mining stress occurs in the drift left wall (LW), while the smallest decrease occurs in the drift back (roof).

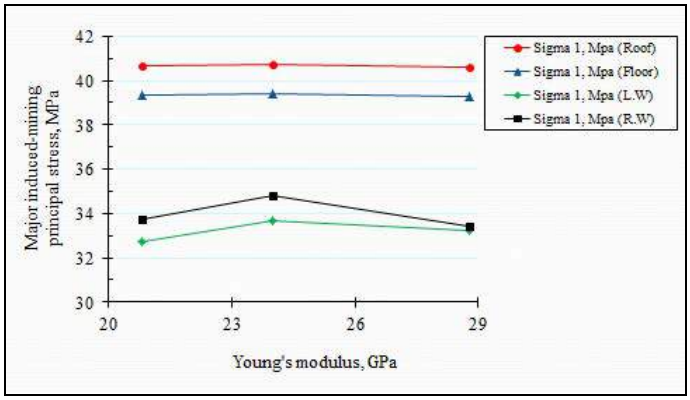

Figure 10. Young's Modulus versus major induced-mining principal stress.

4.3.2 Effect of stiffness on the displacement/convergence criteria

Figure 11 shows that, as stiffness (e.g., Young's Modulus) increases the displacement/convergence of haulage drift due to mining activity reduces. Thus means more stable condition.

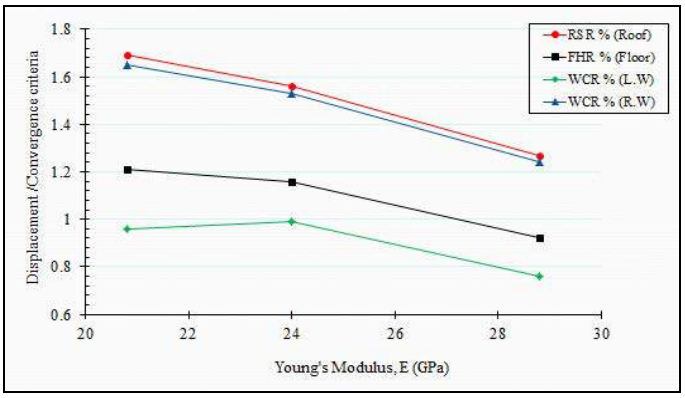

Figure 11.Young's Modulus versus displacement/convergence criteria.

4.3.3 Effect of stiffness on the extent of yielding zones

Figures 12 and 13 illustrate the decrease of the yielding zone extension as stiffness increases. The maximum decrease in the extension of yielding zones happens in the drift sidewalls.

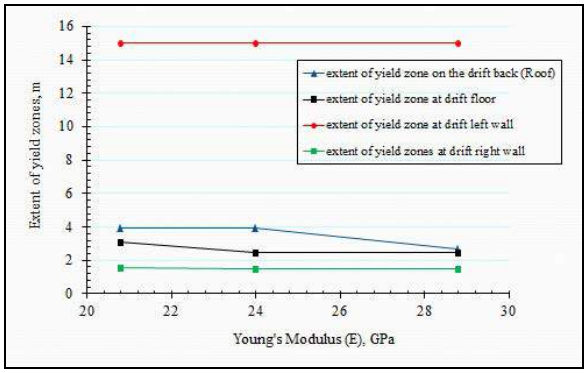

Figure 12. Young's Modulus versus extent of yielding zones.

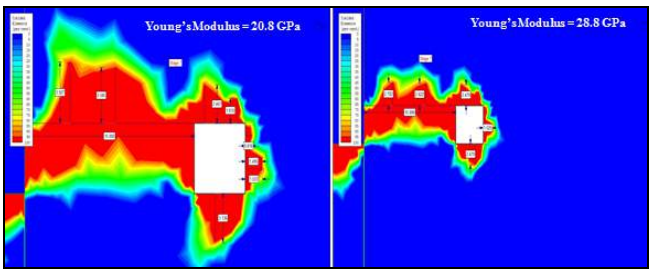

Figure 13. Extents of yield zones around haulage drift at two different stiffness values (final mining step).

4.4 Effect of Friction Angle

Internal friction is caused by contact between particles, and is defined by the internal friction angle; φ. Different rocks have different friction angles.

4.4.1 Effect of friction angle on the stress

As depicted in Figure 14 below, the increase of friction angle of rockmass results in the decrease of major induced-mining principal stress except for the floor of the drift.

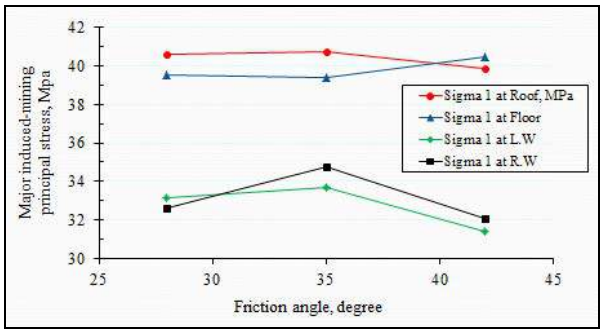

Figure 14. Friction angle versus major induced-mining principal stress

4.4.2 Effect of friction angle on the displacement/convergence criteria

Figure 15 shows that, displacement/ convergence decreases as friction angle increases.

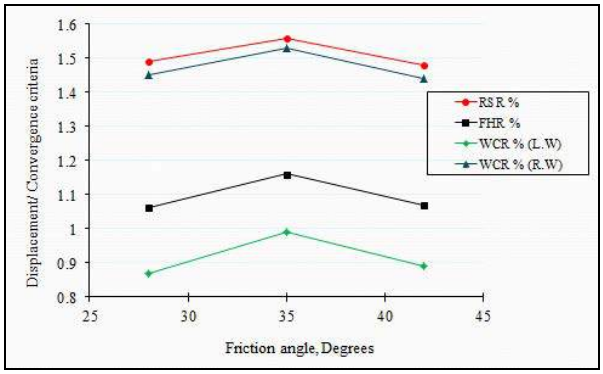

Figure 15. Friction angle versus displacement/convergence criteria.

4.4.3 Effect of friction angle on the extent of yielding zones

As shown in Figures 16 and 17, increase of friction angle produces decrease in the extent of yielding zones around haulage drift.

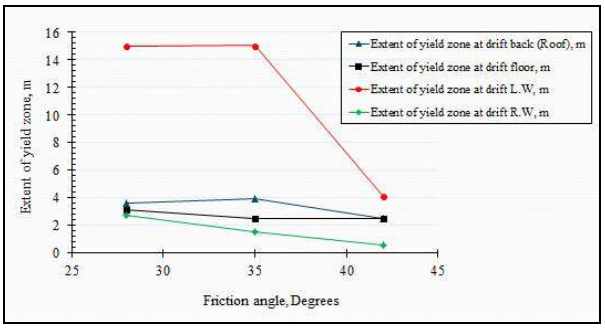

Figure 16. Friction angle versus extent of yielding zones.

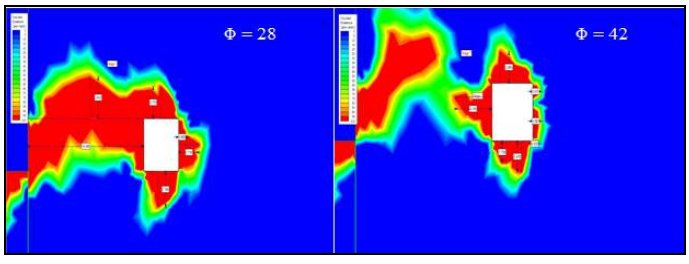

Figure 17. Extents of yield zones around haulage drift at two different friction angle values (final mining step).

4.5 Effect Of Dilation Angle

Dilation angle is one of the parameters that are not easily obtained for elastoplastic simulation of rock materials. The following section presents discussion of the sensitivity of results to the dilation angle and how this may affect the stability of haulage drift in terms of stress distribution pattern, displacements in the rockmass, and extent of yield zone.

4.5.1 Effect of dilation angle on the stress

The dilation angle has practically no effect on the stress distribution pattern and overall magnitude at locations sufficiently far from the drift, i.e. outside the stress relaxation zone. But, it affects the final magnitude of the principal stress inside the stress relaxation zone. Figure 18 illustrates that, major induced-mining principal stress decreases with the increase of dilation angle.

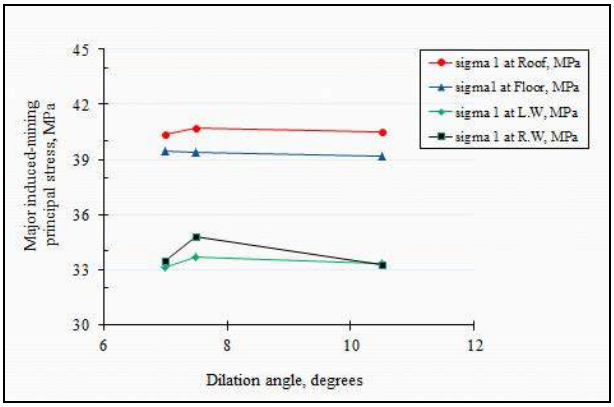

Figure 18. Dilation angle versus major induced-mining principal stress

4.5.2 Effect of dilation angle on the displacement/convergence criteria

The dilation angle is directly increases when friction angle increases (e.g., dilation angle equals one-fourth friction angle ($\Psi = \phi/4$). Thus produces the same effect on the displacement/convergence as the friction angle. Figure 19 shows the effect of dilation angle on the displacement/convergence criteria. As shown, the increase of dilation angle produces decrease in displacement.

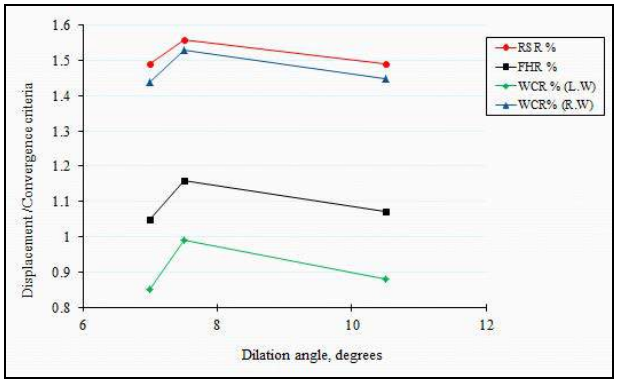

Figure 19. Dilation angle versus displacement/convergence criteria.

4.5.3 Effect of dilation angle on the extent of yielding zones

Dilation angle affects the final yield zones inside the stress relaxation zone. As the dilation increases, the final yield zone decreases. Figure 20 shows the decrease of the length of yielding zones as dilation angle increases.

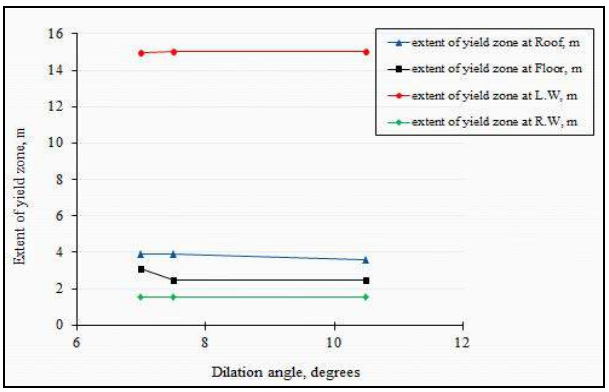

Figure 20. Dilation angle versus extent of yielding zones

5 CONCLUSION

This paper presents a sensitivity analysis to evaluate the stability of a mine haulage drift due to the heterogeneity associated with rockmass geotechnical input parameters. In this method, a single parameter is systematically varied, based on coefficient of variation, while all the other parameters are kept constant. Thus provides better understanding of the effect of each parameter on the overall behavior of the model. The stability of the haulage drift is examined through parametric study of a

nonlinear, elastoplastic, two-dimensional finite element model representing typical mining layout most commonly adopted in Canadian underground metal mines. Stability indicators are defined in terms of displacement, stress and the extent of yield zones, which adopt as a basis for assessing the effect of different parameter on the stability of the haulage drift. Five parameters have been used in this study to check their effect on the stability of haulage drift are: horizontal-to- vertical stress ratio (K), cohesion (C), Young's modulus (E), friction angle and dilation angle (ψ).

6 RECOMMENDATIONS

There are other parameters are not included in this study, e.g. mining depth, distance between haulage drift and stopes and mining sequences. Three-dimensional modelling is required to simulate the real geometry of the case study. Once the model is constructed, in-situ stress measurements should be used to calibrate the numerical model. Rock failure criteria such as Mohr-Coulomb must be calibrated based on underground measurements such as deformations (Multi-Point Borehole Extensometer or MPBX) and rockbolt loads. Although sensitivity gives good understanding of the effect of certain parameter on the overall behaviour of the model, there is not distribution or probability of failure obtained. Therefore, probabilistic analysis should be invoked to study the probability of unsatisfactory performance of the haulage drift.

Geodynamic Zoning for Isolation of Radioactive Waste

V. Tatarinov, V. Morozov, I. Kolesnikov, A. Kagan, T. Tatarinova
Geophysical Center of the Russian Academy of Sciences. Molodezhnaya St. 3, 119296 Moscow, Russia.

ABSTRACT The problem of the selection of the site for underground isolation of radioactive waste is acute for all countries using nuclear power. The paper presents the results of modeling the stress-deformation state of Nizhnekanskiy granitite massif. Shown is the possibility of using such simulations for the geodynamic zoning of areas. The most probable directions of groundwater filtration, which is one of the main threats to the nuclear waste repository, are present.

Keywords: Geodynamic zone, radioactive waste, granite, groundwater filtration

1. INTRODUCTION

Development of nuclear power in Russia is impossible without the resolution of the problem of burial high-level radioactive waste (HLRW) in deep geological formations. The selection of the sites for the environmentally safe underground isolation of high-level radioactive solidified waste remains a major problem for states that use nuclear energy, like Russia.

Methodologically, the choice of site for HLRW disposal is based on the finding in the relatively stable areas of the least disturbed structurally tectonic blocks (STB), which have maximum size [1, 2].

Expert assessments of the current "quality" of the site where the HLRW repository will be built, do not answer the fundamental question: how tectonics will effect of the rock mass safety for 100 thousand years and more, until there will be an environmental hazard of radionuclide. The greatest threat is the formation of new faults or intensifies existing tectonic faults and infiltration of surface water and groundwater to containers with high-level radioactive waste, followed by removal of the radionuclide in the human environment. The basic principle of ensuring safe disposal of nuclear waste is to prevent the formation of zones of dangerous concentrations of stress at the design phase spent nuclear fuel (SNF) repository on the basis of geodynamic zoning. Prediction of the evolution of the stress-deformation state (SDS) of the geological environment is very important.

The main purpose of this paper show the most likely scenario of the development of a tectonic process in Niznekansky granitoid massif. The scenario was generated on the basis of analyses of the structural-tectonic model and the calculation of stress-deformation state of the local. The simulation of the most probable direction of groundwater filtration under the influence of tectonic stress are present too.

2. RESULT AND RESEARCHES

Niznekansky granitoid massif (NKM) is located in a few kilometers to the north-east of Krasnoyarsk. According to geological and geophysical, structural, and geomorphologic studies in the western part of the massif, and partly in the surrounding rocks, three sites for HLRW disposal were pre-selected: «Kamenniy», «Itatskiy» and «Eniseiskiy» [3].

Analysis of geological data displayed [3] that SDS of the massif is determined mainly the compressive forces oriented in the south-west — north-easterly direction. It is used an elastic model of generalized plane stress to simulate the stress-deformation state. As a method of calculation it is used finite element method in the form of movements based on isoperimetric quadrilateral finite elements.

Empowering different finite element the different mechanical properties one can generate a heterogeneous finite element model, which reflects the real properties of rock massif. Fig. 1 displays a structural model of NKM to simulate the distribution of stress fields by finite element method.

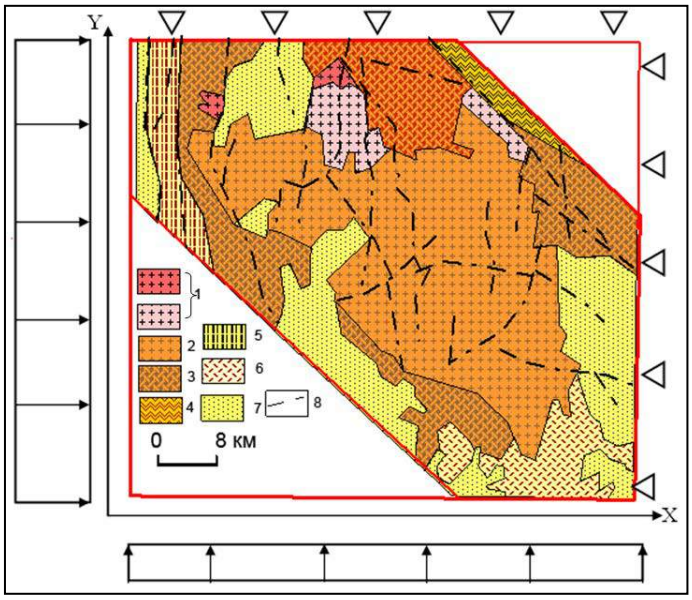

Figure 1. Structural model for simulate the distribution of stress fields by FEM. 1, 2 - contour of NKM granitiods differ in their elastic-strength properties, 3 - gneiss complex (AR); 4 - mylonite areas, 5 - amphibolite, quartzite and marble (AR-PR); 6 terrigenous-volcanic deposits (PZ_2); 7 - terrigenous deposits (J); 8 - main faults

In the model adopted the following values of the projections on the *X* and *Y* axis of the tectonic stresses: sub latitudinal N_x = 30 MPa and submeredian N_y = 10 MPa. These values are close to the stresses in the undisturbed rocks measured in the underground workings [4] at depths of up to 400 m. Detailed program of the stress calculation is presented in [5].

It is used the stress intensity σ_i for analyses the results of simulation, because σ_i is a generalized criterion of the level of SDS. Fig. 2 and Fig. 3 display the contour map of stress intensity and 3-D model of stress intensity respectively in the local area NKM.

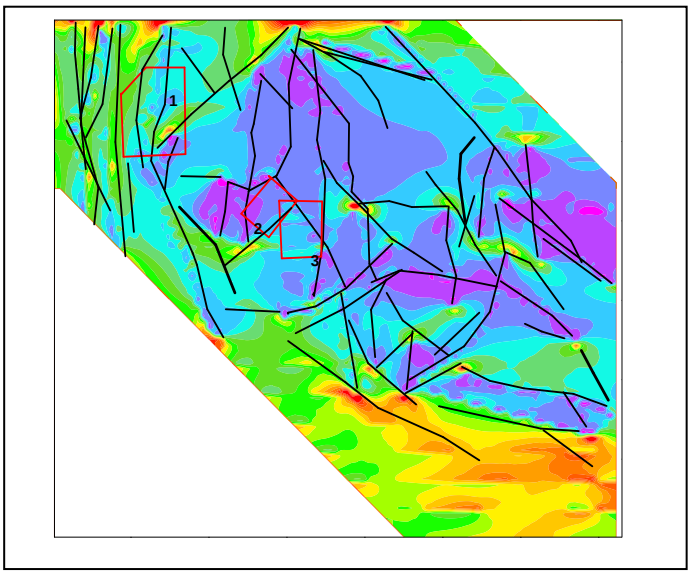

Figure 2. Distribution of stress intensity in the NKM according to calculations by finite element method. Lines indicate faults. The rectangles marked areas of detailed studies: 1– «Eniseiskiy», 2 - «Itatskiy», 3 – «Kamenniy».

The high-level differentiation of the stress intensity σ_i within the model NKM make possible for the selection of potentially dangerous areas (not suitable for isolation of HLRW). 3-D model is the basis for virtually geodynamic zoning in the purpose of the selection of the areas for the geoenvironmental secure underground isolation of HLRW in geological formations.

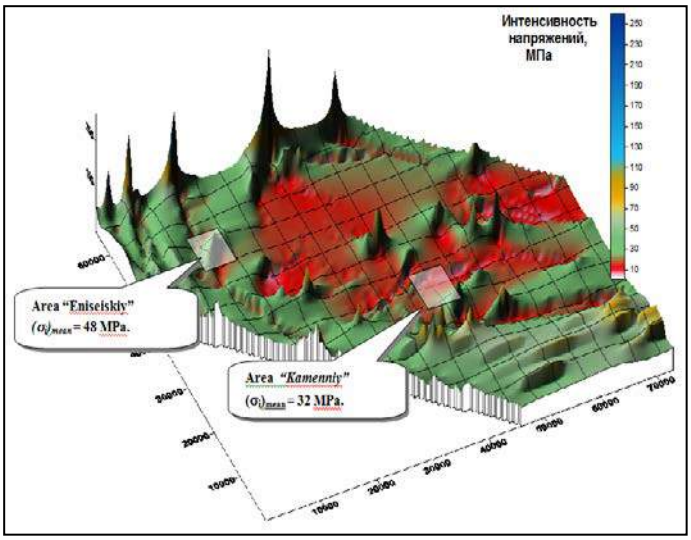

Figure 3. 3D model of the distribution of stress intensity in the NKM

We can confidently assert that the zones of concentration of stress intensity are possible sources of large-scale destruction

of the geological environment under the action of tectonic stress fields.

One of the major threats for the reliability of HLRW repository is the penetration of ground water to the containers [5, 6].

Filtration through an environment is described by Darcy's law:

$$Q = \omega K \frac{dy}{dx},$$

where Q – the flow discharge;

ω – cross section flow area;

$\frac{dy}{dx}$ – pressure gradient of flow;

K – coefficient of filtration.

Just Darcy's law can be written as:

$$V_x = -\frac{k}{\mu}\frac{\partial P}{\partial x},$$

where V – value of the filtration rate through a porous environment;

k – permeability of the medium;

μ – dynamic viscosity of fluid;

P – pressure.

The dimension Coefficient k is a velocity and it depends on the geometry of the porous space (such as the type of environment and the characteristics of pores), as well as it depends on the specific gravity and liquid viscosity. It is constant for a given liquid, if the porous environment is incompressible and isotropic.

For an isotropic environment as for an environment which has the same constant in all directions one can get:

$$V_x = -\frac{k_0}{\mu}\frac{\partial P}{\partial x}, \qquad V_y = -\frac{k_0}{\mu}\frac{\partial P}{\partial y}, \qquad V_z = -\frac{k_0}{\mu}\frac{\partial P}{\partial z};$$

or

$$V = -\frac{k_0}{\mu}\nabla(P) \qquad (1)$$

where V – velocity vector of the filtration.

Applying the divergence operation to the previous equation and using the equation

$$\nabla \cdot V = \frac{\partial V_x}{\partial x} + \frac{\partial V_y}{\partial y} + \frac{\partial V_z}{\partial z} = 0,$$

yield:

$$-\frac{k_0}{\mu}\nabla^2(P) = 0.$$

Thus, filtration through the isotropic environment can be reduced to solving the Laplace equation with appropriate boundary conditions. If the distribution P is known, then the filtration rate can be obtained from Darcy's law in the form (1).

In many cases, the porous environment is anisotropic and the permeability depends on the direction of flow. In this case, the components of the filtration velocity can be written as:

$$V_x = \frac{k_x}{\mu}\frac{\partial P}{\partial x};$$

$$V_y = \frac{k_y}{\mu}\frac{\partial P}{\partial y};$$

$$V_z = \frac{k_z}{\mu}\frac{\partial P}{\partial z}.$$

Turning to the vector form and calculating the divergence, we obtain:

$$\nabla \cdot V = -\frac{k_{0x}}{\mu}\frac{\partial^2 P}{\partial x^2} - \frac{k_{0y}}{\mu}\frac{\partial^2 P}{\partial y^2} - \frac{k_{0z}}{\mu}\frac{\partial^2 P}{\partial z^2}.$$

The previous equation can be written in next form:

$$\frac{\partial^2 P}{\partial x^2} + \frac{\partial^2 P}{\partial y^2} + \frac{\partial^2 P}{\partial z^2} = 0.$$

Thus, we have the Laplace equation again. Consequently, the true physical meaning can be represented as a fictitious isotropic in the transformed coordinates.

Communication between the components of the deformation and the displacement in a plane medium has the form:

$$\varepsilon = \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \varepsilon_{xy} \end{bmatrix} = \begin{bmatrix} \frac{\partial U}{\partial x} \\ \frac{\partial V}{\partial y} \\ \frac{\partial U}{\partial x} + \frac{\partial V}{\partial y} \end{bmatrix}.$$

In accordance with Darcy's law, we proceed from the assumption that the filtration velocity in the gradient field tectonic stress is proportional to the gradient of the effective stress:

$$\vec{V}_f = \begin{bmatrix} \vec{V}_x \\ \vec{V}_y \end{bmatrix} \sim \begin{bmatrix} \nabla\left(kE \dfrac{\partial U}{\partial x} \right) \\ \nabla\left(kE \dfrac{\partial V}{\partial y} \right) \end{bmatrix}$$

or

$$\vec{V}_f = \begin{bmatrix} \vec{V}_x \\ \vec{V}_y \end{bmatrix} \sim \begin{bmatrix} kE\nabla^2 U \\ kE\nabla^2 V \end{bmatrix}$$

assumption a constant filtration coefficient.

Filtration velocity, expressed in terms of stress components, in a plane-stressed state:

$$\vec{V}_f = \vec{V}_x + \vec{V}_y \sim kE\left(\sigma_{xx} + \sigma_{yy}\right)$$

If the rock massif has the anisotropic permeability $\left(k_x \neq k_y\right)$

$$\vec{V}_f = \vec{V}_x + \vec{V}_y \sim E\left(k_x\sigma_{xx} + k_y\sigma_{yy}\right).$$

Then, using these equations, it is possible to calculate and predict the development of hydrogeological conditions in the area of hypothetically construction of nuclear waste repository at the change of SDS rock mass as a result of the predicted tectonic destruction of the rock mass.

The level of the stress state of the rock massif in the local zones determined the value of stress intensity. Transfer to the stress intensity allows one to generate the model of liquid filtration independent on that particular system of coordinates. Based on the assumption that the filtration rate is determined by this integral assessment of the level of working stress in the volume element of rock massif, we have:

$$\vec{V}_f \sim \operatorname{grad}\left(\sigma_i\right). \qquad (*)$$

This simplifies the calculations of the first approximation, since the problem of estimating the stress state and filtration are solved separately. If we knew (from experimental data) the rate of change of tectonic stress in space and time, then the expression (*) reduces to:

$$\vec{V}_f(t) \sim kE\nabla\left(\frac{\partial \sigma_i}{\partial t}\right).$$

In this case, the filtration rate as a function of space and time $V(x,y,t)$, makes it possible to count water inflows in the weakened zones of tectonic fractures as a basis for further calculations of the migration rate and the predicted migration of radionuclide in the mass transfer process. In fact, the possibility of separate solutions of the elastic problem and the filtration process under the influence of local gradients of tectonic stress (i.e., without taking into account the deformation of the pore skeleton of rocks) greatly simplifies the algorithm for calculating of the possible direction of filtration flows.

Algorithm for calculating the stress gradient is introduced into the program of calculation of SDS of the massif. Figure 4 displays the result of calculation of the gradients vectors $\vec{G} \sim \left\langle \operatorname{grad}\frac{\sigma_i}{2} \right\rangle$.

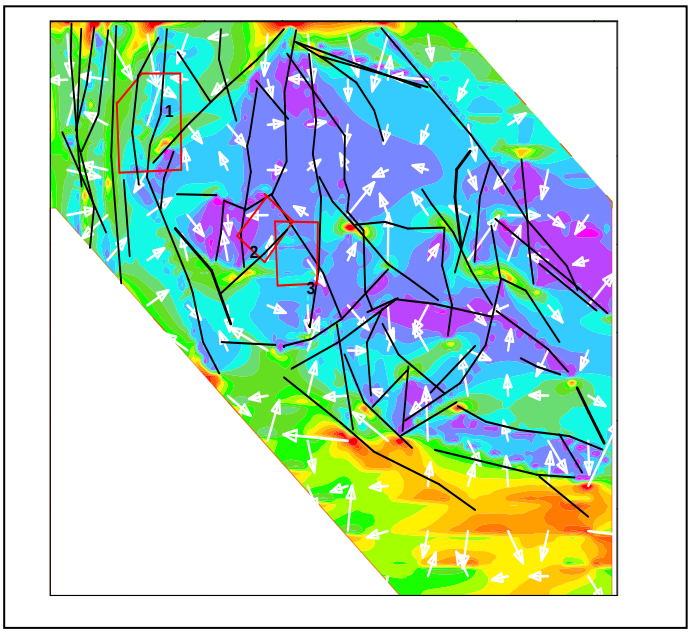

Figure 4. Vectors of filtration velocity in NKM

At the present time, area «Eniseiskiy» is the most promising in terms of creating a repository for HLRW. On this basis, we simulated the stress-deformation state of rock massif within the area «Eniseiskiy». The boundary conditions for this simulation were taken from the model for NKM.

Figure 5 displays the vectors of filtration velocity for «Eniseiskiy» area. Vectors indicate the most probable direction of groundwater filtration under the action of the tectonic stress.

Fig. 6 displays the distribution of the shear stress for area «Eniseiskiy». The

areas with maximum level of shear stress are potentially dangerous from the position of the formation of tectonic movements, i.e. formation of tectonic faults containing the shear component.

On this basis, we have identified the two most probable directions of the development of new active geodynamic zones affecting of «Eniseiskiy» area. They are displayed in Fig. 7 by dotted black lines. These are new the most probable faults in the area of «Eniseiskiy». They should be considered when assessing the environmental safety of HLRW repository.

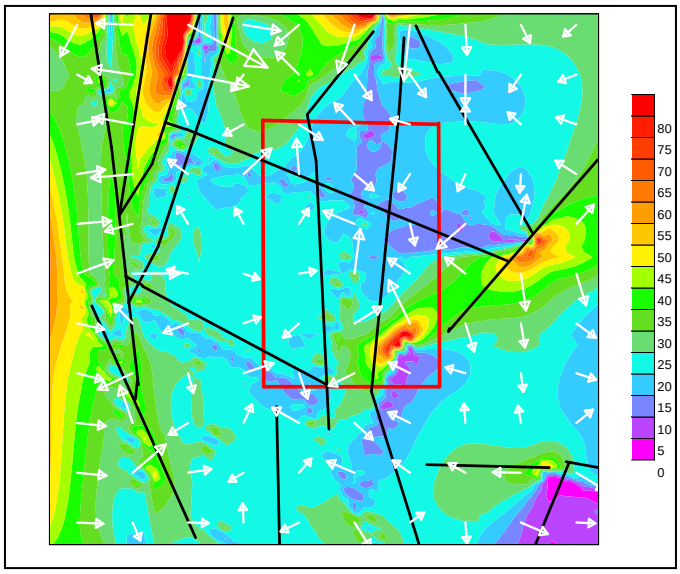

Figure 5. Vectors of filtration velocity in area «Eniseiskiy»

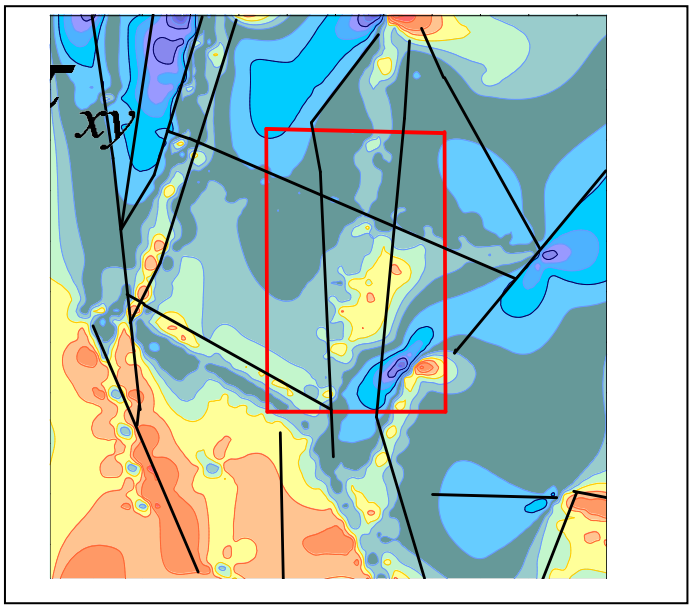

Figure 6. Distribution of shear stress τ_{xy} in «Eniseiskiy»

Directions of the vectors correspond to the movement of groundwater in the weakened zone. Vectors of gradients working stresses are directed into the zones of tectonic disturbances (Fig 7). Thus, these zones are reservoirs for groundwater flow. Filtration of water can also be caused by activation of faults, i.e. run trigger mechanism" tectonic activity.

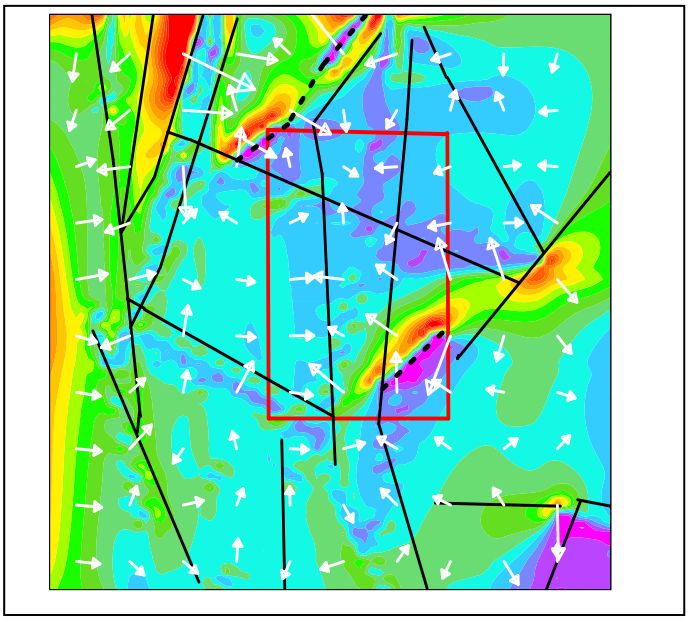

Figure 7. The distribution of stress intensity in the area «Eniseiskiy» and vectors of filtration velocity

The faults are the channels of the intensive filtering groundwater, contributing to extensive migration of radionuclide in the geological environment.

Improving Utilization of Face Rigs in Bord and Pillar Mining: A Zimbabwean Case Study

J. Kwiri, T. Zvarivadza
School of Mining Engineering, University of the Witwatersrand, Johannesburg, SA

ABSTRACT The introduction of mechanized equipment within a mine is an important strategy to improve safety and minimize the cost of mining operations. This research evaluates the performance of face rigs at one of Zimbabwe's hard rock bord and pillar mines and puts forward strategies to improve mine production. In the research, the face rig is considered to be a small business unit which forms but an integral part in the functioning of the mine. The analysis focuses on the cycle of the face rigs and the mine's organizational systems and resources that are related to face drilling rigs. By considering face drilling rigs as an integral part of the mine, the research ensures that a proper insight is obtained in terms of the mine's mining cycle and that face drilling is not just considered as an isolated system.

Making use of an extensive range of mining engineering tools and techniques, a solution has been designed for the problems experienced with the use of face rigs. The solution entails the restoration of the mining cycle, a more disciplined approach to maintenance and pre-development and reducing losses due to idling by having good face preparation. Should this solution be implemented, it will enable the face rigs at the mine to perform to their potential. The mine will be able to extend the introduction of mechanized drilling equipment to other mines, recognizing that the modernization of their mining operations improves production, safety and cost-effectiveness.

Keywords: Face rigs, board and pillar mining, hard rock

1 INTRODUCTION

On a world wide scale, production costs are ever increasing and for the mining industry to be financially viable, efficient technologies are continuously being explored and implemented to ensure the industry's sustainability now and in the future. As a move to improve safety and productivity, several bord and pillar mines in Zimbabwe mechanized their face drilling and support drilling processes by the introduction of face rigs and roof bolters respectively. This research evaluates one of the mines and puts forward practical solutions in resolving challenges related to the utilization of face rigs in mechanised mines. The mine in question experiences challenges in attaining optimum utilization. Looking into the merits the face drilling rigs have brought on one hand and the procurement cost, operating and maintaining the machine, it is very important to assess the performance of these drill rigs on the other hand. Increased mining (drilling, blasting and haulage) costs and reduced throughput are also some of the major constraints in the production system of the mine.

1.1 Research Scope

The research analyses and improves the utilization of face rigs at the mine shaft by providing economically and technically sound solutions without compromising safety and quality. The following were undertaken:

- Measurement of the current utilization of face rigs.
- Identification of the limitations and underlying problems facing the mine in achieving the required utilization target.

- Determination of how the major mining delays and utilization can be optimized.

The analysis and design was predominantly from an operational perspective. The way the face rigs measure up to the expected production performance levels was evaluated. The strategic business goals, systems and resources supporting the face rigs were investigated to optimize the system for higher production performance and reduced operating cost. The face rigs form a small but integral part of the mining system at the mine. While this research has more focus on face rigs, the effect of the rest of the mining system on face rigs was also taken into consideration.

1.1 The Utilization Challenge

An operation's productivity can be verified through the assessment of its equipment utilization. This way, the mine's business model effectiveness can be ascertained. This study indicated that; measured over the last few months, year on year, the average utilization of face rigs has remained low having an average of 44%. This to some extent, resulted in a loss of production for the few months cumulative. In 2003, after the first introduction of face rigs, the mining department improved its blasted tonnage and safety record. The other key performance indicators (KPI's) were also met and the face rigs proved to be reliable and able to perform to expectations. The planning department at the mine declared the project a success. Inexplicably, over the past months, the face rigs started to perform very poorly. All the KPI's were down, in particular face rig utilization. This study investigated the factors that influenced the drop in performance. All the KPI's, the mine's organizational systems and resources associated with the face rigs were examined to optimize the system for higher productivity and reduced operating cost.

Several parameters affect the actual utilization. These parameters include operator performance and proximity of workings to each other. From the data obtained at the mine, the main problem of face rig utilization was the availability hours to drill. A number of face rigs were always under maintenance and there have been a lot of on the job break downs. Availability improved since the implementation of good maintenance program. Utilization on the other hand, did not follow the profile of availability. Utilization still decreased and this prompted the study in an attempt to find the reasons why there was continual decrease in face rig utilization.

2 THE NEED FOR EFFECTIVE FACE RIGS UTILIZATION

The mine is highly mechanized. Mining being the core process, involves four processes which make up a cycle. The processes include lashing, face preparation and drilling, charging and blasting. With the production targets that have been set, 2.5 Load Haul Dumpers (LHDs) with a capacity of 3.3 tons, are required per section but practically each section has got three. This reduces lashing problems and makes it easier for lashing teams to achieve their targets. Charging and blasting follow face preparation and face drilling and these processes do not pose a great challenge. As production targets are dependent on face preparation and face drilling a detailed analysis was done, in particular, face drilling as a large percentage of face preparation depends on the efficiency of face drilling. One of the major challenges resulting in failure to meet the mine call is face rig utilization. Figures 1, 2 and 3 show the planned and actual availability, utilization and blasted tonnages in 2012.

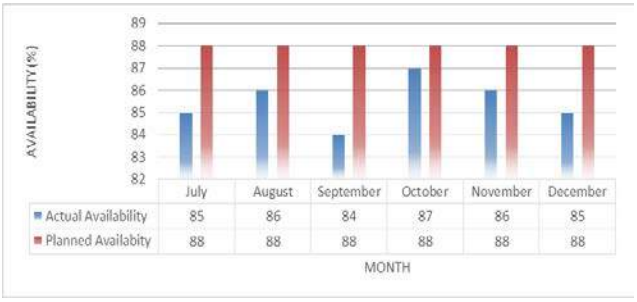

Figure 1. A bar graph showing the planned and actual availability

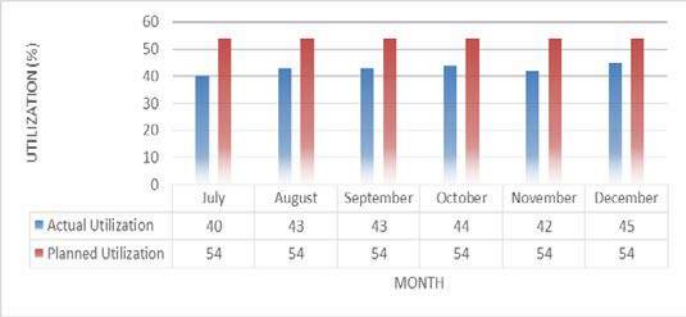

Figure 2. A bar graph showing the planned and actual utilization

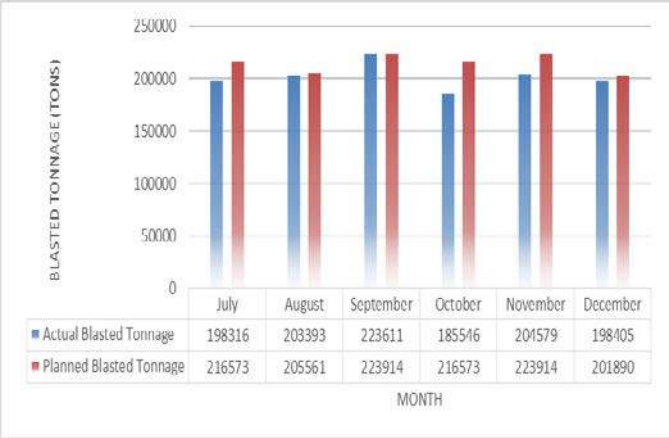

Figure 3. A bar graph showing the planned and actual blasted tonnages

From the bar graphs it can be concluded that low utilization values result in decreased production output. The month of September shows an anomaly and gives the question, "If a section or a mine can still meet its production targets, what is then the reason to worry about utilization?" Looking at one month figure gives a wrong perception and utilization is not only about meeting targets but it is also about making sure that the return on investment, that is buying the drill rigs is obtained. Looking at the financial year of 2012-2013, utilization was very low and the average production was also low. Currently the actual average utilization is 44% against the planned utilization of 54% as shown in Table 1.

Table 1. Availability and utilization of face rigs for Financial Year 2012 -2013

FY 2012 -2013			
KPI	Actual	Plan	% Variance
Face Rig Availabity	86	84	1.9
Face Rig Utilization	44	54	-5.3

From the available time per shift of 7.58 hours, 10 % (which is the difference between planned and actual utilization) is 1. 4 hours. Taking time to drill a blast hole to be 2 minutes, the number of blast holes that can be drilled in 1.4 hours is 42. From a 6m gulley with 51 blast holes, this represents approximately 80% of a production end. A fully blasted end having a capacity to produce 106 tons, 85 tons is lost in each blast. Any mining operation cannot afford the cost of such continuous loss of ore but this is happening and the cost of material loss continues to escalate unabated. As mentioned, with utilization being a factor that affects production the appropriate understanding and mitigation of underutilization of equipment cannot be overemphasized. With the mine having heavily invested in mechanizing most sections, reducing delays and fully utilising the machines is paramount to the success of its mining business.

3 MINING BACKGROUND

It is central to the goals of the mine to have a balanced mix in the extraction of high and low grade ore and move much tonnage while maintaining continuity of ore drilling in a safe and internationally acceptable manner at the lowest possible costs. Flat room and pillar mining method is used to extract the ore. Production and development occur at the same time. Entry of employees and equipment is through a decline shaft and ore is hoisted out through a different decline shaft by a series of connected conveyor belts.

Stope areas vary with class of ground. Classes C and D, stoping is done creating 6m or 9m twin gullies. Pillars separating the gullies are 10m by 3m and 3m by 3m.

Ventilation holings are punched on continuous pillars to allow smooth flow of air. For classes A and B, stoping is done on 15m panels leaving 10m by 3m insitu pillars. A 6m gulley advances at 2.8m and the 9m burden slipes in the advance gulley. Stope heights are 2m to 2.4m and the rooms are 15m wide for Class A and B ground whereas for Class C and D either 6m or 9m twin gullies are employed. Figure 4 shows the mining plan for 6m twin gulleys.

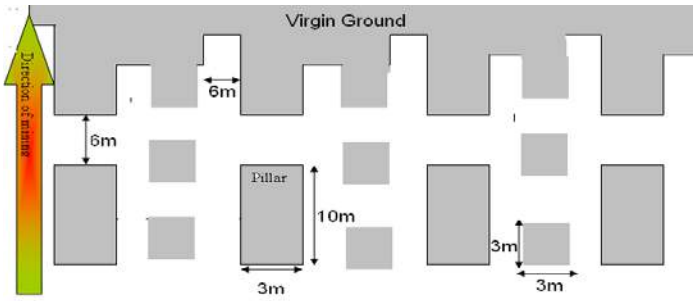

Figure 4. Mining plan for 6m twin gulleys (not drawn to scale)

3.1 Stope Development

Mining is done in two directions, the north and south along the strike direction of the ore body. A 6m gulley is always mined at most 6m in advance of the panel to create a blasting face; the rest of the panel will be slipped into the gulley. After every 10m advance of the panel a ventilation holing is mined perpendicular to the panel advance to create free air circulation.

3.2 Mining Cycle

3.2.1 Stope face drilling and blasting

Stope face drilling is done by low profile (LP) drill rigs. The face is drilled at an angle parallel to the reef dip to allow for highest grade extraction but also ensuring throw blasting of at least 40% of the ore into the advance strike drive (ASD) for easy mucking and lashing. Shock tubes and ammonium nitrate fuel oil (ANFO) explosives are used for charging up after drilling is complete. The drill holes are 3.2m in length and there is an expected advance rate of 2.88m/blast at the stope face. Blasting takes place twice a day on the day shifts at 18:30 and night shifts at 06:30.

3.2.2 Ore lashing and loading

Stope face cleaning and lashing is done by LP load-haul-dumpers (LP LHDs). Ore is collected in the ASD by the LHDs where it is then hauled to the tipping point. The LHDs access the strike conveyor through grizzlies spaced 80m apart. The strike conveyor belt is maintained at a maximum of 80m from the face.

3.2.3 Stope ground control

Roof bolt support is put in place by the use of LP roof bolters and jackhammers. For safety of personnel, jack hammers are gradually being phased out. The way the stope face is supported is based on the rock quality structures, joint angle and spacing, the filling condition and the hanging wall stratigraphy of the specific site.

3.2.4 Mining teams targets

Mining targets are set depending on the condition of ground in which a section is operating so that safety is not compromised. Sections in bad ground (classes C and D) are supposed to prepare, drill, charge and muck blasted rock from three 6m gullies or 18 face metres for each process. For classes A and B the target is 21 face metres. This implies that the daily drilling (or lashing or charging or preparing the face) target is 42 face metres for classes A and B and 36 face metres for classes C and D since there are two shifts per day. With the mining height set to be 1.95m (for design purposes) and the face expected to be blasted to an advance of 2.88m and insitu rock density to be 3.15 tons per cubic meter, Table 2 shows the daily targets for good and bad ground sections. NB: Hoisted tonnage = 0.95*Blasted tonnage to accommodate the losses incurred during the transportation of ore from underground to surface.

Table 2. Production Targets

	Mechanized Bad Ground	Mechanized Good Ground
	6m gully	15m panels
Advance per blast (m)	2.88	2.88
Drilled face meters (m)	36	42
Prepared ends	3	3
Blasted tonnage (t)	636	743
Hoisted tonnage (t)	604	706

4 UTILIZATION CHALLENGES FACED IN THE MINING INDUSTRY

In spite of the tremendous amount of research conducted in the last few decades, no single theory has been developed and accepted that adequately explains the utilization of mining equipment. There is yet no consistent and widely applicable theory but only a number of limited theories, many of which are empirical in nature and based on ideal situations. There are many schools of thought on how utilization and availability should be measured. In this research utilization is obtained as a ratio of drilling time to available time. Availability is the ratio of the difference between planned time and engineering downtime to planned time.

Utilization affects not only the local productivity of the mining department; it even influences the performance of the subsequent combination steps. The stope face, the area where drilling occurs has got the largest number of injuries in narrow reef mining. To improve safety, mining equipment manufacturers and mining companies have realized the need to develop new mining technologies that will improve safety. One of the new technologies currently being employed is the mechanization of underground mining operations. According to Croll (2004), mechanization is the use of powered machinery to replace manual labour. Within the mining context, mechanization refers to human operators being given machines to assist them with stoping functions. However, it does not refer to the use of hand powered tools such as hand held rock drills.

4.1 Mining Benefits for Using Face Rigs

According to Harrison (2008) mining using face rigs has the following benefits:

- Safety is improved because the operator is removed from the sharp end of the face.
- There is an improvement in productivity by more accurate drilling, higher face advance and production rate per employee due to the fully mechanized stoping and development.
- It is more profitable than conventional mining.
- It has the potential to mechanize at stope widths of <1,0m and at reef dips of 18 - 22° gradient.

4.2 Ergonomics of Using Low Profile (LP) Mining Equipment

Underground evaluations were performed to examine the working conditions of the LP equipment operators. The following ergonomic risk factors were identified:

- The operators experience discomfort in the lower back during all the process steps where LP equipment are used. This can be attributed to the operators having to work sitting on a very small seat.
- Discomfort is also experienced in the shoulder regions due to the pulling of the heavy power cable of the LP equipment. This usually occurs when the operator does not have an assistant.
- The control panel used by the operators and dial gauges are not clearly marked and they are frequently covered in dirt. This makes it very difficult to read the labelling on the control and increase the possibility of errors.
- Operators are concerned about the viewing angles and line of sight around the LP machines. During drilling operations the operators are required to move closer to the face machine to ensure that the drill bit are correctly positioned. This provides a potential risk if the operator moves too close to the working mechanisms of the drill rig.

The main objective of face drilling is to get holes for charging up so that rock can be

fragmented to the required size at the lowest possible cost and at the same time complying with the technical specifications and the safety conditions required. Though there are several challenges that are associated with the use of equipment, the advantages that come with efficient equipment utilization cannot be overemphasized. Efficiency in equipment utilization affects productivity and production. Face drilling on its own, is an important parameter in achieving the required targets. High face rig utilization results in more face being prepared for charging and blasting, and as a result it gives more tonnage output of fragmented rock. On the other hand, low face rig utilization results in low production output.

4.3 Losses Related to Face Rig Utilization

There are several types of losses that affect face rig utilization and these include:

4.3.1 Loss due to breakdowns

Time and quantity are two types of losses that result from breakdown losses. Unexpected, sudden or dramatic breakdowns get quick attention and they are easily predictable. Chronic breakdowns are not very common and as such they are often ignored when attempts to solve them do not prove to be successful. Many of the breakdowns that happened at the mine got attention but some were neglected and this resulted in severe problems in the mining cycle.

4.3.2 Loss due to setting up and adjusting

When production equipment is stopped due to changing of parts of equipment, the result is loss due to setting up and adjusting. There were few to none losses due to setting up or adjusting as all equipment is schedule for maintenance every week.

4.3.3 Loss due to minor stoppages and idling

Minor stoppages occur as a result of a small temporary malfunction that results in stoppage of drilling. For example the drill steel might get blocked in the drill hole which may cause the drill rig to idle. Such problems in most cases are overlooked and they result in major delays in future as solving them becomes complex and complicated.

4.3.4 Loss due to reduced penetration rates

Drilling machines are designed to operate at a specific drilling rate. When they operate at a lower rate there is reduced production. This can be a result of unsolved problems within the machine.

4.3.5 Loss due to starting up the drilling

When a machine starts up during the early stages of drilling until it stabilizes, there are losses that occur during this stability ramp up.

5 RESEARCH APPROACH

Two sections of the mine were investigated. One section from the north side and another from the southern side. The section from the northern side had its support installed by roof bolters. The one for the southern side had its roof support installed by using jack hammers.

A theoretical investigation of the required parameters required for full ideal utilization was done. Results were compared to results obtained from actual utilization measured during the course of the research. Measurement of the drilling times and determination of delays was done for the two sections.

5.1 Observations

Observations were made as the face rig was operating and the following parameters were measured.

- Rig Availability
- Rig Utilization
- Cycle Time
- Down Time

5.1.1 Rig availability

Availability is defined as a percentage of time that a machine is able to operate and is in a committable state when it is needed at any time (Memidex, 2014). The availability of the face rigs was measured and compared to the one captured by data capturing clerks.

5.1.2 Rig utilization

Face rig utilization is a key performance indicator (KPI) that reflects on the usage of the machine within its available time. Utilization was determined from the cycle time.

5.1.3 Rig cycle time

This includes time for collaring, penetration rate (drilling), inter-hole delay and time for reaming. All these times were recorded as the machine was being operated.

5.1.4 Down times

A minor stoppage is when the production stops for a temporary malfunction, or the equipment is idling. This includes non-productive time due to travelling, tramming, blasting, re-entry and no face to drill. These times were also measured during the course of the shift.

6 RESULTS AND ANALYSIS

After the identification of the status quo, practical solutions in mitigating the identified challenges were proposed as a means of bridging the gap between the actual utilization and the planned utilization.

6.1 Time Distribution Models

Table 3 shows the time distribution model for an operator during a shift.

Table 1. Drill Rig Time Distribution Model A

DRILL RIG TIME DISTRIBUTION MODEL			
Activity	From	To	Fraction of the Time
Travelling to Waiting place	8:00:00 AM	8:35:00 AM	0.583
Waiting place Procedure	8:35:00 AM	8:50:00 AM	0.250
Travelling to Workplace	8:50:00 AM	9:05:00 AM	0.250
Setting Up	9:05:00 AM	9:15:00 AM	0.167
Drilling	9:15:00 PM	17:05:00 PM	7.833
Engineering Down Time			1.480
Travelling to Waiting place	17:05:00 PM	17:25:00 PM	0.333
Travelling to Surface	17:25:00 PM	18:00:00 PM	0.583
Blasting And Re-entry	18:00:00 PM	20:00:00 PM	2.000
Total			12.00

Table 4 gives the fraction of time that is spent on each task during a shift.

Table 4. Drill Rig Time Distribution Model B

DRILL RIG TIME DISTRIBUTION MODEL			
Activity	Without Maintenance	With Maintenance	Weekly Calculations
Travelling (op)	2.33	1.75	15.75
Tramming	1.17	0.92	7.92
Setting Up	1.67	0.83	10.83
Drilling	11.37	6.77	75.01
Eng D/Time	2.96	9.48	27.24
Blasting & Re-entry	4.50	4.25	31.25
Total	24.00	24.00	168.00
Available	0.88	0.61	0.84
Total hours	21.04	14.52	140.76
Effective Utilization	0.54	0.47	0.53
Overall Utilization	0.62	0.52	0.61

Face rig utilization is a KPI that reflects on machine usage against its availability. Rig availability is measured against planned shift time of 24 hours. Availability was determined for situations with and without maintenance (mtce).

Availability (%) (without mtce)
= (planned time – engineering downtime)/planned time
= [(24 – 2.96)/24]*100%
= [21.04/24] * 100%
= 88%

Availability (%) (with mtce)
= (planned time – engineering downtime)/planned time
= [(24 – 9.48)/24] * 100%
= [14.52/24]*100%
= 61%

Maintenance is done once per week. Therefore the weighted average availability per week is;

Availability (%) (weighted average per week)
= {[(0.88 * 6) + (0.61 * 1)]/7}*100%
= 84%

Actual Rig Availability (%)
= Possible working hours – engineering downtimes

Engineering down times include mechanical and electrical breakdowns, over-run services and low penetration i.e. penetration rate > 2 minutes

Rig utilization is measured within the available time.

Effective rig utilization (%) (without mtce)
= (drilling time/available time)*100%
= (11.37/21.04)*100%
= 54%

Effective rig utilization (%) (with mtce)
= (6.77/21.04)*100%
= 47%

Effective rig utilization (%) (weighted average/week)
= {[(0.54 * 6) + (0.47* 1)]/7}*100%
= 53%

Actual rig utilization = available hours – mining downtimes/available hours

Where available hours = possible working hours – engineering down time

Mining downtime is a result of re-entry, travelling, tramming, setting up time, idle time, preparation time, no drilling tools, water - hose bursts and no power.

6.2 Observations

Table 5 shows the results of rig 16 which operated in a section that had its support system installed by hand held rock drills (jackhammers).

Table 2. Observations from face rig with jackhammers being used to install support

6.3 Analysis of Results

Figure 7 shows the major delays for the face rig from a section that uses roof bolters to install support.

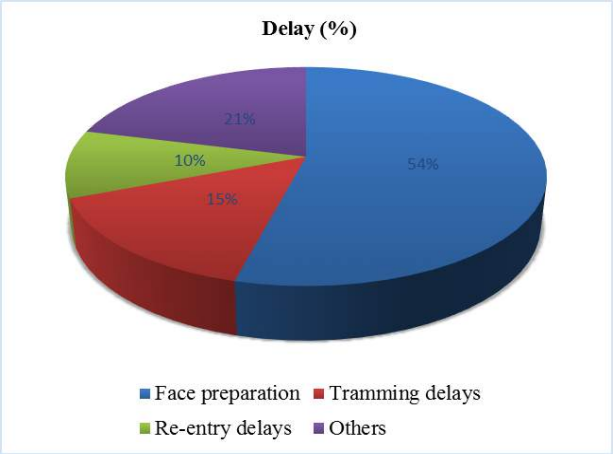

Figure 7. Pie chart showing the major delays for face rig 31 with bolters being used to install support

Figure 8 shows the major delays for the face rig from a section that uses jackhammers to install support.

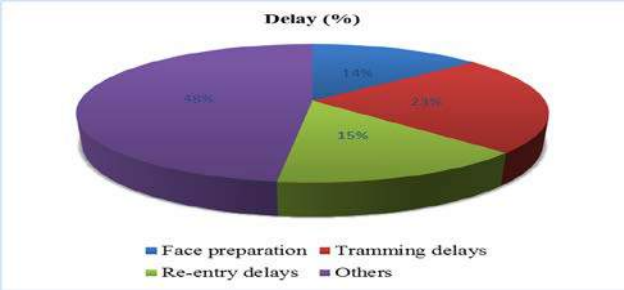

Figure 8. Pie chart showing the major delays for face rig 16 with jackhammers being used to install support

6.3.1 Major delays

Preparation delays – Figures 9 and 10 show that face preparation contributes more to major delays in sections that uses bolters to install roof support compared to the sections that uses jackhammers. This is attributed to the fact that bolter operators are relatively inexperienced and other mining delays cause failure to meet target. Jackhammers have been in operation since the beginning of mining at the mine therefore operators are more experienced in using jackhammers. A large percentage of delays due to face preparation affects face rig utilization by increasing idle time for face rigs due to non-availability of ends for drilling. Time lost in face preparation delay on average is 1. 75 hours per shift and this converts 105 tons of ore. For each day, 310 tons of ore are lost due to delay in face preparation. On the other hand, the face rig has no allowance made in its schedule for the operator to make safe the end before drilling but rather for inspection of an end that should have been made safe by team leaders or assistant miner. Making safe consumes around 40minutes; Watering down – 15 minutes; barring down – 20 minutes; Cleaning of sockets and plugging = 5 minutes.

For the ends available for drilling, making safe will consume 135 minutes ~ 68 holes at 2 minutes per hole ~ 1.33 ends lost per shift due to making safe.

Tramming delays- Due to distorted cluster of operations there is an increase in tramming times. Though this is a challenge due to ground conditions where geology can recommend ends to be stopped, failure to stick to the 3 ends per cluster result in spaced ends which increase tramming delays and setting up times compromising on the actual rig utilization. On average, tramming delays consumes 30 minutes. This is equivalent to 15 blast holes or a quarter of an end (26 tons of ore)

Other delays- Unavailability of drilling tools (rods and bits) and water due to water hose bursts and failure of boom to fit in gulley. If water hoses are damaged by being run over by mobile equipment (LHDs, Utility Vehicles (UVs) and rigs) or they have corroded due to wear and tear, they fail easily and disrupt drilling causing time losses during mending time. The average time that is lost is 40 minutes which is equivalent to 20 blast holes (~40 tons).

Rig effectiveness- The product of rig availability and utilization is called drill rig effectiveness that is:

Rig Effectiveness (%) = availability * utilization. Planned rig effectiveness
= 0.84 * 0.54 = 0.45 = 45%

Drill rig effectiveness focuses on business efficiency and reflects on the overall benefit of the machine to the organization and

therefore has a bearing on investment decision making by the company. For instance, a rig machine with low availability due to heavy maintenance schedules and breakdowns yet capital intensive cannot be a suitable investment because it will have low utilization and impact negatively on the Return on Investment (ROI). Figures 9 and 10 show the planned and actual rig effectiveness for rig 16 and rig 31 respectively.

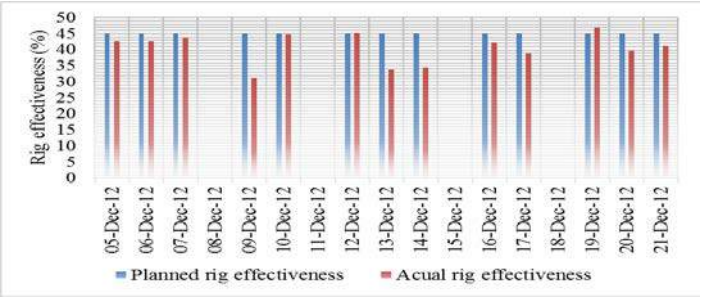

Figure 9. Bar graph showing planned and actual rig effectiveness for rig 16

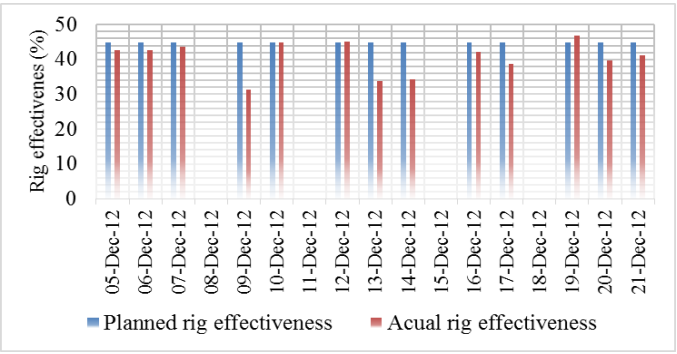

Figure 10. Bar graph showing planned and actual rig effectiveness for rig 31

6.3.2 Effect of down times and breakdowns

The effect of engineering down times is lower rig availability and mining down times represent reduced drill rig utilization and result in low rig efficiency. Rigs operating at low efficiency affect achievement of target face meters per day.

7 CONCLUSIONS

Utilization is a key performance indicator that is used to assess asset performance and production performance. From the study, the main problems that were found include dispersed workings, mechanical breakdowns, poor operator performance, and longer travelling times from surface. Improving utilization by clustering the workings will reduce the time needed for tramming and setting up. A single blast initiative has also been proposed as it will increase the available hours as well as utilization of face rigs. In order to improve operator efficiency, blending of operators proves to be effective as it provides the unskilled operator more time to get skilled. Full rig utilization for maximum production has shown that unified and mutual coordination between operators is very important as it gives the operators a way to communicate to each other through a communications log book.

In-situ Stress Measurements From Oriented Sub-cores Using Kaiser Effect

M. Karakus, S. Perez
School of Civil, Environmental & Mining Engineering, The University of Adelaide, SA 5005 Australia

D. Goodchild
OZ Minerals, Parkside, SA 5063, Australia

ABSTRACT Measuring in-situ stress in areas at great depth in which access is only available by exploration boreholes is a challenging task. This paper aims to investigate magnitude and orientation of in-situ stresses from cored rocks using acoustic emission (AE) and deformation rate analysis (DRA) at the exploration-drilling site in South Australia. Six independent sub-cores having different orientations for different depths of 640 m and 915 m were extracted from the original core whose dip and azimuth in mine grid are 64.4° and 186.06° respectively. Each sub-core was subjected to three cycles of loading. As the take-off point at first cycle is more pronounced than other successive cycles, calculation of stresses is based on first cycle data. Different threshold values were also tested to investigate their influence on locating take-off point. It was observed that threshold values lower than 15 mV tend to conceal point of inflexion. In AE analysis, locating point of inflexion was found to be difficult in some samples for which we also used DRA for cross checking. Therefore, we suggest that DRA should be used along with AE to ensure that the correct point of inflexion is located.

Keywords: Acoustic emission, deformation rate analysis

1 INTRODUCTION

Magnitude and orientation of in-situ stress in rock masses has to be estimated or measured before designing any underground structures or implementing a mine layout as the principal stresses will influence the overall stability of these structures. However, stress measurement, in principle, faces with an obstacle as such that stress is not a physical phenomenon than can be measured directly. Therefore, in order to determine stress in a finite body, a relation in the form of stress-strain is required (Fairhurst 2003). Seto et al. (1998, 1999) reported that common stress measurement techniques suffer from deficiencies and limitations. For example, overcoring and hydraulic fracturing are usually expensive and require highly skilled technical staff as well as being time consuming. Measuring in-situ stress in remote areas at great depth in which access from large boreholes and mine workings are hard is one of the deficiencies of these techniques.

Non-Destructive Techniques (NDTs) have been proposed to estimate in-situ stresses from cored rocks recovered at depths in order to remove limitations and deficiencies with the conventional stress measurement techniques. Kaiser effect involving acoustic emission (Kaiser 1953), and deformation rate analysis (Seto et al. 1999) are amongst the most popular unconventional stress estimation techniques. These techniques basically utilize irreversible damage process to estimate in-situ stresses.

This paper aims to analyse the results of AE and DRA to calculate in-situ stresses from cored rocks obtained from Carrapateena drilling site, SA. For this purpose, AE monitoring systems, which was developed by the first author in the school of Civil, Environmental and Mining Engineering (CEME), was used.

Six independent subcores from different orientations for depths of 640 m and 915 m have been extracted from oriented core whose dip and azimuth in mine grid are -64.4° and 186.06° respectively. Each sub-core was subjected to cyclic loading up to 52 MPa, which exceeds stress level at level 640m and 915m. Normal stresses found from AE were used to calculate stresses tensor according to Mine X=north, Y=east and Z=vertical directions. In the next stage Eigenvalue analysis is applied to calculate the principal stresses and their directions according to mine grid.

2 AE AND DRA ANALYSES

2.1 Acoustic Emission

Irreversible damage occurs in the rock when rock material subjected to loading exceeds the previously applied stress. Manifestation of micro-cracks can be observed by acoustic signals at this peak stress value where the number of acoustic hits or signals significantly increases. This effect known as Kaiser Effect (KE) is the signature of a memory of the maximum previously applied stress in a material, which was first discovered by Joseph Kaiser in 1950s. The KE is the absence of detectable AE events until the load imposed on the material exceeds the previously applied stress level (Yuan and Li, 2008).

The KE can be recognised as an inflexion (change of slope) in the dependency ‘‘cumulative AE hits versus stress’’. In order to determine the value of in situ stress (σ_m) more accurately, the curve may be approximated by two straight lines (bilinear regression). The point of their intersection projected onto the stress axis indicates the KE stress level (Lavrov 2003).

As reported by Seto et al. (1998), AE activity that occurs on the interface between the sample and loading end-platens during testing granular materials is a serious problem. In order to eliminate this AE activity, they used a 0.15 mm thick sheet of polyethylene placed between the sample and each end, while Mori et al. (2009) used stiff paper. A 10-mm thick plate of Bakelite was inserted by Li and Nordlund (1993) at each end of the specimen to block the noise from the hydraulic system of the testing machine. In order to eliminate the noise in our tests we used pre-stressed MDF material, which reduce the contact noises significantly.

2.2 Deformation Rate Analysis

In-situ stress estimation by Deformation Rate Analysis (DRA) was initiated by Yamamoto et al. in 1990. Earlier work that laid the foundation of this method was a method called differential strain curve analysis (DSCA) by Strickland and Ren (1980) that is also extension of differential strain analysis (DSA) introduced by Simmons et al. (1974). DRA uses the principles of the KE where strain is recorded under uniaxial cyclic loading. The difference in inelastic deformation in a specimen between two successive loading cycles was used to determine the previously applied stress. The strain difference function $\Delta\varepsilon_{j,i}(\sigma)$ is defined as:

$$\Delta\varepsilon_{j,i}(\sigma) = \varepsilon_j(\sigma) - \varepsilon_i(\sigma); \quad j > i \tag{1}$$

where σ is the applied axial stress and $\varepsilon_i(\sigma)$ is the reduced axial strain for the ith loading. $\Delta\varepsilon_{j,i}(\sigma)$ is approximated by a straight line with a positive gradient at stresses less than the previous peak stress that rapidly bends at or near the previous peak stress to have a negative gradient. Yamamoto et al. (2009) states that this negative gradient at applied stresses is higher than the previous peak stress indicates that the rock specimen can be easily deformed in the first loading than in the second one of two successive loading cycles. This is due to the specimen enlarging pre-existing cracks and/or to create new cracks at its first experience of a higher stress being applied. Considering what the Kaiser effect implies, this should happen especially when the applied stress exceeds the peak value of previous stress. The strain resulting from this phenomenon is irreversible for two successive cycles and not cancelled in the strain difference function defined by Eq. 1.

Many other researchers also reported that DRA is practically effective method to

estimate in-situ stress (Yamamoto et al. 1990; Hsieh et al. 2013; Wang et al. 2011; Karakus 2014). Therefore, we utilised DRA to cross validate AE results before calculating stress tensor at the drilling site.

3 EXPERIMENTAL METHODOLOGY

In order to construct stress tensor at the site, minimum six subcores are needed. Therefore six subcores were drilled from field core (master core). Orientation of the subcore samples relative to master core orientation has been converted to real mine grid (See Fig. 1).

Rock samples were prepared according to ISRM compressive testing standards. Height to diameter ratio for subcores was kept within approximately 2.

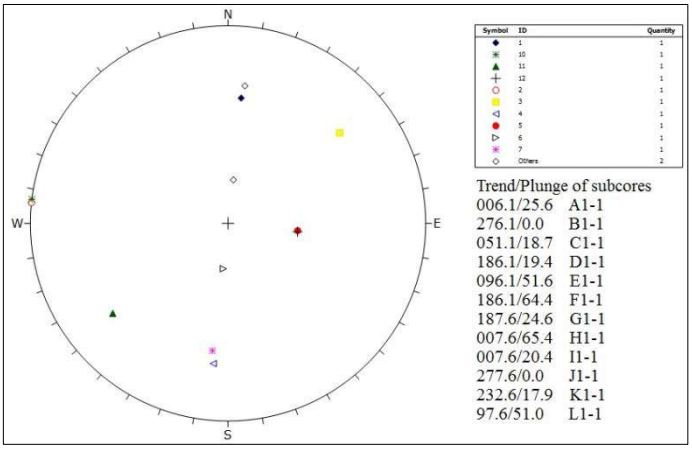

Figure 1. Pole plots for Subcore orientations (Lower Hemisphere – Equal area projection).

AE and DRA tests were carried out using Instron 1342 servo controlled hydraulic testing machine with 300 kN load capacity. The Instron controller consists of hardware components and software applications that provide closed-loop control of servo-hydraulic test equipment. This machine consists of a compression loading frame, an axial dynamic loading system and a data acquisition system. The data acquisition system consists of a signal conditioning, and an acquisition unit interfaced with a computer. Multiple or single data acquisition processes can collect data on all channels. This machine is able to perform cyclic test in both load and displacement control modes.

The AE monitoring system (see Fig. 2) consisted of AE sensors with pre-amplifiers, which were connected to a trigger signal generator with a NI PCI-6133 data acquisition unit. Frequency bandwidth of AE pico sensors is 200-800 kHz. Recording and visualisation of signals were done using a signal processing software developed in house using Labview. A set of 2/4/6 series filters with 20/40/60 dB gain single ended differential preamplifier was used to amplify signals 60dB.

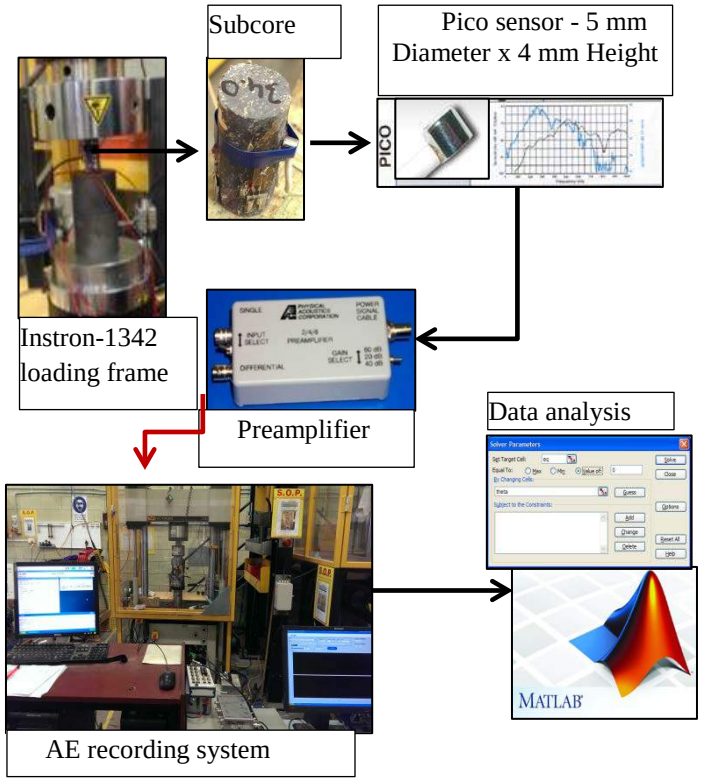

Figure 2. Schematic view of AE monitoring system.

Recent publication by Hsieh et al. (2013) on the influence of sample bending on deformation rate analysis suggests that use of four strain gauges can eliminate and reduce any errors when locating bending point for in-situ stress estimation. Therefore, each subcore was instrumented with four strain gauges and their average values were used to calculate overall strain for DRA. At the same time an acoustic sensor was attached to each sample to achieve simultaneous measurements. Acoustic pulses and axial strain during loading cycles (approx. 20 kN max. load) were continuously recorded leading to very large amount of data (approx.

12 GB). The dominant frequency for outside noise was found to be 320kHz. We, then applied digital filtering to remove outside noises so that all AE activities can be captured. When processing filtered data, we were able to apply as small as 5-10mV threshold values for AE hits. However, we found that less than 15 mV threshold value, locating point of inflexion is becoming very difficult. Therefore use of threshold limits ranging from 15mV to 150mV is suggested for AE tests.

4 EVALUATION OF THE RESULTS

In this section, firstly examples of graphical results from AE and DRA will be given to illustrate point of inflexions found in both analyses.

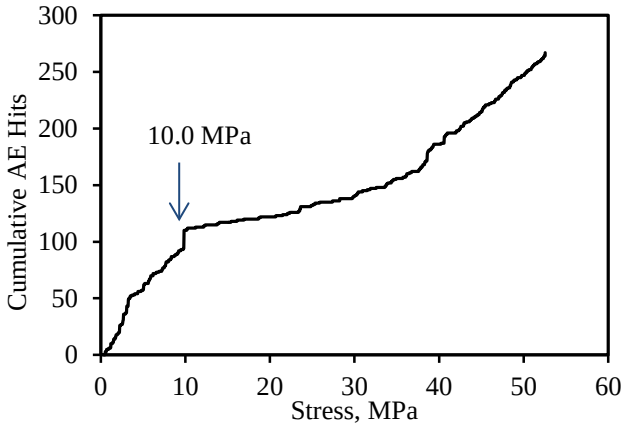

Figure 3. Cumulative AE hits versus stress for subcore D1-1.

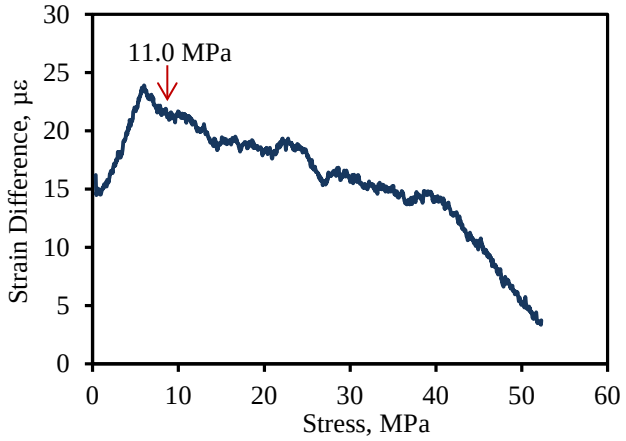

Figure 4. DRA result for subcore D1-1.

A clear take-off point at 10.0 MPa can be seen in Fig. 3 along with few other small sudden jumps which is due to the stress history that rock mass was subjected in the drilling site. Similar results as in the manifestation of strain differences can be seen in Fig. 4 where we found in situ stress is 11.0 MPa. Table 1 summarises the results from AE and DRA analysis.

4.1 Stress Tensor Calculations

Each subcore orientations were converted to real mine grid using the relations between field core orientations and relative subcore orientations. For this transformation the following equation is used:

$$cos\theta_{uv} = [\cos(\alpha_u - \alpha_v)cos\beta_u cos\beta_v] + [sin\beta_u sin\beta_v] \quad (2)$$

Where θ_{uv} is the angle between field core trend/plunge α_u/β_u and subcore trend and plunge α_v/β_v. As the angle θ_{uv} is known, using the Eq. 2 and solver in excel, orientations of the each subcore was calculated and given in Table 1. The average values of AE and DRA results were used to calculate stress tensor at the corresponding depths where the subcores were recovered.

Table 1. Orientations and locations of subcores along the master core and estimated stresses.

ID	Location (m)	Orientation (Degrees)		Stress (MPa)	
		α	β	AE	DRA
A1-1	642.0	6.1	25.6	17.0	13.9
B1-1	643.2	276.1	0.0	19.1	19.5
C1-1	642.7	51.1	18.7	25.7	25.5
D1-1	644.0	186.1	19.4	10.0	11.0
E1-1	643.6	96.1	51.6	16.8	12.2
F1-1	643.3	186.1	64.4	12.7	12.1
G1-1	915.9	187.6	24.6	21.6	17.8
H1-1	916.4	7.6	65.4	31.9	31.6
I1-1	916.7	7.6	20.4	33.3	32.1
J1-1	918.7	277.6	0.0	12.0	14.2
K1-1	919.5	232.6	17.9	14.0	18.5
L1-1	920.2	97.6	51.0	28.9	21.6

In order to obtain stress tensor for principal stress calculation, 6 independent normal stresses from subcores were used. (X=mine north, Y=mine east and N= Vertical – right handed coordinate system).

Based on the average of six normal stresses from AE and DRA results for depths of 640m and 915m, stress tensor [$\boldsymbol{\sigma}$] in the mine grid (X, Y, Z) was calculated using the following equation:

$$[\boldsymbol{\sigma}^*] = [\boldsymbol{R}][\boldsymbol{\sigma}][\boldsymbol{R}]^T \quad (3)$$

Where, $\boldsymbol{\sigma}^*$ is the stress matrix relative to the subcore axis (*l*, *m*, *n*) and [$\boldsymbol{R}$] is the rotation matrix. In an explicit form, Eq. 3 can be written as:

$$\sigma_{ll} = l_x^2\sigma_{xx} + l_y^2\sigma_{yy} + l_z^2\sigma_{zz} + 2l_xl_y\sigma_{xy} + 2l_yl_z\sigma_{yz} + 2l_xl_z\sigma_{xz} \quad (4)$$

Where, σ_{ll} is the normal stress measured in the direction of *l* in AE tests and l_x, l_y *and* l_z are the direction cosines local coordinate system and Cartesian coordinate system. Eq. 4 yields six simultaneous equations that are used to calculate stress tensor in the mine grid. For this purpose solver in excel were used to calculate stress tensor by minimizing the sum of squared errors between stresses calculated by solver and measured average normal stresses from AE and DRA analysis. The stress tensor calculated for depth of 640m is given below (in MPa):

$$\begin{bmatrix}\sigma_{xx} & \sigma_{xy} & \sigma_{xz}\\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz}\\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz}\end{bmatrix} = \begin{bmatrix}10.03 & 9.66 & 3.60\\ 9.66 & 21.47 & -2.26\\ 3.60 & -2.26 & 15.67\end{bmatrix}$$

We can see that normal stress at N-S direction is 10.03 MPa, E-W is 21.47 MPa and Vertical direction is 15.67 MPa.

Shear stresses found in the direction of N-S/E-W are 9.66 MPa and N-Vertical 3.60 MPa and E-Vertical is -2.26 MPa.

In the same manner, stress tensor is calculated for 915m depth as (in MPa):

$$\begin{bmatrix}\sigma_{xx} & \sigma_{xy} & \sigma_{xz}\\ \sigma_{yx} & \sigma_{yy} & \sigma_{yz}\\ \sigma_{zx} & \sigma_{zy} & \sigma_{zz}\end{bmatrix} = \begin{bmatrix}26.30 & 3.73 & 8.33\\ 3.73 & 13.87 & 6.60\\ 8.33 & 6.60 & 24.39\end{bmatrix}$$

4.2 Principal Stresses Calculations

Having calculated stress tensor, principal stress components can be calculated by Eigenvalue analysis. Using Matlab, principal stress components can easily be calculated. As described by Brady and Brown (1994), characteristic equation also known as cubic equation in principal stress (σ_p) calculation is given by:

$$\sigma_p^3 - I_1\sigma_p^2 + I_2\sigma_p - I_3 = 0 \quad (5)$$

where, the quantities I_1, I_2 and I_3 are first, second and third stress invariants given as:

$$I_1 = \sigma_{xx} + \sigma_{yy} + \sigma_{zz} \quad (6)$$

$$I_2 = \sigma_{xx}\sigma_{yy} + \sigma_{yy}\sigma_{zz} + \sigma_{xx}\sigma_{zz} - (\sigma_{xy}^2 + \sigma_{yz}^2 + \sigma_{zx}^2) \quad (7)$$

$$I_3 = \sigma_{xx}\sigma_{yy}\sigma_{zz} + 2\sigma_{xy}\sigma_{yz}\sigma_{zx} - (\sigma_{zz}\sigma_{xy}^2 + \sigma_{xx}\sigma_{yz}^2 + \sigma_{yy}\sigma_{zx}^2 \quad (8)$$

There are three distinct values of σ_p (principal stress) that provide solutions of the characteristic Eq. 5 by some general method. Three distinct values of the principal stresses; σ_1, σ_2, σ_3 are identified as major, intermediate and minor principal stresses respectively (Brady and Brown 1994). Similar procedures to calculate principal stresses are also described by Villaescusa et al. (2002).

Table 2. Principal stress magnitude and their directions in the mine grid.

Principal stresses	Depth, m	Magnitude MPa	Trend (°)	Plunge (°)*
σ_1	640	26.97	240.5	1.0
σ_2		17.10	333.4	71.3
σ_3		3.08	150.2	18.7
σ_1	915	36.08	24.5	41.4
σ_2		17.79	156.4	37.1
σ_3		10.68	268.5	26.5

Based on the assumptions described earlier, Table 2 summarizes the principal stresses at

640m and 915m depths. As can be seen from these results principal stresses are orthogonal to each other indicating correct calculations.

5 CONCLUDING REMARKS

Unconventional AE and DRA are proven to be practical, effective and low cost methods in estimation of in-situ stresses from cored rocks. These techniques are very efficient for the cases where there is no access to underground. Main difficulty arises when the cumulative acoustic emission curve does not include a clear take-off point where the use of DRA will be required to cross validate AE results. It was also found that filtering the outside noise is the imperative stage in AE analysis. Threshold values in the range of 15mV and 150mV were found to be the best range to locate point of inflexion in AE analysis. Threshold values less than 15mV and above 150mV will conceal the point of inflexion leading to inaccurate estimation of stresses. It is observed that use of four axial strain gauges also improved the results of DRA which supports the argument postulated by Hsieh et al. (2013).

Lastly, when calculating stress tensor, particular attention should be given to conversion of sub-core orientations to mine grid as this will influence the principal stress calculations.

ACKNOWLEDGEMENTS

Brett Triffett, Technical Manager, and Robert Bluff, Study Manager from OZ Minerals are gratefully acknowledged for their supports for the project. Lab technicians Adam Ryntjes and Simon Golding are also thanked for their time and effort in the preparation and testing of the core samples.

Assessment of In Situ Behaviour and Properties of Cemented Paste Backfill: Influence of Stope Height

E. Yilmaz
University of Quebec in Abitibi-Témiscamingue (UQAT), Department of Applied Sciences, 445 Boul. de l'Université, Rouyn-Noranda (Québec) J9X 5E4 Canada

ABSTRACT This paper presents key results from an experimental study aimed at examining the effect of stope depths (i.e. 0 m that imitates near the top of a given stope, 5 m, 10 m, 15 m and 20 m that imitates near the bottom of a given stope) on in situ behaviour and properties of cemented paste backfill CPB. Based on a new laboratory tool (CUAPS: curing under applied pressure system), all samples were prepared using the binder contents of 3, 4.5 and 7 wt% and tested after curing of 7, 14 and 28 days. One can state that as the stope depth increases, the CPB's strength increases. This may be explained by lower porosity and higher solid contents at the bottom of the stope (20 m) than higher porosity and lower solid content at the top of the stope (0 m). An evolution of CPB's geotechnical and chemical properties were also presented.

1 INTRODUCTION

Mine wastes generated and disposed at mine sites are problematic, because they contain harmful substances and require monitoring, treatment and safe disposal. Some techniques have been developed in the mining industry in order to prevent, rectify, lessen or remove the potential environmental impacts of mine wastes (Grice, 2001; Potvin et al., 2005; Bussière, 2007; Yilmaz, 2011). One practical tailings management system for underground mines involves refilling detrimental wastes as paste backfill into underground stopes created by ore extraction (Archibald et al., 2001; Kump, 2001; Landriault et al., 2001; Henderson et al., 1998; Benzaazoua et al., 1999; Ercikdi et al., 2012).

Cemented paste backfill CPB has become an increasingly popular system of optimizing underground mine excavations and tailings management systems to obtain a number of operational, economic and environmental benefits (Landriault, 2006). CPB is basically defined as a complex mixture of fine tailings (having 70-85 wt% solids), single or binary binder (usually 2-7 wt%) and sufficient water (required for reaching 15-25cm slump). Most investigations to date have been done on the backfill quality, and have focused on effect of tailings, binder and water (Benzaazoua et al., 2002, 2004; Kesimal et al., 2003, 2004, 2005; Fall et al., 2005, 2010; Cihangir et al., 2008; 2012; Ercikdi et al., 2009, 2010, 2014; Yilmaz et al., 2009, 2011; Ouattara et al., 2010; Fall and Pokharel, 2011; Abdul-Husain and Fall, 2012; Wu et al., 2013). But, CPB presents some difficulties with regard to the representativeness of laboratory samples and data to actual in situ materials. In fact, replicating field CPB placement and curing conditions at laboratory using plastic moulds is a challenging task, first, because it is not possible to exactly duplicate field conditions, and second, due to the absence of appropriate lab equipment and methods (Ouellet et al., 1998; le Roux et al., 2005; Orejarena and Fall, 2011; Pokharel and Fall, 2013).

The behaviour and properties of field CPB material vary principally depending on the method of preparation, placement method and particular mine conditions. Once CPB is prepared at paste plant, it is delivered (via pump or gravity) into mined-out stopes at a proper filling rate. The quicker filling rate may lead to a failure of the barricade formed. CPB is usually held in place by barricades, built across the access drift near the bottom of the stope. It is vital the pressures induced

by paste backfill do not surpass the barricade strength as costs and safety hazards linked with their failure are considerable (Bloss and Mathew, 2001; Cayoutte, 2003; Belem et al., 2004, 2010; Revell and Sainsbury, 2007; Yumlu and Guresci, 2007; Dehn et al., 2007; Grabinsky and Thompson, 2009; Thompson et al., 2010; Hughes et al., 2010). In order to design an efficient backfilling strategy, it is indispensable to assess the stress state within CPB, which often evolves over hydration. As the paste backfill's stiffness is weaker than the surrounding rock walls, it tends to settle under self-weight upon placement and create shear stresses along the rough wall surfaces. This can induce an arching effect that affects the stress distribution in stope (Hassani et al., 1998; Belem et al., 2004; Fourie et al., 2007; Pirapakaran and Sivakugan, 2007; Li et al., 2005; Li and Aubertin, 2010; Grabinsky, 2010; Thompson et al., 2012; Emad et al., 2013; El Mkadmi et al., 2014).

In current practice, the performance and properties of CPB samples are assessed by unconfined compression testing undertaken on laboratory-prepared samples with plastic moulds. But, this test does not allow backfill designers to consider how consolidation and hydration mechanisms influence the strength and stress distribution in the stope (Ouellet et al., 2005, 2006; Belem et al., 2007; Helinski et al., 2007, 2011; Yilmaz et al., 2011, 2012; Veenstra et al., 2011). A number of works have shown that, for a given backfill recipe, there are the huge differences between lab and in situ samples, whose performance are known to be underestimated. The observed differences between samples are attributable to specimen size effects, placement methods and field curing conditions (Cayoutte, 2003; Belem et al., 2007; Fourie et al., 2007; Fahey et al., 2011; Helinski et al., 2011; Yilmaz et al., 2014, 2015a,b).

It should be however confessed that more info is needed to have a better understanding of field paste backfill properties. In situ testing is crucial to obtain a real mechanical CPB response in order to improve the design of the backfilled stopes, and thus to improve safety and cut costs involved. Fortunately, these properties can be well simulated in the laboratory using a modified apparatus called the CUAPS (curing under applied pressure system; Benzaazoua et al., 2006; Yilmaz et al., 2010) which allows for the application of different pressure increments to the backfill samples during curing. As a result, aspects linked to in situ properties and conditions of CPB samples that affect greatly its strength and durability performance need to be further investigated experimentally.

The originality of this paper consists in the assessment of the influence of different stope heights and stope filling rates on behaviour and properties of CPB samples, employing sing the CUAPS apparatus. A number of the backfilled stope height scenarios, namely, 0 m (often used as control samples or mould-poured sample cured under zero pressure), 5 m, 10 m, 15 m, and 20 m were considered. In this case, 0 m simulates near the top of a given backfilled stope while 20 m simulates near the bottom of a given backfilled stope). An evolution of mechanical and geotechnical properties of paste backfills were made using different binder contents (3, 4.5 and 7 wt%) and curing times (7, 14 and 28 days).

2 MATERIALS AND METHODS

2.1 Materials

Tailings samples were taken representatively from a hard rock polymetallic mine located in Eastern Canada for laboratory preparation of paste backfill mixtures. A small portion of paste samples were air dried to conduct a set of experimental tests needed for the material characterization. All the tests were conducted consistent with American Society of Testing Materials standards and testing procedures. The entire tests were done in triplicate and their average results are reported. Additional knowledge on material characterization tests can be found in Yilmaz (2010).

2.1.1 Physical characterization testing of tailings and binders

The particle size distribution of the tailings used was analysed by a Malvern Mastersizer laser diffraction particle size analyser and shown in Figure 1. Besides, Tables 1 lists the

physical properties of tailings and binders. It can be observed that tailings were found to have a 45% fraction finer than 20 µm and more broadly graded with a coefficient of uniformity C_u (D_{60}/D_{10}; D_{60}: grain diameter at which 60% of the material passes, µm; D_{10}: particle diameter at which 10% of the material passes, µm) of ~8.

Specific gravity G_s and specific surface S_s of tailings and binders used in the study was measured using a Micromeritics AccuPyc 1330 helium pycnometry to be 3.7 and 2.9, and a Micromeritics Gemini surface analyzer to be 2.2 and 3.2 for tailings and binder, respectively. The relatively-high G_s value of tailings can be explained by their sulphide content (note that higher sulphide content implies higher density). The S_s of the tailings augments with increasing fine contents.

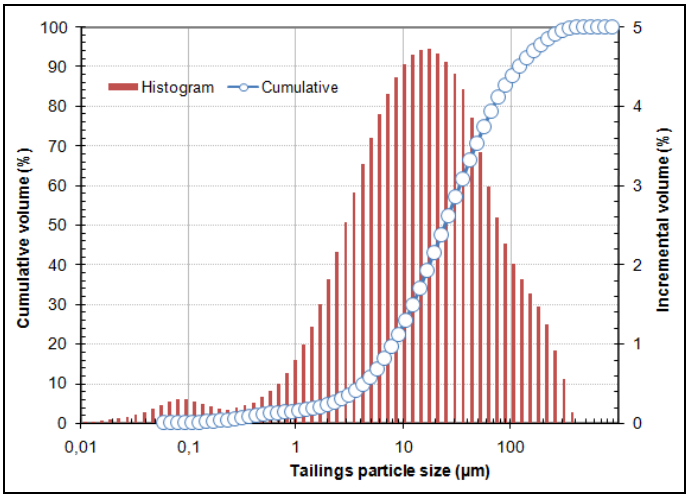

Figure 1. Cumulative and incremental grain size distribution of the studied tailings

2.1.2 Chemical and mineralogical testing of tailings and binders

The chemical composition of the tailings and binders used in this study was determined by a Perkin-Elmer Optima 3100 RL ICP-AES (inductively coupled plasma-atomic emission spectroscopy) and the obtained results were recorded in Table 2. The tailings contained 39.2% Fe_2O_3 and 51.3% total sulphur as determined by major oxide and elemental analysis, respectively. The slag-based binder contained 42.8% CaO, 30.9% SiO_2, 8.4% Al_2O_3 and 6.2% MgO.

Table 2. Chemical characterization testing of tailings and binders

Mineral (wt%)	Tailings (100%)	PCI-Slag (20-80%)	PCI (100%)	Slag (100%)
Al_2O_3	5.29	8.39	4.86	10.24
B_2O_3	0.61	0.13	0.03	0.48
CaO	0.79	42.82	65.76	31.41
Fe_2O_3	39.2	0.64	2.44	0.55
K_2O	0.24	0.55	0.83	0.51
MgO	0.16	6.19	2.21	11.29
Na_2O	0.40	2.03	2.11	2.01
SO_3	51.34	3.35	3.67	3.27
SiO_2	1.07	30.91	19.51	36.22
TiO_2	0.07	0.48	0.26	0.61
ZnO	0.44	0.00	0.03	0.00

The mineralogy of tailings was determined using the Bruker AXS D8 Advance X-ray diffractometer and evaluated using Rietveld full-pattern fitting method equipped with the TOPAS software. The X-ray diffraction and semi quantitative analyses revealed that the most abundant mineral within paste tailings was pyrite (47%), followed by quartz (32%), chlorite (9%), paragonite (7%), muscovite (3%), talc (1%) and gypsum (1%).

Table 1. Physical properties of paste tailings and hydraulic binders used in the experiments

Element (unit)	S_s (m^2/g)	G_s (-)	D_{10} (µm)	D_{30} (µm)	D_{50} (µm)	D_{60} (µm)	D_{90} (µm)	C_u (-)	C_c (-)	U (-)
Paste tailings	2.17	3.71	4.26	12.2	24.3	33.6	119.2	7.88	1.04	4.73
PCI-Slag / 20-80%	3.15	2.93	0.55	3.6	8.1	10.9	27.4	19.7	2.15	3.30
PCI (100%)	1.59	3.08	3.8	3.8	8.2	11.1	33.4	27.0	3.07	4.02
Slag (100%)	3.55	2.89	0.5	3.1	7.3	9.8	22.9	19.4	2.01	3.07

Note: S_s: specific surface area; G_s: specific gravity; C_u: Coefficient of uniformity (D_{60}/D_{10}); C_c: Coefficient of curvature ($D_{30}^2/D_{60}\times D_{10}$); U: Uniformity of graduation (D_{90}-D_{10})/D_{50}).

2.1.3 Geochemical testing of mixing water

The two types of mixing water: namely, as-received tailings interstitial water and added tap water were used for the preparation of CPB mixes. The concentrations of species in the mixing water were chemically analyzed using the ICP-AES method. Table 3 lists the results of chemical and geochemical testing. It can be observed clearly that the tailings interstitial water is highly aggressive in terms of sulphate content (SO_4^{2-} content around 4880 ppm) but also contains calcium (Ca content about 560 ppm). The origin of the sulphate was likely ferrous and/or copper sulphate that was added for cyanide removal (tailings are treated before mine backfilling), precipitating iron/copper cyanide complexes. Besides, the origin of calcium was likely the lime added during ore processing plant (often used as pH modifier).

Table 3. Geochemical analysis of tailings interstitial water and additional tap water

Relevant parameters	Tailings interstitial water	Added tap water
Al (mg/L)	0.21	0.01
Ca (mg/L)	560	40.9
Cu (mg/L)	0.29	0.84
Mg (mg/L)	1.83	2.27
SO_4^{2-} (mg/L)	4880	120
Si (mg/L)	0.89	0.90
K+ (mg/L)	32	0.71
pH	9.41	7.82
ORP (volt)	0.15	0.43
EC (mS/cm)	7.42	0.27

ORP: Oxidation-reduction potential; EC: Electrical conductivity

A Benchtop pH/ISE meter Orion Model 920A coupled with a Thermo Orion Triode combination electrode was employed for the pH, oxidation-reduction potential (ORP) and electrical conductivity (EC) measurements and the results obtained were tabulated in Table 3. The pH, ORP and EC of tailings interstitial and tap water were 9.4, 0.15 volt and 7.42 mS/cm, and 7.82, 0.43 volt and 0.27 mS/cm, respectively. The relatively high EC observed within interstitial water shows the presence of dissolved conducting ions.

2.1.4 Mixing and curing of paste backfills

The paste ingredients (that contain a range of proportions of different hydraulic binders, a predetermined amount of tailings and mixing water) were weighed. The constituents were then mixed homogenously for 10-15 minutes using an electrical Hobart A200 model mixer until the paste having a fixed slump content of ~18 cm was achieved. Slump is a measure of paste consistency and obtained using the standard 12-inch-high concrete industry cone slump apparatus. The samples were prepared using three different binder contents: 3, 4.5 and 7 wt% for slag-based binder (note that only 4.5 wt% binder proportion was used for both general use Portland cement (PCI) alone and fly ash-based binders. The backfill mixes produced were then poured into the Perspex moulds of 10 cm in diameter and 20 cm high. The prepared moulds were then sealed to keep away from evaporation and oxidization and cured in the newly-developed laboratory apparatus (CUAPS: curing under applied pressure system) for curing of 7, 14 and 28 days. Samples were left to cure in the foggy room maintained at 70% relative humidity and 25°C temperature to repeat underground mine conditions until compression testing. Figure 2 demonstrates a number of CUAPS apparatuses filled with paste backfill mixes and cured in the humidity chamber.

Figure 2. Photo showing the backfill samples cured within the CUAPS apparatus

2.2 Methods

2.2.1 Developed experimental setup

A schematic representation of the laboratory setup developed to simulate different in situ and curing conditions is shown in Figure 3. The setup consists mainly of three parts: *i*) a top loading device intended to apply vertical stress to the CPB sample at air pressures up to 600 kPa (with an LVDT for measuring vertical deformation and a loading piston), *ii*) a Perspex mould to hold CPB sample in the middle part ($D \times H$: 102 × 204 mm) covered by metal cylinder and *iii*) a bottom drainage hole (equipped with a pore water pressure transducer) to drain free water from sample. A full description of the CUAPS apparatus is beyond the scope of this paper. However, ordetailed information on its features can be found elsewhere (Benzaazoua et al., 2006; Yilmaz et al., 2010; Yilmaz, 2010).

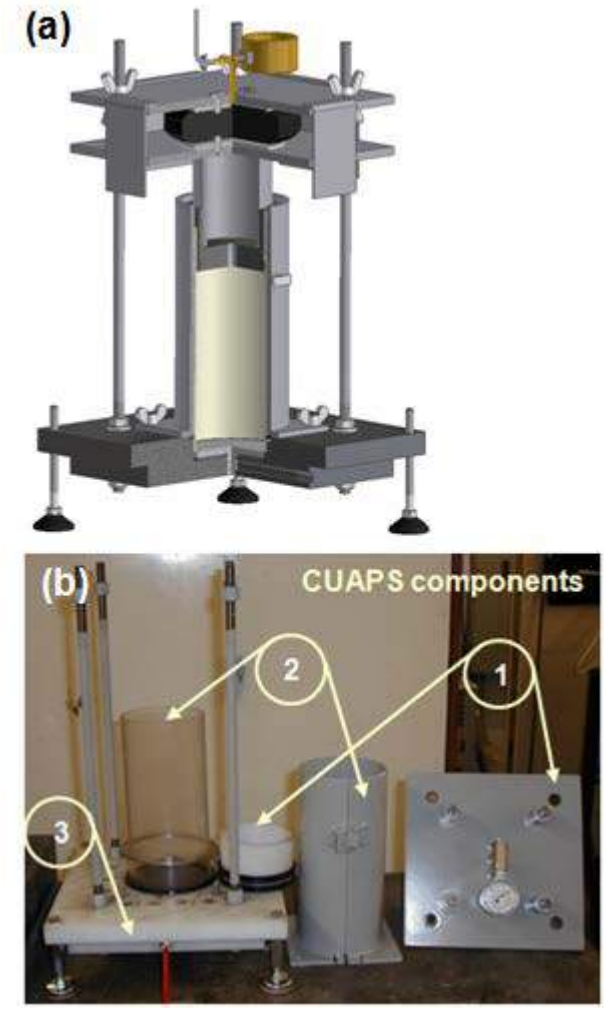

Figure 3. The developed experimental set-up: a) schematic illustration, and b) the essential components of the CUAPS apparatus

2.2.2 Backfilled stope height tests

These tests aimed to reproduce the influence of different stope filling rates and backfilled stope heights on the resultant properties of CPB samples. A number of the test scenarios that consider the four different stope heights h of 5, 10, 15 and 20 m were implemented to CPB samples. The scenarios experimented were based on the applied vertical pressure which can be taken as overburden pressure, as shown in Eq. [1] below.

$$p_v = \rho \times g \times h = \gamma_{wet} \times h \qquad [1]$$

Where, p_v is the ultimate applied vertical pressure (kPa); ρ is the density of the fluid paste backfill mixtures; γ_{wet} is the hydrostatic or pressure; h is the height of the backfilled stope; g is the gravitational constant.

Table 4 and Figure 4 provide a number of pressure application scenarios during testing simulating the underground backfilled stope heights. One can state that during the first 12 hours after the CPB's placement, no pressure was applied vertically.

Table 4. The different pressure scenarios for simulating the backfilled stope heights

Elapsed time (hours)	Applied vertical pressure p_v (kPa)	Equivalent height h (m)	Equivalent filling rate (m/h)
Scenario A (stope height = 5 m)			
12	28	1.3	0.10
24	57	2.5	0.10
48	*113*	*5.0*	*0.10*
Scenario A (stope height = 10 m)			
12	57	2.5	0.21
24	113	5.0	0.21
48	*227*	*10.0*	*0.21*
Scenario C (stope height = 15 m)			
12	85	12.3	1.03
24	170	24.6	1.03
48	*340*	*49.3*	*1.03*
Scenario D (stope height = 20 m)			
12	113	16.4	1.37
24	227	32.9	1.37
48	*453*	*65.7*	*1.37*

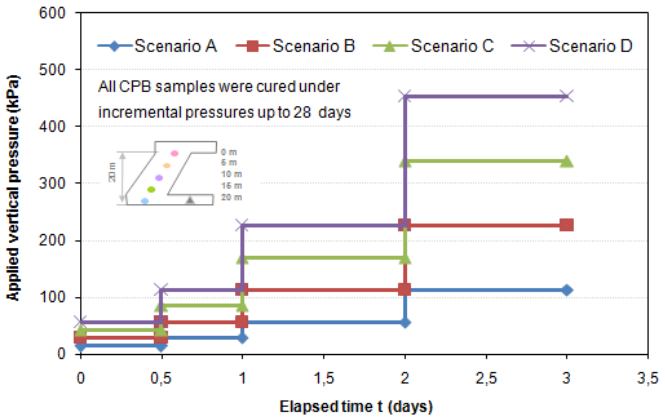

Figure 4. Plot of the four different backfilled stope heights based on applied pressure

After that, pressures were progressively increased up to the final pressure of 113 kPa (scenario A: stope height = 5 m), 227 kPa (scenario B: stope height = 10 m), 340 kPa (scenario C: stope height = 15 m) and 453 kPa (scenario D: stope height = 20 m) for a total duration of 48 hours, corresponding to a filling rate sequence of 0.1, 0.21, 1.03, and 1.37 m/h. Each sample was then left to cure for 7, 14 and 28 days (see Table 4). These tests were run to consider the quality and behaviour of in situ cemented paste backfills and compare it to that of CPB samples in the laboratory conditions. All pressures were applied to paste backfill samples within a curing period of 48 hours and left to cure for 7, 14, and 28 days.

2.2.3 Unconfined compression tests

Following the prescribed curing times of 7, 14, and 28 days, all the CPB samples were extracted gently from their Perspex moulds using a manual push specimen extruder. The two ends of the Perspex mould filled up with paste backfill samples were open and the two porous discs (both at the bottom and the top of Perspex mould) were placed at these ends for better practising the pressures to samples without having any significant damage. After paste backfill cylinder faces were rectified in order to provide a flat surface, the length and weight of the samples were measured and recorded. CPB samples were subsequently subjected to unconfined compression testing (UCS) in order to determine their mechanical strength acquisitions.

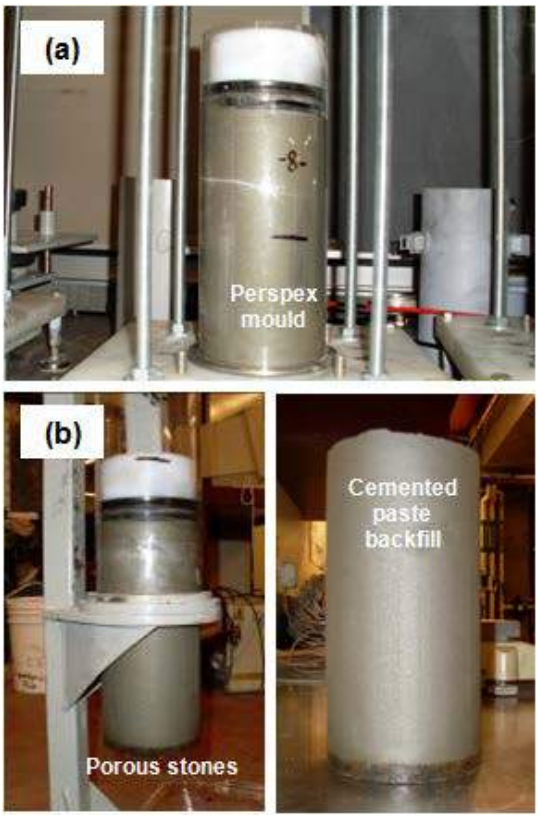

Figure 5. Photos of a) a Perspex cylinder filled with paste backfill and b) sample extractor and extracted CPB sample

The UCS tests of CPB samples were done using an automatic mechanical press (MTS 10/GL; Figure 6). The press has a nominal loading capacity of 50 kN. The compression tests were performed at a stable deformation rate of 1 mm/min. Axial deformations were automatically recorded by an electronic data acquisition system. The observed UCS value corresponds to the maximum stress (failure peak) reached during the compression test. The average values from triplicate tests were presented in the results.

Figure 6. CPB sample subjected to UCS test

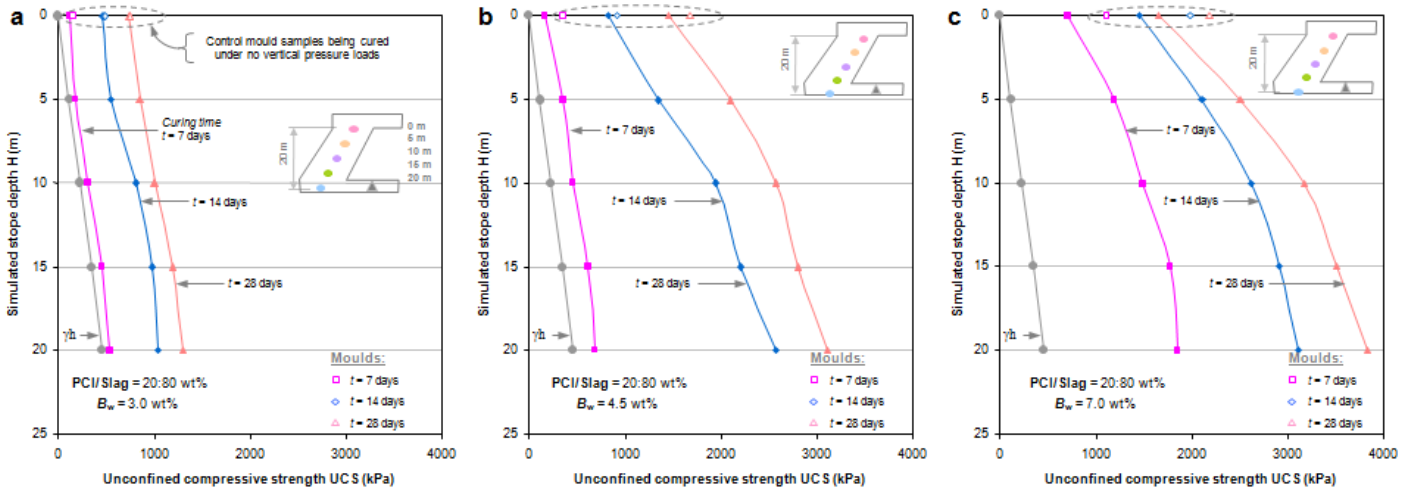

Figure 7. Variation in compressive strength with simulated stope heights for CPB samples containing slag-based binder: a) 3wt% binder, b) 4.5 wt% binder, and c) 7wt% binder.

3 RESULTS AND DISCUSSION

3.1 Effects of Simulated Stope Heights on Compressive Strength of Paste Backfill

Figure 7 shows an evolution of compressive strength with the simulated stope height for the paste backfills placed in a "virtual" stope. Note that the stope depth is taken as the dept from the top of the newly added paste fill layer. As expected, CPB's strength increases with increasing depth for a given curing time, following the same trend as overburden pressure ($\sigma_v = \gamma \times h$). After curing of 28 days, a compressive strength of 1.5, 2.1, 2.6 and 3.1 MPa were obtained from CPB samples containing 4.5wt% of slag-based binder at stope depths of 0, 5, 10, 15 and 20 m, respectively. This confirms that compressive strength of the backfilled stopes increases from the top to the bottom due to self-weight consolidation effect. In fact there are others which may greatly affect the reason why the lower part of stope produce higher strengths than the upper part of the stope. These are self-desiccation (improved effective stress) and backfilling rate (void ratio reduction and increased solid content).

Figure 8 also shows paste backfill strength with the stope dept. Samples were prepared at 4.5wt% of three different binding agents as a function of 7, 14 and 28 days. Results indicate that, at 14 and 28 days, slag-based binders create much more strengths than both general use Portland cement alone and fly ash-based binders because of their included additive amount and chemical composition. This strength difference observed remained the same during the course of 7 days.

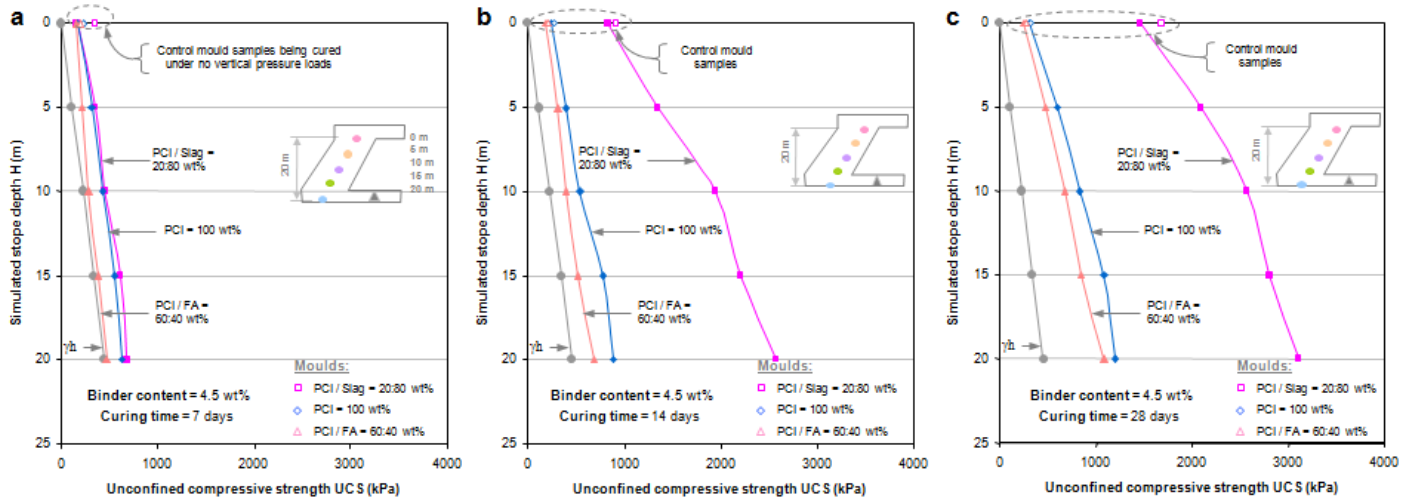

Figure 8. Variation in compressive strength with simulated stope heights for CPB samples containing different binder agents: a) 7 days, b) 14 days, and c) 28 days.

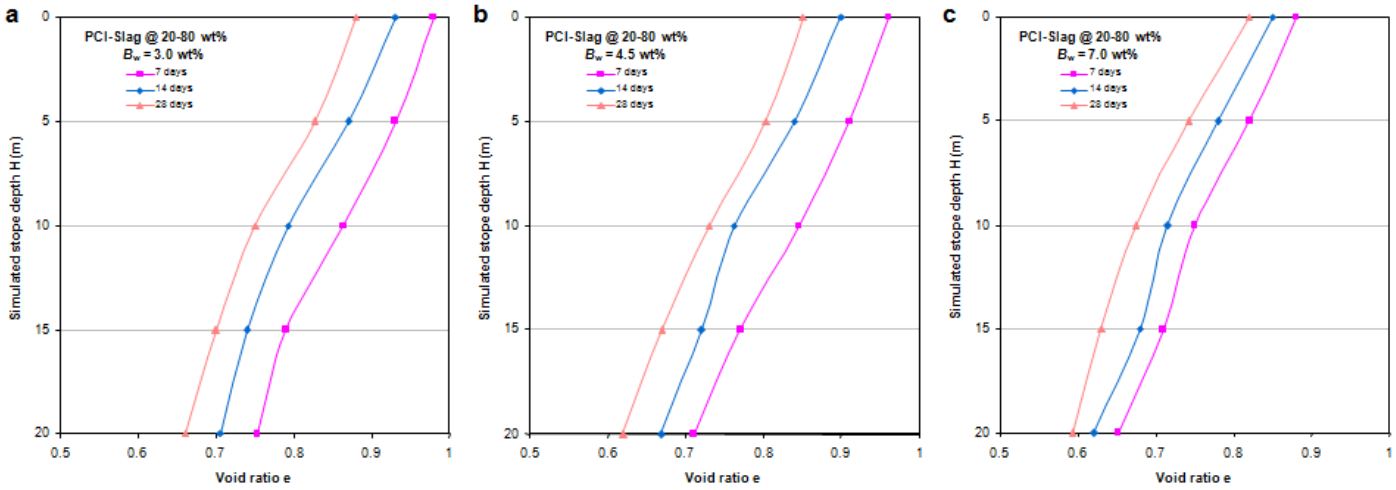

Figure 9. Variation in void ratio (porosity) with simulated stope heights for CPB samples containing slag-based binder: a) 3wt% binder, b) 4.5 wt% binder, and c) 7wt% binder.

3.2 Effects of Simulated Stope Heights on Void Ratio (Porosity) of Paste Backfill

Figure 9 illustrates an evolution of void ratio with the simulated stope heights for CPB samples having slag-based binder. Overall, the void ratio ranges between 0.6 and 1 for all samples. It can be inferred from Figs. 9 and 10 that the void ratio or porosity reduces with increasing backfilled stope depth since the corresponding relative density increases as a result of applied consolidation pressure (newly-added layer with 5 m height creates extra pressure over the already-added layer) during curing. One can say that void ratio of the backfill samples near the top of the stope changes between 0.85 and 0.95 while the void ratio of samples near the bottom of the stope changes between 0.65 and 0.85.

This is because the lower the void ratio, the closer the paste backfill particle packing, and accordingly, the lower the friction angle that develops and the stronger the material (corresponding to high cohesion). Figure 10 shows an evolution of porosity with different paste backfilled stope depths as a function of different binding agents. Observation can make clearly that CPB containing slag-based binder gives less porosity than those obtained from samples with fly ash-based binder and general use Portland cement. After curing of 7 days, there are no big differences between samples due to the fact that cement hydration products could not get well being filled with the gaps between solid particles. However, as curing time increases from 7 days to 28 days, the related porosity decreases notably.

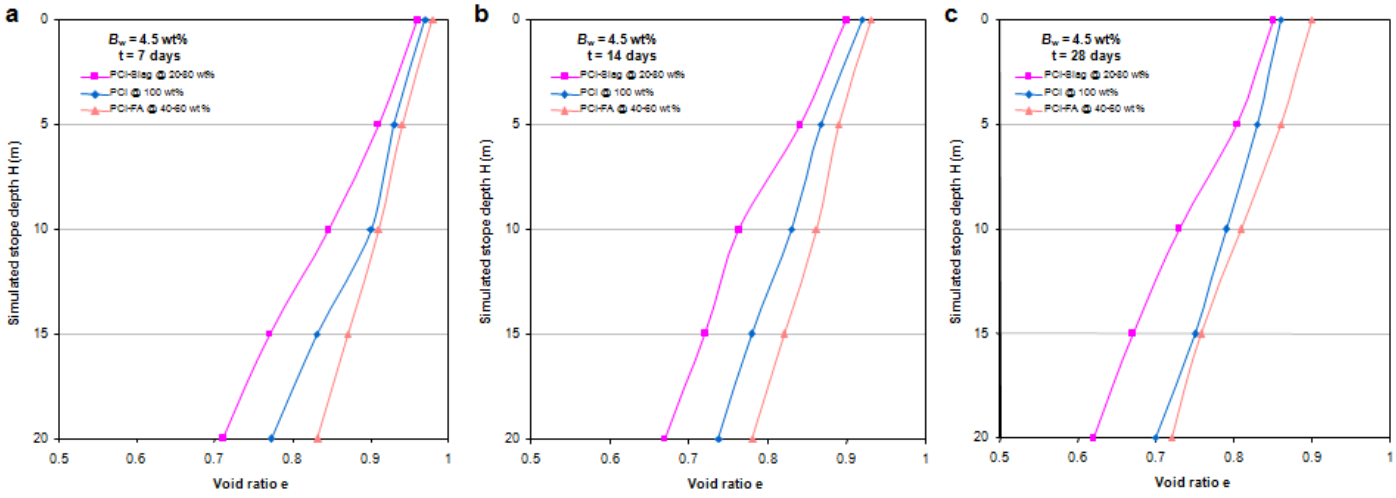

Figure 10. Variation in void ratio (porosity) with simulated stope heights for CPB samples containing different binder agents: a) 7 days, b) 14 days, and c) 28 days.

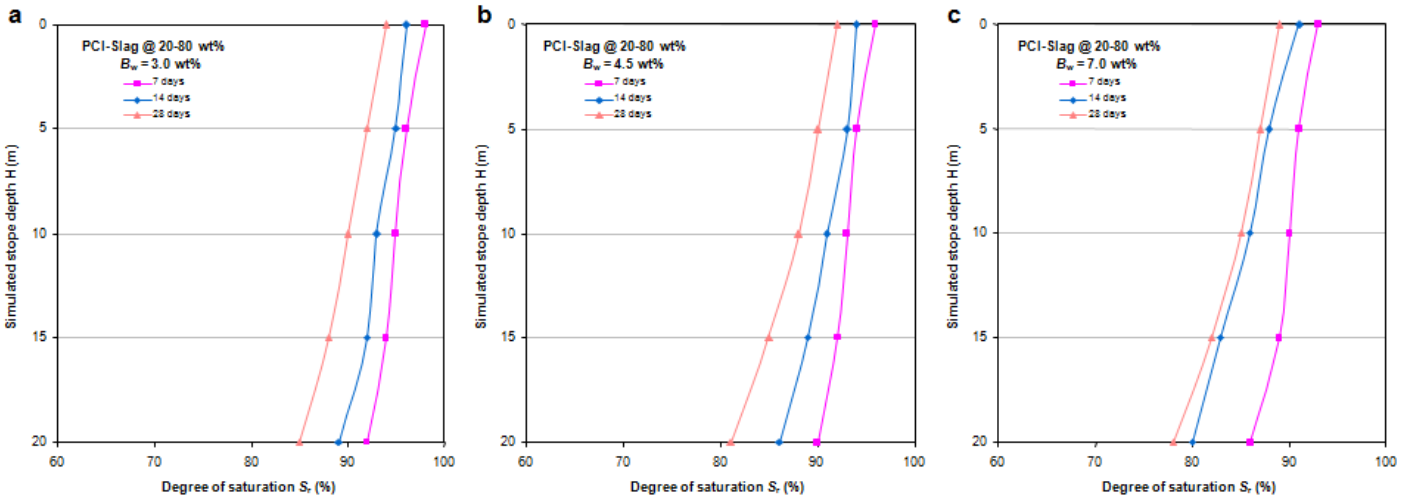

Figure 11. Variation in degree of saturation with simulated stope heights for CPB samples containing slag-based binder: a) 3wt% binder, b) 4.5 wt% binder, and c) 7wt% binder.

3.3 Effects of Simulated Stope Heights on Degree-Of-Saturation of Paste Backfill

Figure 11 presents the variation in degree of saturation with the simulated stope depth for CPB samples containing slag-based binder. The overall trend is that degree-of-saturation reduces slightly with increasing curing time and binder content for the whole samples. In general, the degree of saturation ranges 85-98% for 7 days, 81-95% for 14 days, and 78-92% for 28 days. The amount of the binder added to the paste backfill mxiture is directly related to their saturation index value. This means that the higher are the binder contents and curing times, the greater are the cement hydration products, thereby reduced degree of saturation for a given CPB material.

Figure 12 demonstrates an evolution of the degree of saturation with stope depth for the samples with three different binding agents. After 7 days, the degree of saturation for all samples remains 90-99% while, the samples cured after 28 days, the degree of saturation decreases remarkably up to 80%. Moreover, the degree of saturation is highly affected by the drainage or consolidation of cemented paste backfills. It is quite apparent that the CPB samples containing the highest binder content (7 wt%) exhibits the lowest degree of saturation, when compared to the remaining binder contents (3 and 4.5 wt%). This could be explained readily by the different water-to-cement ratios and the amounts of water required for binder hydration.

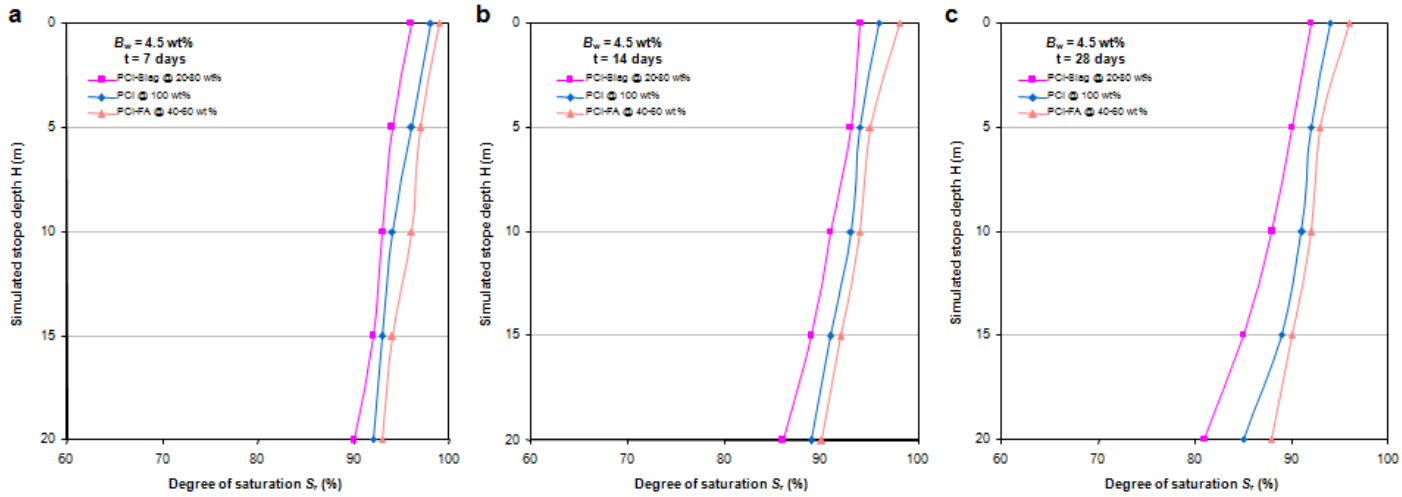

Figure 12. Variation in degree of saturation with simulated stope heights for CPB samples containing different binder agents: a) 7 days, b) 14 days, and c) 28 days.

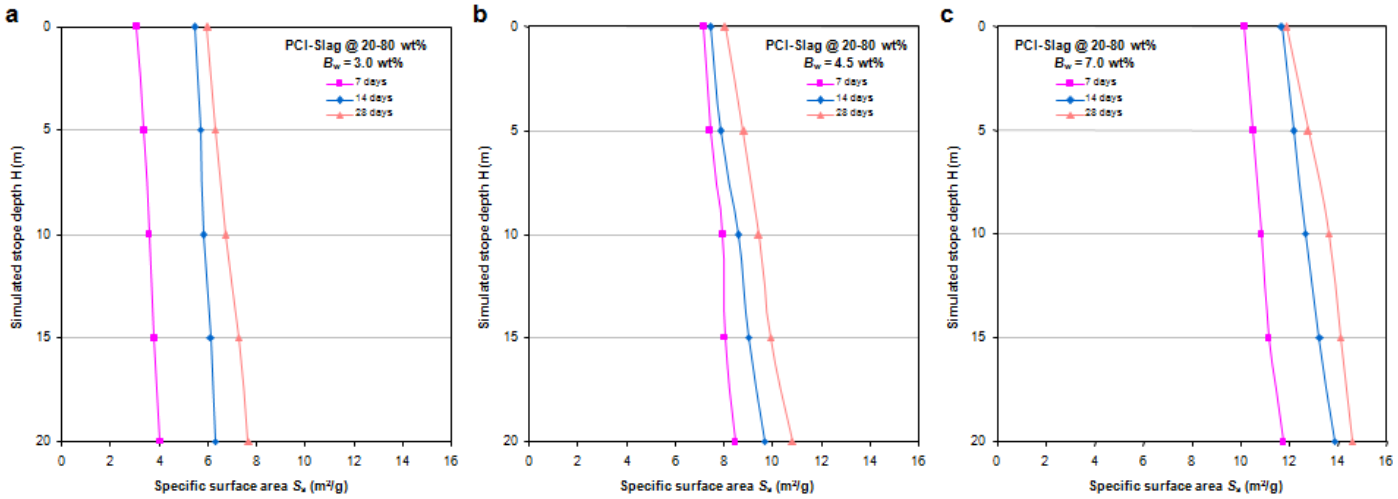

Figure 13. Variation in specific surface area with simulated stope heights for CPB samples containing slag-based binder: a) 3wt% binder, b) 4.5 wt% binder, and c) 7wt% binder.

3.4 Effects of Simulated Stope Heights on Specific Surface of Paste Backfill

Figure 13 presents the evolution of specific surface area with simulated stope depth for CPB samples with slag-based binder. Note that specific surface is directly related to the hardening phase formation during curing. The higher the binder ratio used, the higher the specific surface of CPB becomes due to the growth of hydration products. In general, the specific surface of paste backfill ranges 4-8 m^2/g for 7 days, 8-11 m^2/g for 14 days, and 12-15 m^2/g. Specific surface increases with the increasing stope depth and curing time for a given binder content. The highest specific surfaces were obtained from CPBs near the bottom of the stope ($\leq$ 11 m^2/g).

One can remark that the change in specific surface area has remained limited since all the CPB samples were consolidated under progressively-increased pressures or stresses during curing. Figure 14 shows an evolution of specific surface area with stope depths for the backfills containing the 4.5wt% of three different binding agents. The lowest specific surface area values were obtained from CPB samples with fly ash based binders (6, 7, and 8 m^2/g for 7, 14, and 28 days, respectively). The greatest specific surfaces were obtained from CPB samples with slag-based binders (9, 10, and 11 m^2/g for 7, 14, and 28 days, respectively). Note that the increased specific surface may be explained by formation and contribution of precipitated hydrates.

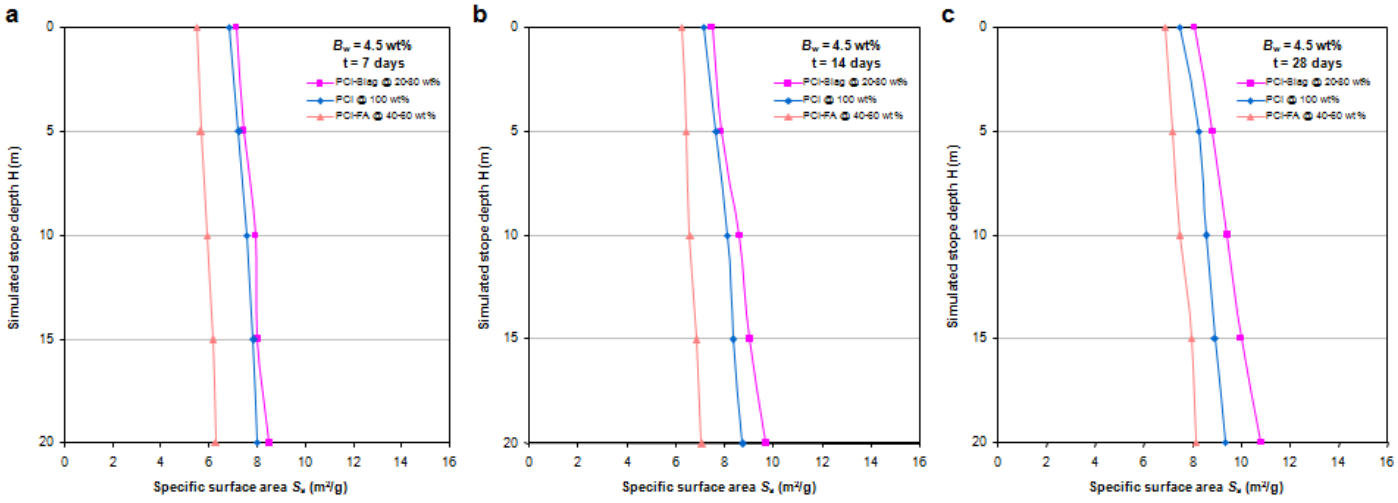

Figure 14. Variation in specific surface area with simulated stope heights for CPB samples containing different binder agents: a) 7 days, b) 14 days, and c) 28 days.

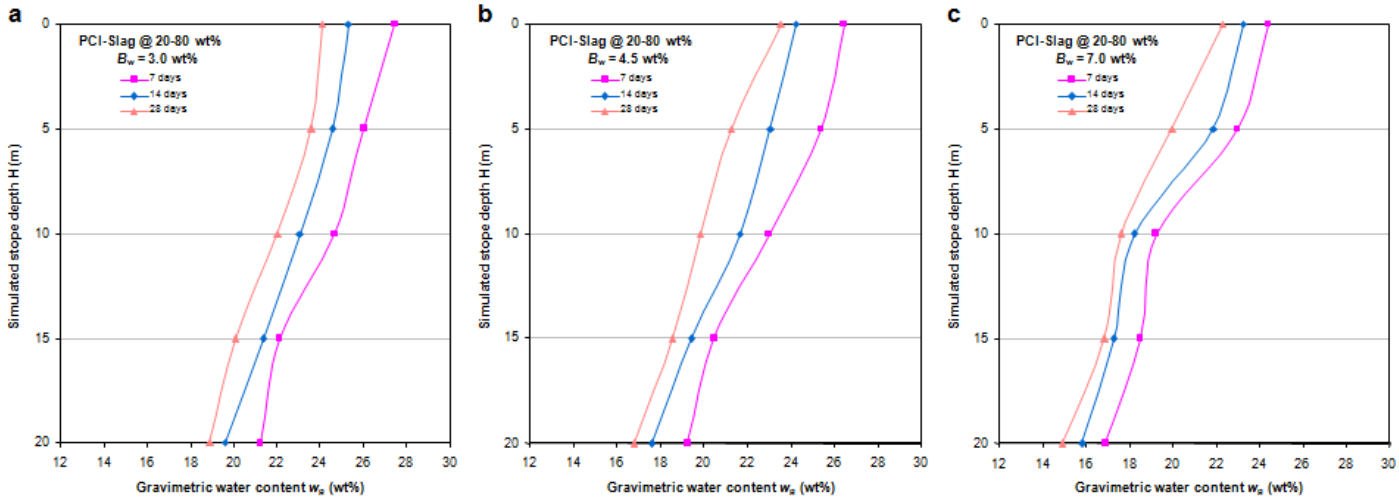

Figure 15. Change in gravimetric water content with simulated stope heights for CPB samples containing slag-based binder: a) 3wt% binder, b) 4.5 wt% binder, and c) 7wt% binder.

3.5 Effects of Simulated Stope Heights on Water Content of Paste Backfill

Figure 15 shows the evolution of gravimetric water content with simulated stope depth for CPB samples containing slag-based binder. For a given binder content, the lowest water contents (15-21 wt%) were obtained from 28-day cured CPB samples near the bottom of the stope. For CPB samples near the top of the stope (5-10 m height), the water content decreased from 23-27 wt% to 18-20 wt% when the corresponding binder content of the backfill samples increased from 3 to 7 wt%. The final water content is mainly controlled by the newly-added layer of cemented paste backfills and the amounts of excessive water required for cement hydration.

In general, the CPB samples placed at the base of the stope (subjected to overburden or hydrostatic pressure coming from each paste backfill layer having each 5 m) keep less free water in their structures, compared to CPB materials near the top of the stope where no stress is applied during the course of curing. Figure 16 shows the evolution of gravimetric water content of the simulated stope depths for CPB samples containing the 4.5 wt% of three different binding agents. As expected, the lowest water contents came from CPB samples located at the base of the stope (19-21 wt% for 7 days, 18-20.5% for 14 days, and 16.5-20 wt% for 28 days. In addition, the samples with slag-based binder exhibited the lowest water contents among others.

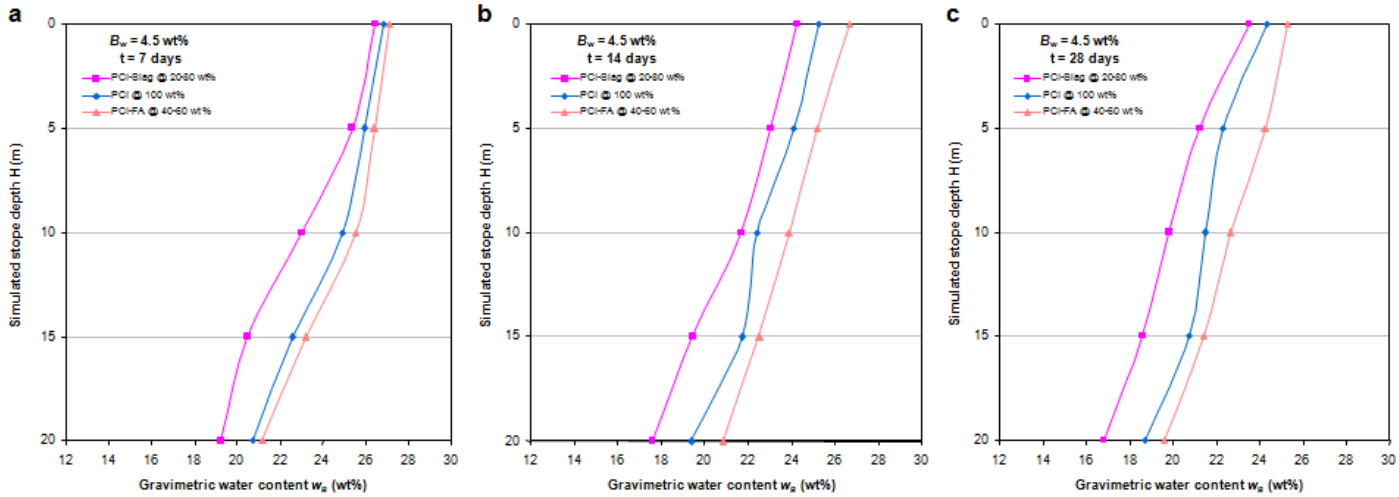

Figure 16. Change in gravimetric water content with simulated stope heights for CPB samples containing different binder agents: a) 7 days, b) 14 days, and c) 28 days.

4 CONCLUSIONS

This paper presents the promising results of a laboratory study undertaken for assessment of in situ behaviour and properties of CPB samples. The effect of stope height on paste backfill performance was investigated using an improved laboratory apparatus (CUAPS: curing under applied pressure system). A variety of CPB samples were prepared using the 3, 4.5 and 7 wt% binder contents of slag-based, fly ash-based and general use Portland cement alone and subjected to a number of pressure sequences which may simulate the different stope depths of 0 (reflects the CPB material near the top of the stope), 5, 10, 15, and 20 m (reflects the CPB material near the bottom of the stope). Results indicate that this investigation has not only presented a better understanding of in situ performance and quality of laboratory-prepared backfill samples but also identified procedures and (or) techniques that can be used to conduct field paste backfill testing in the laboratory. It is a well-known fact that conducting field testing is a challenging task because modern mines usually do not want to risk the safety of personnel or cause property damage or production losses and delays. Consequently, it is strongly believed that the results of this research work will bring a new light to paste backfill planners, practitioners, operating and regulatory professionals and researchers. It will be also a valuable tool for mines in order to characterize in situ behaviour of their CPB materials in the laboratory, saving time and money on quality control tests.

ACKNOWLEDGEMENTS

The author acknowledges the financial support from Canada Research Chair on the Integrated Management of Sulphidic Tailings using Mine Backfill Technology and the Industrial NSERC-Polytechnique-UQAT Chair on the Environment and Wastes Management. Canada Foundation for Innovation (CFI) is gratefully acknowledged for manufacturing CUAPS tools. Special thanks are extended to Denis Bois, Tikou Belem, Bruno Bussière and Mostafa Benzaazoua for UQAT-URSTM lab facilities, to URSTM expert people for their technical assistance during testing.

Investigation of Strength Properties of a Sandstone Rock

A.Boutrid, M.Chettibi, S.Bensehamdi and K.Talhi
Annaba University, BP12- Algeria, Faculty of Earth Sciences, Mining Department, Annaba 23000

ABSTRACT This research aim to assess the effect of water saturation on the mechanical properties of sandstone rocks using a servo-controlled testing machine. Stress-strain curves were obtained from which the uni-axial compressive strength, Young's Modulus and the brittleness index were measured for specimens prepared from a single block of Sandstone from the Hassi Messaoud site investigation , Algeria. To see how the strength properties were affected by changes in saturation level (likely to occur on site), the specimens were divided into three groups which were prepared for testing under different conditions of saturation content.

Keywords: saturation; mechanical properties uni-axial compressive strength, Young's Modulus , brittleness index

1 INTRODUCTION

Estimation of rock mechanis properties of rocks to be is considered the most important components in any engineering project. In this regard, one of the most commonly used fundamental mechanical parameter is the uniaxial compressive strength (UCS) (Bruno et al. 2012; Minaeian and Ahangari 2011).

For both excavation and stability problems, knowledge of ground properties is essential so that excavation and stability system can be matched to the ground (Bhasim, and al.1996) . The UCS strength is one of the most widely used test for determination these properties and the purpose of this research was to study the variation in the UCS with saturation content.

Aqueous pore fluids exert significant mechanical and chemical effects on rocks. Previous studies have shown that the brittle strength of a rock is generally reduced in the presence of water (Yang et al, 2000). The water-weakening effect may arise from two mechanisms. The mechanical role of pressurized pore fluid tends to weaken rocks, and the chemical influence of pore fluids is to further weaken the rock through a reduction of surface free energy (Paterson, 1978), subcritical cracking mechanism such as stress corrosion (Atkinson and Meredith, 1987), or both combined.

Using a servo-controlled testing machine, complete stress-strain curves were obtained for specimens. Because specimen failure was controlled, brittleness of the sandstone could be studied from the form of the stress-strain relation after the peak load has been reached. Specimen preparation and the testing technique are described and stress-strain results are presented.

The UCS and Young Modulus , brittleness values are then correlated with saturation contents.

2 SITE AND SAMPLE DETAILS

A large, intact block of sandstone was obtained from the Hassi Messaoud site investigation which is situated 850 kilometers a way of Algeria. Lithologically, the rock is grey, medium-grained, weakly cemented sandstone. A sample of the rock was disaggregated by gentle pressure with a pestle and mortar, taking care not to crush individual grains. The particle size distribution and specifie gravity of the sample were determined. It was found that 85 % of the particles fell in the medium sand range (0.2-0.6mm) and 10% in the fine sand range (0.06-0.2mm) and that the particle specific gravity was 2.66.

3 EXPERIMENTAL PROCEDURE

3.1. Specimen Preparation and Testing

The representative cores for use in the experimental work are obtained from block sample. Coring of the block samples was accomplished by a diamond core drill. The original core of 95 mm was plugged with a diamond cores drill having 38 mm as nominal diameter. All core samples were cut to length/diameter ratio of 2.5:1. The ends of cores were flat and parallel (see Figure 1). The diameter and length of each specimen were measured with a vernier to the mearsest 0. 01 mm.

The specimen were divided into three groups, one group was saturated by using a vacuum –saturation process, similar to that suggested by the U.S. Bureau of reclamation (1953),this process consists of :

1. Oven- drying the specimen for a period of 24 hours at 105°C,
2. Placing the specimen in a bell joir under a vacuum exceeding 50. 80 cm for 24 hours.
3. Immersing, the specimen in water while continuing with vacuum for another 24 hours.
4. Removing the vacuum and exporing the water containing the immersed specimen to the atmosphere for at least 48 hours.

Figure 1. Cylindrical sandstone specimen

This procedure eliminates air entering in rock pores and de–airs the water. It drives water into the rock, thus assuming a complete in saturation 5 day cycle, the specimen is removed from the water surface dried, and then weighed. The saturation content is computed. The second group of specimens was immersed in water. The third group was allowed to air dry because the oven-drying may sometimes cause erratic changes in the physical property. The mass of each specimen was determined immediately before testing, and the saturation content is calculated immediately after. The affixing to the specimens of two axially oriented foil strain gauge are aixed on the sample. These pairs are placed diametrically opposite each other and located centrally on the specimen. During testing the pairs are connected up with pairs of gauges. on dummy sample away from the machine to give temperature variation compensation. This wheastone bridge is formed and strain changes are monitored by changes in the voltage across the bridge. The testing procedure was essentially the same as that described by (Hudson and Morgan1975) and the following account, slightly modified. The compression tests were carried out in a response, closed-loop, programmable testing machine (Figure.2). This type of machine was used because a constant displacement rate can be achieved throughout the test- i.e. failure is controlled after the maximum load bearing capacity of the specimen has been reached; and because it is programmable and automatic. The closed-loop, servo-control principle is shown in Fig.3. A feedback signal (f) representing the actual condition of an experimental variable, in this case the axial displacement, is continually compared with a program signal (p) representing the required experimental condition. The feedback signal corresponding to the displacement between the specimen ends was generated by four displacements transducers located at 90 degree intervals around the specimen. The individual transducer outputs were summed to provide a voltage equivalent to the average specimen displacement. This feedback signal was compared with the program signal produced by a function generator. The program signal increased linearly with tune enabling a constant displacement or strain rate to be achieved. An error signal (e) occurred if there was any difference between the feedback and program signals; this activated a servo-valve causing the hydraulic pressure in the loading ram to be adjusted and the

error signal to be reduced. Feedback and program signals were frequently compared and high speed adjustments made so that the experimental condition followed the programmed condition. The control mechanism and advantages are explained further by (Hudson, et all 1972). To carry out a test, the specimen was inserted in the testing machine between platens having the same diameter as the specimen. The program was switched on and the specimen was then displaced at a constant rate of 2x10-3 mm/sec, corresponding to an axial strain rate of about 3x10-3 per cent/sec. Displacement was thus the independent variable and force was the dependent variable. Failure was then controlled beyond the peak force because the displacement was programmed to increase at a constant rate regardless of whether this necessitated a rise or fall in applied force. The load was monitored with a pressure transducer and a complete force-displacement curve obtained for each specimen on an X-Y recorder. Axial load was additionally monitored by a remote X-Y chart recorder which was used to monitor the axial displacement detected by the strain.

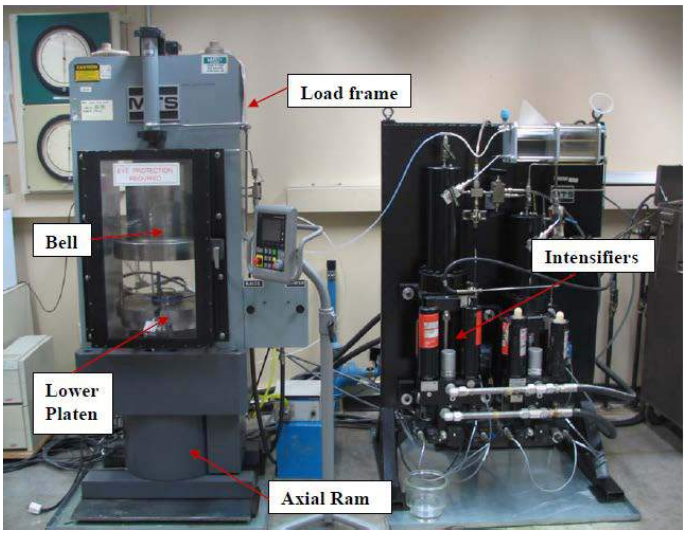

Figure.2. Machine with tests servo controlled on the test sample**.**

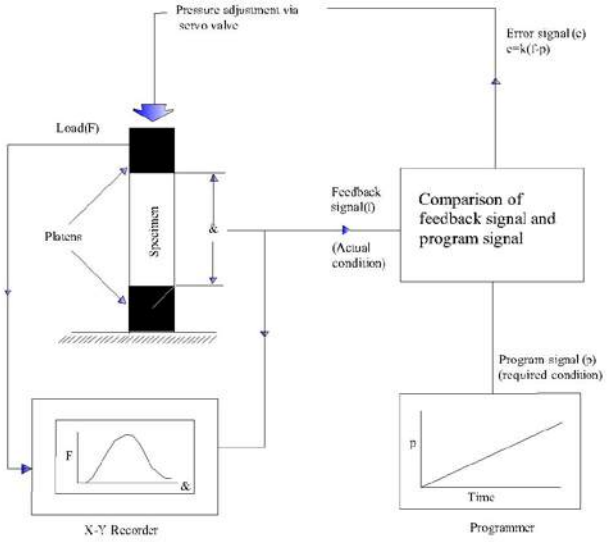

Figure 3. Closed –loop programmable testing machine control system

4 RESULTS

Load displacement curves obtained from the X-Y recorder were converted to stress-strain curves by dividing the load by the original cross- sectional area of the specimen to give stress and by dividing the displacement by the original length of the specimen to give strain; a typical result is shown in Fig.4. The brittleness index (B) defined by Hudson and Morgan (1975)as

$$B = AE/ (AE + Ap) \qquad (1)$$

Where AE is the area beneath the stress-strain curve before the peak stress and Ap is the area beneath the stress-strain curve after the peak stress (see Fig.4) was obtained for each curve by Tamaya Digital Planimeter measurements. The value of B can range from 0 to 1, for perfectly brittle rock with a post-failure curve descending vertically, B is unity since Ap is zero; for perfectly ductile rock with a horizontal post-failure curve, Ap is infinite and B becomes zero.Areas under the wves mere measured by Tamaya digital planimeter.

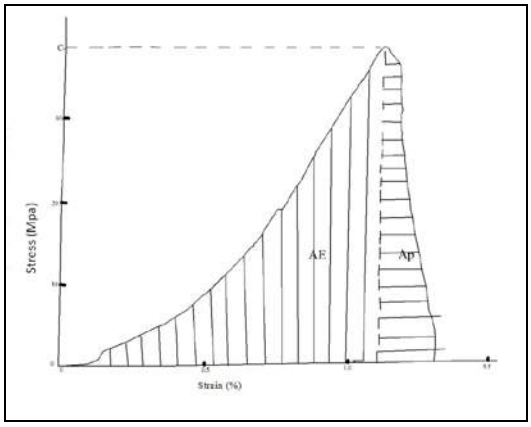

Figure 4. The stress-strain curve by Tamaya

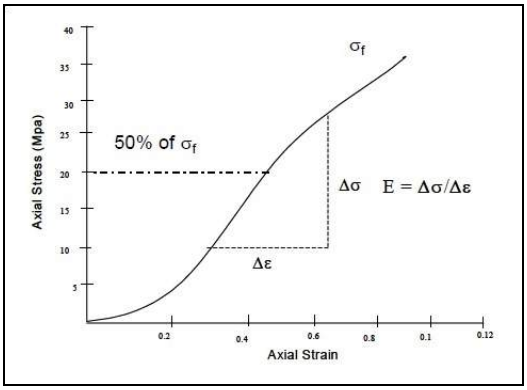

Figure 5. Calculation of Young's Modulus at 50 % of peak strength.

The uniaxial compressive strength (Co) was obtained from the peak of each curve. Young's Modulus (E) and Poisson's Ratio (μ) was obtained from the stress-strain curve (see Fig.5 and 6). Young's modulus and Poisson's ratio, are determined from the stress strain relationships for each stage. Young's Modulus is equal to the ratio of axial stress to axial strain50% of the failure load. Poisson's ratio is equal to the ratio of lateral strain to axial strain at50% of the failure load. As shown in (Fig .5), the Young's modulus is calculated from the slope of the straight-line portion of the stress-axial strain curve. Poisson's ratio can be calculated using the average slope of the straight-line portion of the stress-radial strain curve and the average slope of the axial curve.

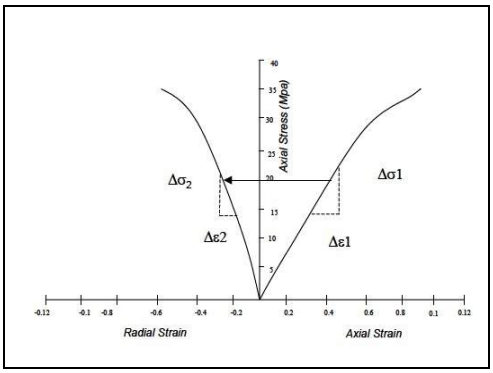

Figure 6. Calculation of Poisson's ratio from stress-strain data.

The results are summarised in Table1. To study the effect of saturation level on the strength properties, individual values of uniaxial compressive strength, Young's Modules and brittleness index have been plotted against individual values of saturation for each specimen in Figures 7,8 and 9

Table 1. Mechanical property test results

Statistical characteristics properities	Number of specimens	State	Mean	Standard deviation
Uniaxial compressive strenghth (C_0) Mpa	30	Dried	36.78	2.64
	30	Immersed in water	30.01	3.78
	30	Saturated	29.68	4.73
Young's Moudulus (E) Gpa	15	Dried	16.42	2
Poisson's ratio (μ)	15	Dried	0.25	0.05
Brittleness index (B)	15	Dried	0.65	0.09
	15	Saturated	0.68	0.08
Saturation (%)	20	Remaining 2 Weeks in Lab	0.02	0.08
	20	Immersed in water	4.57	0.82
	15	Saturated	6.90	0.55
Unit weight g/cm3	30	Dried	2.19	0.045

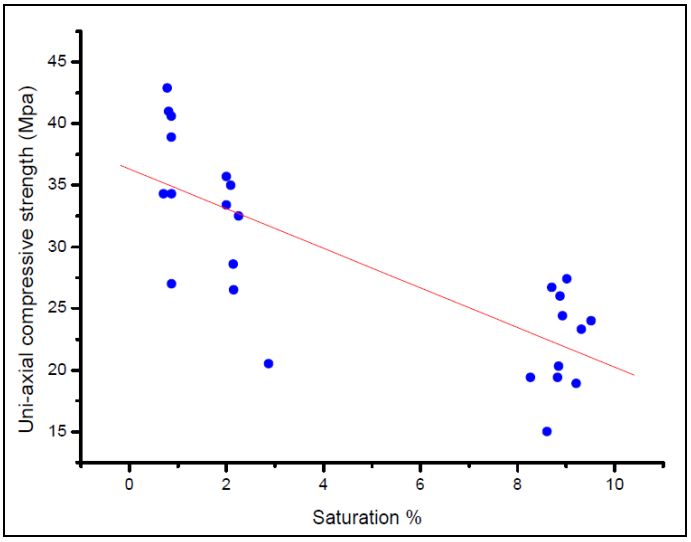

Figure 7. Effect of saturation on uniaxail compressive strength

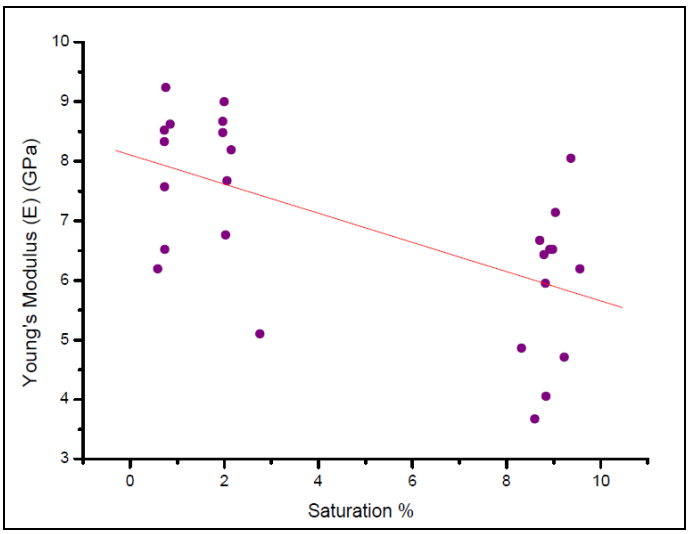

Figure 8. Effect of saturation on Young's Modulus

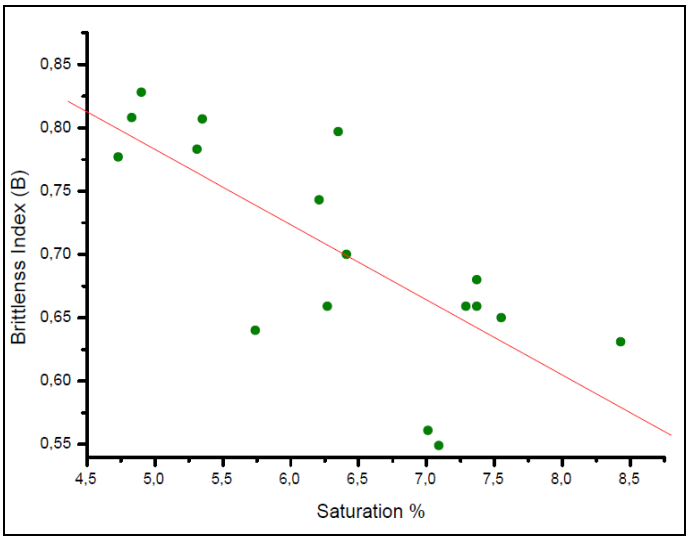

Figure 9. Effect of saturation brittlenss index

5 DISCUSSION AND CONCLUSION

Figures 7,8 and 9 show the effect of saturation content on the uni-axial compressive strength, Young's Modulus and brittleness index of the sandstone, respectively. There is a general tendency for both the uni-axial compressive strength and Young's Modulus to decrease with increasing saturation level. For the brittleness index the trend is not clear and it is not possible from these data to see whether the index is unaffected by absorption content or it has a maximum at some intermediate saturation level. On each of the figures a least square regression line for the data is shown together with the value of the computed correlation coefficient (r). A value of $r^2 \geq 0.6$ has been considered in rock mechanics as indicating a reasonable correlation . Judged by this criterion, Figures 8 and 9 show that Young's modulus and brittleness index of the sandstone are not significantly affected by saturation changes over the range from air dry to saturation. However, . Fig.7 shows that the effect of saturation on uniaxial compressive strength is just significant, the strength of the sandstone decreasing with increasing saturation . The mean uni-axial compressive strength of the air-dry sandstone 37 MPa (see Table 1. However, while the mean strength of the saturated sandstone had fallen to 23 MN/m2 that of the saturated chalk marl had fallen to 2 MPa, showing a very different response to increasing absorption content. The mean Young's modulus of the Sandstone varied from 7.2 GN/ m2 for air dried rock to 5.5 GN/ m2 for saturated rock (see Table 1). Even the lower of these values is higher than the maximum value of 3 GN/ m2 reported for the chalk and shows the sandstone is the stiffer of the two rocks. The mean brittleness index of the Sandstone varied from 0.61 to 0.77 (see Table 1). These values are lower than the values of 0.83 to 0.85 reported for the chalk and, shows the sandstone is the less brittle of the two rocks when judged by the criterion of brittleness index.

Determination of Slake Durability Index on Spherical Samples with Lime-Water Treatment

Kireç Banyosu Uygulanan Küre Örnekler Üzerinde Suda Dağılmaya Karşı Duraylılık Indeksinin Belirlenmesi

H. Ankara, G. Bayar, M. Aksoy
Eskişehir Osmangazi Üniversitesi, Maden Mühendisliği Bölümü, Eskişehir

ÖZET Bu çalışma Eskişehir-Derbent beyaz tüf örnekleri üzerinde kireçli su banyosu sonrası suda dağılmaya karşı duraylılık indeksini belirlemek için yapılmıştır. Önce suda dağılmaya karşı duraylılık testi için önerilen yeni örnek hazırlama yöntemi (Paşa yöntemi) ile eşit boyutlu küre örnekler hazırlanmıştır. Bu küreler 7 gün süresince kireçli suda bekletilmiştir. Daha sonra kireçli suda bekletilen örnekler ile normal küre örneklerin ikinci çevrim indeks değerleri kıyaslanmıştır. Orijinal küre örneklerinin indeks değerleri % 94,89-95,56 iken kireçli su ile muameleye tutulan küre örneklerin indeks değerleri % 95,02-96,64 olarak bulunmuştur. Bu çalışmanın sonuçlarına göre, kireçli su ile muamele edilen tüfler ile herhangi bir işlem yapılmayan tüflerin indeks değerlerine göre, kireçli su banyosunun suda dağılmaya karşı duraklılık indeks değerinin iyileşmesinde bir etkisi olmadığı görülmüştür.

Anahtar Kelimeler: Kireç banyosu, Suda dağılmaya duyarlılık, Beyaz tüf

ABSTRACT In this study, white tuff samples at the tuff quarries located at the Eskisehir/Derbent region in Turkey were treated with lime-water bath to determine the slake durability index. Firstly, Equal-sized spherical samples are prepared according to the new method, Pasha Method. Then, slake durability index tests have been applied on spherical samples kept for 7-day in lime-water bath. The second cycle index values of spherical samples subjected to lime-water bath have been compared with the index values of original spherical samples. Although the index values of original spherical samples were found as 94.89-95.56 %, the index values of spherical sample sets treated with lime-water bath were found to be in 95.02 and 96,64 %, respectively. According to the results of this study, it can be concluded that lime-water treatment has no effect on enhancement of the slake durability index values of spherical samples when compared to those of spherical samples with no treatment.

Keywords: Lime-water treatment, Slake durability index, White tuff

1 INTRODUCTION

Slake durability Index test (SDI) is widely used to provide an Index value that is related to resistance of rocks against degradation when they are subjected to two standard cycles of wetting and drying. This test was originally developed by Chandra in 1970, and improved by Franklin and Chandra (1972). After 1972, the test has been widely accepted and applied in rock mechanics. As a result of this acceptance and usage, the test was standardized and suggested as a standard test for rocks by the International Society for Rock Mechanics (ISRM, 2006). The test was also accepted by American Society for Testing and Materials, and standardized as ASTM D4644 (ASTM, 1990).

It can be said that Slake durability Index has become an important engineering parameter, and has been used extensively in literature in order to determine the durability of the rocks, especially weak and clay

bearing rocks (Bella et al 1997; Çetin et al 2000;Gemici 2001;Dhakal et al 2002; Viterbo et al 2007 ve Erguler ve Ulusay 2009).

Lime stabilization is one of the methods widely used to improve the mechanical properties of soil (Yong and Ouhadi, 2007, Fresno et al, 2011, Hejazi et al, 2012). The interaction between lime and soil in this method has been investigated by several authors and it is stated that lime stabilization enhances the strength, stiffness, plasticity and water adsorption of raw soil (Ciancio et al, 2014). In this study, it is also stated that the lime-soil reaction can be described by three general phenomena: cation exchange, pozzolanic reaction and carbonation.

This method is also applied to improve the strength of white tuff of Eskisehir Derbent region by Emir et al (2011) and they have claimed that lime treatment enhanced the uniaxial compressive strength of this tuff about 64-105 %.

The aim of this study is to investigate the effect of lime-water treatment on the slake durability index values of white tuff of Eskisehir Derbent region.

2 MATERIALS AND METHODS

2.1 White Tuff Samples

Tuff and ignimbirites type rocks were used to build historical monuments, and are being used as decorative material, nowadays in Turkey because of their softness and easy processability. For example, some important natural and historical monuments of Turkey such as Phrygian valley, Phrygian monument and chimneys of Cappadocia were formed of these type rocks. The tuffs on other regions are produced as decorative material. One of the tuff production places is near to Derbent village of Eskisehir province. Tuff bloks collected in this place is called as Derbent white tuff. The mineralogical structure of white tuff consists of Quartz, K-Feldspar, biotite and phenomenon crystals of opaque minerals. Besides, various metamorphic rock and white pumice pieces can be observed. Phenomenon crystals, rock pieces and white pumice are buried in the structure of slightly decayed tuff. In tuffs, the existence of volcanic glass pieces is very common (Sözmen, 2000). The samples used in this study were collected from Derbent white tuff quarry.

2.2 Experimental Study

The preparation of equal-sized spherical test samples consists of three stages. First stage is to cut cubes whose size is accordance with final spherical sample diameter from collected rock samples. At this stage, the length of cube edge is calculated as follows; the final sample weight is required to be 50 g by standards. Therefore, the diameter of the spherical sample is calculated from volume and dry density of the rock. After the determination of diameter, the edge length of the cube is set to be the diameter plus 2 mm (Ankara et al, 2013a,b).

Second stage is to cut cubes to form a pre-spherical shape which is called as Pasha Cut. Pasha cut is performed in two steps. The first step is to cut the edges of cube (Ankara et al, 2013a,b). This shape is shown in Figure 1-a. Second step is to cut the corners of the samples after first step. It is shown in Figure 1-b.

The final stage is to obtain equal sized spherical samples from Pasha Cut by means of an instrument modified for this purpose. After pasha cut step, samples are placed into sphere preparation machine (Covington brand). Special cutter cups having a diameter of 35 and 40 mm were designed and manufactured. Abrasive type used in these cups is diamond. This whole sample preparation process is called as Pasha Method (Ankara et al, 2013a,b).

Total of 20 spherical samples was prepared for lime-water bath and slake durability test. Firstly 20 spherical samples kept for 7 days were taken into lime-water bath. After 7 days, oven-dried samples as two sets were placed in drums mounted in the respective troughs filled with water. The drums were rotated at 20 rpm for a period of 10 min. All samples retained in the drums were carefully removed and put in the oven

for a period suggested by ISRM and ASTM standards, and the oven-dried weight was taken. The samples were again put in the drums and the whole process repeated four times. The data were used to calculate the Slake Durability Index after each cycles.

Figure 1. Pasha Cut; first step, edge cut (a) and second step corner cut (b)

The equal sized spherical samples shown in Figure 2 a and rounded were subjected to the slake durability test according to ISRM standard and results are given in Table 1. The condition of samples after the test for spherical samples also is shown in Figure 2 b.

Table 1. The results of slake durability index test

Index	Set-1 %	Set-2 %
I_{d1}	98.88	97.85
I_{d2}	96.64	95.02
I_{d3}	94.56	92.50
I_{d4}	92.78	90.02

b

Figure 2. Samples before test (a) and after the tests (b).

3 CONCLUSIONS AND DISCUSSIONS

In this study, slake durability tests were carried out on the equal sized spherical samples taken from Eskisehir Derbent white tuff quarry. Index values after fourth cycle for equal sized spherical samples kept for lime-water bath were found to be 90.02 and 92.78 %. Index values after Second cycle for spherical samples were found to be 95.02 and 96.64 %. Preliminary researches for index values of spherical samples after second cycle were determined between 94.89 and 95.56 % (Ankara et al, 2011). Index values of rounded samples after second cycle were found to be 91 and 93.8 %, being not to close each other when compared to spherical sample results (Sözmen 2000; Daloğlu 2008).

White tuff can be classified as strong according to the results of equal sized spherical sample tests. However, it can be classified as moderately strong according to the results of rounded sample tests. Second

results, index values for samples kept for lime-water bath are close each other when compared to no-treatment spherical sample results. Enhancement of slake durability index of samples kept for lime-water bath has been not observed according to no-treatment samples.

Micro-Mechanical and Micro-Structural Aspects of Strength Variation in Rocks under Various Loading Conditions

N. Erarslan
Adana Science and Technology University, Turkey
The University of Queensland, Australia

M. Ghamgoshar, D.J. Williams
The University of Queensland, Australia

ABSTRACT This research focuses on the micro-mechanical and micro-structural aspects of strength variation in macro-scale rock structures, because final failure of rocks comes about through a process of interaction/coalescence among the many load-parallel or load-inclined tensile fractures that are generated by micro pre-existing cracks. Provide major contributions to the understanding of stress-induced micro-fracturing of rock under various loading conditions, static and dynamic, resulting in the degradation of macro-scale rock strength, or possibly strain-hardening, of rocks. The outcome of this research is expected to provide rock cutting, civil-geotechnical and mining design engineers with access to new, more accurate rock strength estimation methods, of high value for minimising the risks associated with rock strength uncertainty.

A brittle rock type Brisbane tuff specimens were tested. Through the combined use of laboratory tests, Scanning Electron Microscope (SEM) techniques, and Computed Tomography (CT) scan technique, the damage mechanism of rocks under various loading conditions, including static and cyclic, were examined in nano-scale and the results were compared with each other for the first time in literature. Moreover, the sub-critical crack propagation phenomena , which is used to explain the premature failure of ceramics and metals and Fracture Process Zone (FPZ) phenomena, are explained in this research in terms of micro-mechanical strength reduction due to rock fatigue. Thus, modelling and understanding the crack propagation behaviour depending on different amplitude and frequencies are believed very important for the dynamic rock cutting researches and rock cutting machine manufacturers.

Keywords: Rock strength, Micro-mechanical, Micro-structural, Damage mechanism

1 INTRODUCTION

1.1 Background

Rock strength is the key parameter for the design of many rock structures and applications; in building-stone, rock cutting, civil and mining underground openings, e.g. tunnels, radioactive repositories, drilling and blasting, oil and gas reservoirs, etc. Its variation is explained by a number of factors, including mineral composition, density, porosity, fabric, moisture content, state of alteration or changes due to weathering, shape and size of the test specimen, and test conditions such as temperature, strain rate, etc. Surprisingly, the effect of micro-mechanical features (including the existence of micro-scale pre-existing cracks and their orientation in the rock, pre-existing and/or stress-induced intra-granular and/or inter-granular micro-cracks) and micro-structural parameters (such as grain size, grain shape, micro-lithologies, and petrography) on the strength of rocks continue to receive little attention due to absence of the application of laboratory techniques such as nano-scale imaging and stiff testing frames with dynamic testing capability.

It has been postulated that the final failure of rocks comes about through a process of interaction/coalescence among the many load-parallel or load-inclined tensile fractures that are generated by micro pre-existing Griffith cracks (Griffith, 1920, 1924; Bienawskie, 1964; Hoek, 1968). At the micro-scale, defects causing stress concentrations include micro-cracks, grain boundaries, pores and bedding planes, while at the macro-scale geologic fractures causing stress concentrations are referred to as joints (opening) or faults (shearing), based on their genesis (Lajtai, 1969, 1971; Rao et al., 2003). Numerous experimental and theoretical efforts have been devoted to understanding crack initiation, propagation and coalescence in brittle materials such as rocks. However, the Griffith theory in itself is not sufficient as it is restricted to only static compressive and tensile stress conditions.

Beside the Griffith theory, other well-known and internationally-used theories and rock failure criteria such as Mohr-Coulomb and Hoek-Brown also do not adequately explain the mechanism of micro-scale damage of rocks and rock strength depending on various loading conditions. The Mohr-Coulomb and Hoek-Brown criteria are concerned with failure in a continuum sense, in which the rock or rock mass undergoes permanent damage affecting its ability to sustain load. They do not consider rock as a heterogeneous/discontinuous material due to its existing natural defects, minerals, etc., and do not consider the ultimate stress of crack initiation, crack propagation or the direction of crack propagation.The effects of micro-mechanical and micro-structural parameters on rock strength have, over the last decade, been used to explain rock strength reduction and the relative damage mechanism under various loading conditions (Nasser and Deng, 1994; Zhao and Li, 2000; Xu et al., 2002; Attawel and Farmer, 1973; Haimson, 1978; Erarslan, 2011, 2012).

In geomaterial like concrete and rocks, the region near the crack tip containing micro cracked zone and ligament connections is called Fracture Process Zone (FPZ). The effect of FPZ on propagation of a tensile crack has been a subject of considerable interest over the years, and is the subject of this research (Tang and Yang, 2012, Labuz et al., 1987). The description of FPZ zone in rocks is more difficult than in metals due to complexity of the fracturing process in rock (Whittaker et al., 1992).

The full benefits of improvement in rock cutting efficiency will arise from a clear understanding of rock fracture mechanics principles. Therefore, fracture mechanics principles will be applied to the rock cutting as the nature the rock fragmentation process is based on the rock fracturing. The different types of fatigue damage mechanisms were obtained depending on the various cyclic loading conditions in literature (Ghamgoshar and Erarslan, 2014). Therefore, modelling and understanding the crack propagation behaviour depending on different amplitude and frequencies are believed very important for the dynamic rock cutting researches and rock cutting machine manufacturers.

2 EXPERIMENTAL STUDY

2.1 Mode I Fracturing and Computed Tomography (CT) Scanning Tests

The Cracked Chevron Notched Brazilian Disc (CCNBD) samples were used in both static and cyclic loading to determine the Mode I fracturing value of the selected rock types. The CCNBD specimens were preferred to use in entire test series rather than using Short Rod (SR) specimens. As far as a general comparison between the two methods is concerned, the CCNBD method definitely had advantages in terms of simplicity of sample preparation and less material required for testing. It is also unnecessary to perform pre-cracking for a CCNBD specimen because it uses a chevron notch that self-pre-cracks during testing and leads to stable crack propagation. Another remarkable advantage of the CCNBD method over the SR method in terms of accuracy is higher load capacity and

consistent results for each test. Moreover, it is believed that obtaining the FPZ zone with CCNBD geometry is more precise than obtaining with SR specimen geometry as CCNBD has an embedded chevron notch crack whereas SR specimen has edge notch crack.

The tests were carried out on Brisbane tuff, which is a host rock of Brisbane's first motorway tunnel, CLEM7, from which core samples were obtained. A series of BTS specimens were tested to evaluate the effect of cyclic loading on the tensile strength of brittle tuff rock specimens. CCNBD tests were carried out to determine the mode I fracture toughness of rocks (Fig. 1).

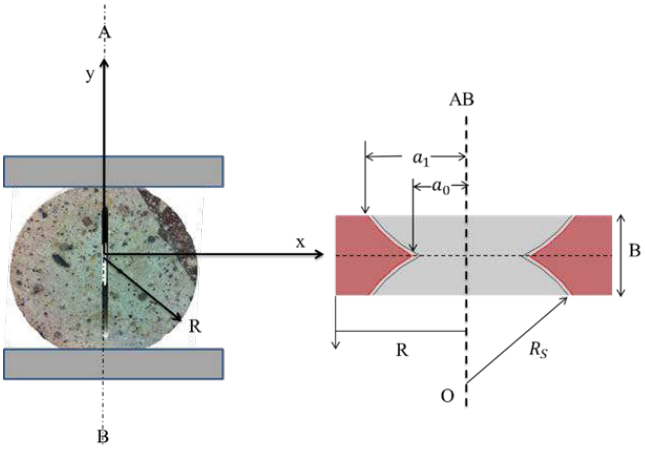

Figure 1. Prepared CCNBD sample according to the ISRM suggestions.

All geometrical dimensions were selected according to the specifications recommended by ISRM (Fowell et al., 1995). In order to achieve valid results, there are two important dimensions, that is, notched crack length α_1 and the ratio of specimen thickness to diameter α_R that must fall within the ranges outlined in ISRM suggested method (Fowell et al., 1995). In this study, the thickness of monsonite disc-shaped samples, $\mathbb{B}$, was 22.3mm, inner chevron crack notch half length, α_0, was 5.8mm, outer chevron notched crack half length, α_1, was selected 15.6mm.

An Instron loading machine with a capacity of ±150 kN (+/- 25,000 kgf, +/- 56,000 lbf) was used for static and cyclic loading tests. An Instron 2670-132 series Crack Opening Displacement (COD) gauge was used to measure the crack mouth displacement. The disc specimens were diametrically loaded parallel to the diametral compressive loading directions with a notch crack inclination angle of zero ($\beta = 0°$) to provide a mode I fracture condition. The applied load, diametral displacement, and crack mouth displacement, were continually recorded during the tests by using a computerised data logger.

Following the diametral loading tests, 3-D X-ray micro-focus CT scanning techniques was used in this study to investigate and quantify the physical properties of the damaged zone, such crack porosity (cracked volume/total volume) and crack density (number of cracks per mm^3). These samples were tested at the University of Queensland, Julius Kruttschnitt Mineral Research Centre (JKMRC). The X-ray detector is a high-resolution digital X-ray camera detector system. This detector accumulates all the energy of the transmitted photons and provides the numerical data to be used in reconstructing an image. For each head, 1500 views of the sub-sample were taken over 360° rotation. Each sample was placed vertically within the scanner so that the X-ray intersected the sample perpendicular to the longitudinal axis. Once the scans were finished, the collected raw data (the series of rotational X-ray images) were reconstructed with an ultra-high resolution noise reducing filtered back-projection. For the SkyScan 1172, the X-ray micro focus tube with 8 µm focal spot operates at 20-80 kV and 100 µA current while the source working at 20-100 kV and 0-250 µA has a 5 µm spot size. The special X-ray CCD camera is based on a 4000×2300 (10 Mp), or 1280×1024 (1.3 Mp) cooled CCD sensor with fibre optic coupling to the X-ray scintillator. For the 10Mp camera, the X-ray shadow projections are digitized as 1000 ×575 to 8000×2300 pixels with 4096 brightness gradations (12 bit). The reconstructed cross sections have a 1000×1000 to 8000×8000 pixels (floating point) format. The pixel size is isotropic and continuously variable from 0.9 µm to 35 µm. Fig. 4 represents the experimental set up for

the CT scan test and a rock sample after a fracture toughness test.

3 EXPERIMENTAL RESULTS

3.1 Mode I Fracture Toughness under Static and Cyclic Loading

Seven CCNBD samples were tested under load-control test conditions. The specimens were placed under the platens with a crack inclination angle of zero ($\beta = 0°$) to provide mode I loading conditions. The loading rate was chosen as 9 kN/s to cause failure within 20s as suggested by the ISRM (Fowell et al. 1995). The maximum recorded load and the calculated KIC values obtained from both ISRM standard tests are shown in Table 1.

Table 1 Mode I fracture toughness values of Brisbane tuff obtained by CCNBD tests.

Rock type	P_{max} (kN) CCNBD	K_{IC} (CCNBD) ($MPa\sqrt{m}$)
Brisbane tuff-1	5.2	1.3
Brisbane tuff-2	5.1	1.3
Brisbane tuff-3	4.6	1.2
Brisbane tuff-4	5.1	1.3
Brisbane tuff-5	4.1	1.1
Brisbane tuff-6	4.0	0.9
Brisbane tuff-7	3.5	0.8
Average	4.5	1.1

The series of diametral compressive increasing cyclic loading tests was performed on 12 CCNBD Brisbane tuff samples. Fracture toughness values of Brisbane tuff under static loading were calculated as 1.12–1.5 MPa√m using the ISRM suggested methods as discussed above. The fracture toughness reduction because of cyclic loading is found up to 45% by comparing with static fracture toughness values. The main purpose of this comparison is to show the clear reduction of ultimate failure load that resulted in the reduction of the mode I stress intensity factor because of rock fatigue. It is shown that crack propagation causing failure is possible with lower stress intensity values (K_I) at the crack tip than the critical stress intensity value (K_{IC}). This result goes against the classical theory, which predicts that there will be no crack growth as long as $K_I < K_{IC}$. According to the obtained results, the maximum reduction, 46% of static KIC, was obtained with the highest amplitude, 1.99 kN at 40% SUL, of cyclic loading. The mode I fracture toughness value of Brisbane tuff (NST50) was reduced from 1.12 MPa√m to 0.61 MPa√m with the highest amplitude under increasing cyclic loading. This reduction has important implications for the investigation of the effect of cyclic loading on the fracture resistance of cracks in rocks.

3.2 CT Scan Test Results

The CT scan technique was used to quantify the FPZ under different cyclic loadings. As discussed earlier, nucleation of micro-fractures is the main reason of fracturing leads to failure in brittle rocks. The CT scan tool provides a clear monitoring of micro-cracks initiation and propagation in and around FPZ zone. Dislocation of micro-fractures takes place in different ways with different rock types. In general, it was observed breaking the bonds between minerals and rock forming matrix happened due to two reasons: 1) concentration of stress at the tip of fractures and 2) formation of transcrystalline and inter-crystalline cracks. All those dislocations occurred because of the micro-fractures such as intergranular and intragranular cracks caused by the inelastic behaviour of rocks (Fig.2). This mechanical behaviour shows that decohesion and loosening start with the development of FPZ in front of the notched crack under the cyclic loading.

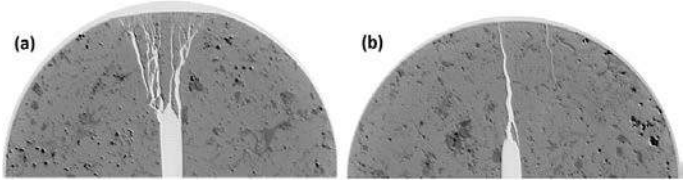

Figure 2. 5 CT-scan images of CCNBD specimens with FPZ developed under (a) cyclic and (b) static loading.

Further CT scans on CCNBD specimens showed the self-orientated stress-induced micro fractures and their interactions caused subcritical cracks and enhance energy dissipation. Static tests revealed the main crack propagation associated with the very small damage zone started from the tip of notch crack and ended at the CCNBD circumference without any fracture branches. That is why; any subcritical crack propagation before the final failure would not be expected. However, a great number of smooth and smaller cracks occurred in and around fracture process zone leads to formation of subcritical cracks under cyclic loading. Fig. 3 shows a close look in the FPZ and crack branches developed in rock matrix under the cyclic loading with increasing amplitude from 10% Static Ultimate Load (SUL) to 50% and 80% SUL.

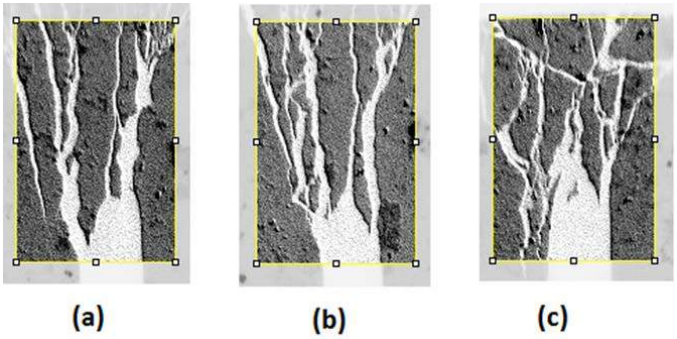

Figure 3. Different branching of the cracks in FPZ depending on the different amplitudes used with stepped cyclic loading: (a) 10%SUL, (b) 50%SUL and (c) 80% SUL.

3.3 SEM Test Results

A typical feature of rock fatigue in experimental tests can be observed by producing a progressive accumulation of permanent strain in the specimen, rather than any significant decay in the material's elastic modulus. Accumulation of plastic deformation is responsible for the fatigue damage; the magnitude and increasing trend of the irreversible deformation influences the cumulative fatigue damage.

Plots of permanent along both x and y directions show that both the CMOD and diametral axial displacement increase with increasing damage increments but at different rates.

The characteristics of the fracture surfaces were examined by means of a JEOL JMS-6460 LA SEM. The JEOL JSM-6460 LA is a tungsten low-vacuum analytical SEM. In this study, all rock fracture images were obtained under low vacuum chamber pressures, that is, 1–50 Pa (with adjustable pressure between 10 Pa and 270 Pa). This allowed certain samples to be observed uncoated and reduced damage to the specimens caused by the effects of high vacuum.

Two fatigue mechanisms were observed in the cement of Brisbane tuff: (1) grain decohesion in secondary microcrystalline quartz cement intrusions (Fig. 4) and (2) fatigue striations in primary silica cryptocrystalline cement.

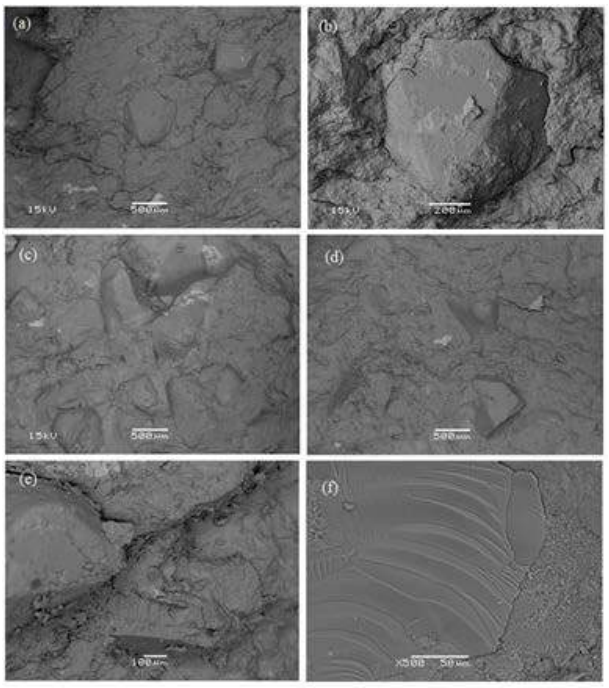

Figure 4. Grain decohesion and loosened grains (a), (b), (c), (d), (e) and fatigue striations in damaged grains under high magnification (× 500) at the surface of the fatigue crack (f).

Some microcrystalline quartz cement intrusions were seen in the primary silica cryptocrystalline cement after petrographic analyses. Similar to the fatigue damage in the cement, there were two fatigue damage mechanisms seen with grain-related damage: (1) intergranular cracks causing grain decohesion (a primary mechanism) and (2) intragranular cracks (a secondary mechanism).

4 CONCLUSIONS

This research showed the crack propagation causing failure is possible with lower stress intensity values (KI) at the crack tip under cyclic loading than the critical stress intensity value(KIC) obtained under static loading.

CT scan results indicate that FPZ obtained with the static loading is smaller than the FPZ obtained with the cyclic loading ($FPZ_{Static} < FPZ_{Cyclic}$). This finding was verified with the obtained CMOD plastic strain accumulation plots.

SEM imaging revealed that the primary fatigue damage mechanisms in front of a chevron notch crack are grain decohesion and intergranular cracks. Debris and dust are the results of fatigue damage in Brisbane tuff cement and around loosened grains. The fatigue cracks in the cement are restricted around the grains and cannot grow through the grains. Therefore, it can be deduced that those fatigue cracks are stable (subcritical) cracks that coalescence to form macroscale fatigue cracks resulting in failure. The different types of fatigue damage mechanisms were obtained with the numerical analyses depending on the various cyclic loading conditions. Therefore, modelling and understanding the crack propagation behaviour depending on different amplitude and frequencies are believed very important for the dynamic rock cutting researches and rock cutting machine manufacturers. Because the full benefits of improvement in rock cutting efficiency will arise from a clear understanding of rock fracture mechanics principles, the specific fracture mechanics principles would be applied to the rock cutting as the nature the rock fragmentation process is based on the rock fracturing.

Numerical Study of the Undrained Bearing Capacity of a Strip Footing Near a Slope

M. Baazouzi, M. Mellas A. Mabrouki, D. Benmeddour
Civil Engineering Laboratory, Biskra University, BP 145 Biskra 07000 Algeria.

ABSTRACT The bearing capacity of shallow foundation near slope has always been one of the subjects of major interest in geotechnical engineering for researchers and practical engineers. This study focuses on the numerical analysis of the undrained bearing capacity for a strip footing near a slope, and subjected to a centered vertical load, using the explicit finite difference code FLAC (Fast Lagrangian Analysis of Continua). In this study, several geometrical and mechanical parameters have been considered in order to evaluate the effect of the slope on the undrained bearing capacity. The numerical values have been compared with those available in the literature. The results show the influence on the undrained bearing capacity of the location of the footing with respect to the slope.

Keywords: Strip footing, bearing capacity, slope, shallow foundations, FLAC

1 INTRODUCTION

The bearing capacity problem of footings has been extensively studied for many decades. There is an extensive literature dealing with the bearing capacity of foundations, from both theoretical and experimental standpoints; in addition, the study of foundations requires an adequate understanding of several influenced factors such as load inclination, slope inclination, footing shape.

The bearing capacity of a shallow strip footing is generally determined by the Terzaghi method (Terzaghi, 1943). For undrained conditions the ultimate vertical bearing capacity q_u of a surface footing can be expressed by:

$$q_u = N_c c_u \quad (1)$$

where N_c is the bearing capacity factor (=2+π ; Prandtl, 1920), c_u is the undrained shear strength of the soil.

A number of engineering structures require foundation systems to be placed near an existing slope. Theoretical and experimental studies confirm that, when a strip footing is near a slope, the bearing capacity must be assessed using reduction coefficients. Meyerhof (1957) proposed design charts which are currently adopted by many design manual. Also, the bearing capacity equations of Hansen (1961) and Vesic (1975) include empirical factors for sloping ground. Giroud and Tran-Vo-Nhiem (1971) and Graham et al. (1988) provided solutions for the bearing capacity factor for a strip footing on the top of a slope in granular soil based on the method of slip-line.

Many analytical and numerical studies in bearing capacity have been conducted using different approaches. Upper bound bearing capacity solutions for strip footing on slope have been proposed by Kusakabe et al. (1981) and de Buhan and Garnier (1998). The limit equilibrium method has also been applied by several investigators to provide solutions and design charts for footing on slope (Saran et al., 1989; Castelli and Motta, 2008). Some experimental works on the bearing capacity of foundation near slope have been conducted by Shields et al. (1977) and Bauer et al. (1981). Also, Gemperline (1988) and Bakir (1993) used centrifuge tests. The finite element, upper bound plasticity and stress field methods were used by Georgiadis (2009) to investigate the influence of load inclination on the undrained bearing capacity of strip footing on or near slopes. Also, Georgiadis (2010) used the finite element analysis to investigate the influence of the distance of the foundation from the slope, the slope

height and the soil properties on bearing capacity of strip footings on or near undrained soil slopes. Shiau et al. (2011) used the finite element limit analysis method to obtain both lower and upper bound bearing capacity for strip footings placed on purely cohesive slopes.

In this study, series of numerical computation using the finite difference code FLAC (2005) are carried out to evaluate the influence of the various parameters that affect undrained bearing capacity of strip footings on or near slopes. The results of the analyses are compared to available methods.

2 NUMERICAL MODELING PROCEDURE

The finite-difference code FLAC (2005) was used to estimate the undrained bearing capacity of a strip footing on or near slopes under conditions of plane strain and subjected to a centred vertical load. FLAC (Fast Lagrangian Analysis of Continua) is a two-dimensional explicit finite-difference program for engineering mechanics computations; it simulates the behaviour of structures built of soil, rock or other materials that undergo plastic flow when their yield limits are reached. Many researchers have used the finite difference code FLAC to study the bearing capacity of strip and circular isolated footings (e.g., Frydman and Burd, 1997).

The geometry of the problem analyzed is shown in Figure 1. In the current study, we consider a rigid and rough strip footing of width B=2m on an undrained soil slope. Three slope angles β = 15°, 30° and 45°, also several slope heights H and normalized footing distances from the crest of the slope (λ = footing distance/footing width) were used in order to investigate the influence of these three parameters. The soil is modelled as a Tresca material using the Mohr–Coulomb elastic-perfectly plastic constitutive model with φ = 0. In order to make a comparison with the finite element results given by Georgiadis (2010), the model is characterized by the undrained Young's modulus E_u=30 MPa, Poisson's ratio ν = 0.49 and unit weight γ=20 kN/m^3, while the undrained shear strength was varied (c_u= 40, 100 and 200 kPa).

The footing is modelled as an elastic material with concrete Young's modulus of E_c=25 GPa and Poisson's ratio of ν = 0.4. The interface between the soil and footing is rough, it is characterized with normal stiffness K_n =10^9 Pa/m and shear stiffness K_s=10^9 Pa/m.

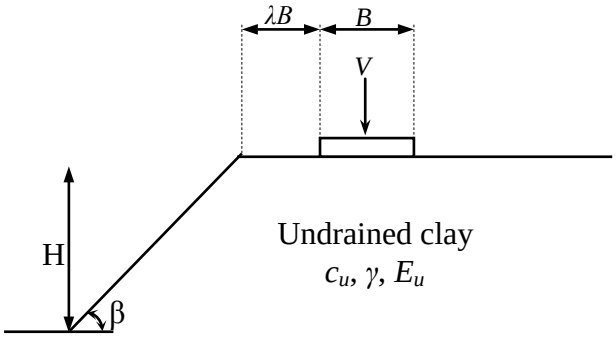

Figure 1. Problem geometry

Because of the nonsymmetrical problem, the entire model is considered in the computations. Figure 2 shows a typical finite-difference mesh, used for the case of footing located at the crest (λB=0). In all cases, the mesh is refined at the region most close to the boundaries of the foundation, under the base and near the crest of the slope. The displacement of the left and right vertical sides is constrained in the horizontal direction only. The base of the model is constrained in all directions (Fig. 2).

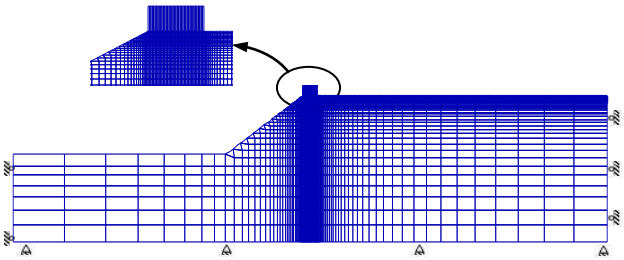

Figure 2. Finite difference mesh and boundary condition for the case λB=0.

3 RESULTS AND DISCUSSIONS

3.1 Bearing Capacity

The loading of the rigid strip footing is simulated by imposing equal vertical velocities at the area representing the footing. It is worthwhile noting that different mesh sizes with several vertical velocity values have been tested. The progressive displacement of the footing induced by the vertical velocity applied at the footing nodes is accompanied by the increase of the pressure in the soil. Finally, the pressure under the footing stabilizes for a value that indicates a limit load (Fig. 3).

The vertical bearing capacity q_u=5.225c_u was predicted in the present study for a surface footing, representing an overestimation of less than 2% from the analytical solution of q_u=5.14c_u. It means that numerical prediction obtained using FLAC, is in excellent agreement with the exact solution obtained by Prandtl (1920).

Figure 3 shows the load–displacement curves, i.e., the curves of the vertical load V versus the vertical displacement. The comparison is made for three values of slope inclination. From the results of Figure 3, it is seen that the limit load V_u decreases substantially with increasing β.

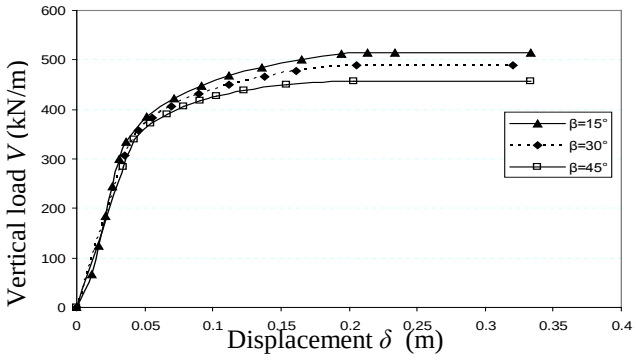

Figure 3. Load–displacement curves

3.2 Influence of the Slope Inclination

Figure 4 shows the variation of the calculated values of the undrained bearing capacity factor for a footing with the slope angle β for different $c_u/\gamma B$ ratios. The results presented in this study are compared to the solutions of Hansen (1961), Vesic (1975), Bowles (1996), Kusakabe et al. (1981) and Georgiadis (2010) for the case of a footing at the crest of a slope. The present study confirms a linear decrease of the undrained bearing capacity factor with the increase of the slope angle. Also, the finite difference results show a decrease of the value of N_c with the decrease of the ratio $c_u/\gamma B$. It is seen that the results of Bowles (1996) which gives a decrease of N_c with the decrease of $c_u/\gamma B$, is in good agreement with the finite difference results for $c_u/\gamma B$=5.

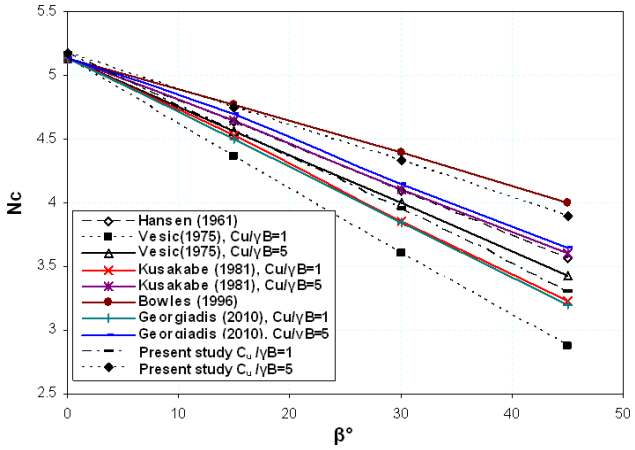

Figure 4.Variation of N_c with slope angle β for footing at crest of slope, λ =0 (Figure modified from Georgiadis, 2010)

3.3 Influence of Slope Height

The influence of slope height on the failure load for vertical loading was studied with finite element analysis by Georgiadis (2010). Figure 5 shows the variation of bearing capacity factor N_c with normalized slope height for β=30° and $c_u/\gamma B$=1. It is seen that the values of results obtained from the present study are in good agreement with the solutions presented by Georgiadis (2010). Depending on the slope height, two distinct displacement modes can be observed. The first mode shown in Figure 6 (a) is similar to the displacement mode for the case of horizontal ground surface. The second displacement mode (Fig. 6(b) involves the whole of the slope. The finite difference and finite element results give the expected initial reduction of N_c starting from the horizontal ground value, which is followed

by a horizontal section of constant N_c corresponding to bearing capacity failure and a final drop corresponding to overall slope failure.

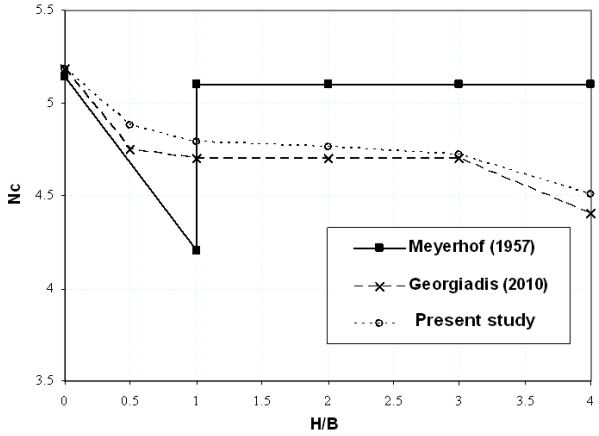

Figure 5. Variation of N_c with normalized slope height for β=30° and $c_u/\gamma B$=1 (Figure modified from Georgiadis, 2010).

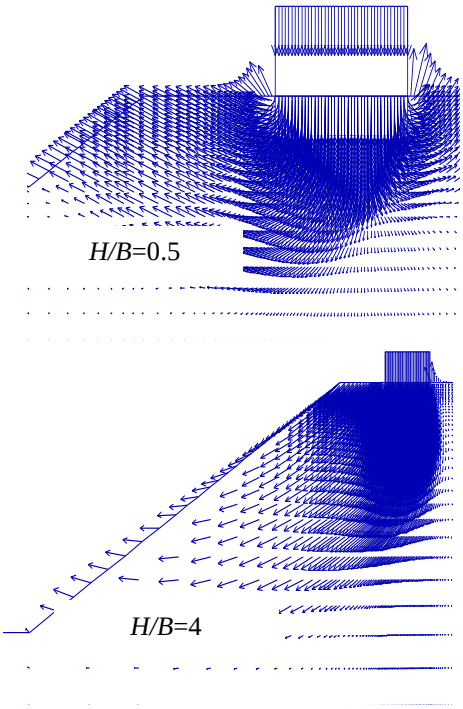

Figure 6. mode of displacement

3.4 Influence of Normalised Footing Distance

Figure 7 shows the variation of N_c with λ for slope angles 30° and 45°. Meyerhof (1957) overestimates the value of bearing capacity factor N_c. For all values of β, the increase in footing capacity tends to stop at certain values of λ. From the present study N_c reaches a constant value of 5.25 approximately at λ=1.5 for β = 30°. For β = 45° the limit value of N_c is reached at λ=2.5. The finite difference results are in good agreement with the finite element results solution proposed by Georgiadis (2010).

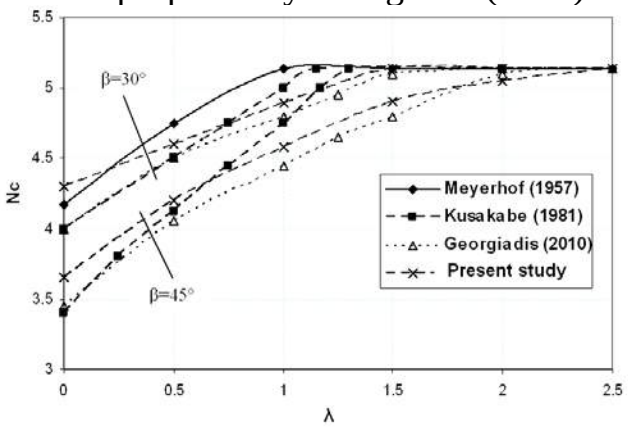

Figure 7. Variation of N_c with λ for $c_u/\gamma B$=2.5, β=30° and 45°

(Figure modified from Georgiadis, 2010)

4 CONCLUSIONS

The finite-difference code FLAC was used to study the influence on the undrained bearing capacity of strip footings on or near slopes under vertical load. Various geometries and soil properties were considered, the results of the analyses were compared to other available solutions. It was found that the bearing capacity factor N_c depends on the slope height, the distance of the footing from the slope and the slope angle. It is worth noting that most of the available methods for the evaluation of the undrained bearing capacity factor N_c do not take account of these parameters.

The increase of the distance of the footing from the slope increases the value of bearing capacity factor N_c, Also, at high values of *H/B*, overall slope failure is observed. The footing capacity decreases as the slope angle β is increased.

Numerical Study of the Effect of Increasing Strength with Depth on the Undrained Bearing Capacity of Strip Footings

M. Ouahab, A. Mabrouki, M. Mellas, D. Benmeddour
Civil Engineering Laboratory, Biskra University, BP 145 Biskra 07000 Algeria

ABSTRACT The problem of the bearing capacity evaluation for a strip footing has been widely studied using theoretical and experimental approaches. This paper focuses on the bearing capacity of a strip footing on non-homogeneous clay. A series of numerical computations was carried out to evaluate the undrained bearing capacity of vertically loaded, rigid strip footing, using the finite element software PLAXIS 2D. The objective of this study is to analyse the effect of linearly increasing undrained shear strength with depth on the bearing capacity of a strip rough and smooth footing. The results of the present study are compared with those available in the literature. The values of the bearing capacity factor, obtained by the present analysis are in good agreement with the results calculated by the slip line method. It is confirmed that the correction factor is given as a function of dimensionless heterogeneity factor.

Keywords: Strip footing, bearing capacity, slip line method, PLAXIS 2D

1 INTRODUCTION

Foundations of engineering structures are designed to transfer and distribute their loading to the underlying soil. Design of shallow footings entails both settlement and bearing capacity calculations. The bearing capacity problem of footings has been extensively studied for many decades. In engineering practice, the bearing capacity of foundations (both drained and undrained) is usually estimated using well-established bearing capacity formulae (e.g. Terzaghi, 1943).

Many analytical and numerical methods can be used to estimate the vertical bearing capacity of a rigid strip footing; these methods may be classified into the following four categories:

- limit equilibrium method (e.g., Terzaghi, 1943; Meyerhof, 1951; Kumbhojkar, 1993);
- slip line method (e.g., Sokolovskii, 1960; Houlsby & Wroth, 1983 ; Martin, 2004)
- limit analysis method (e.g., Chen, 1975; Michalowski, 1997; Merifield et al., 1999);
- finite element or finite difference analyses (e.g., Griffiths, 1982; Gourvenec & Barnett, 2011; Edwards et al, 2005).

Skempton (1951) showed that for a cohesive soil (φ=0°) the value of the bearing capacity factor N_c increases with the value of the foundation depth, z. The bearing capacity of a strip footing on nonhomogeneous clay was studied by Davis & Booker (1973). By means of the theory of plasticity, their results showed that the rate of increase of cohesion with depth plays the same role as density plays in the bearing capacity of homogeneous cohesive−frictional soils. In addition, this problem has been studied previously by Houlsby & Wroth (1983) and Tani & Craig (1995). Davis & Booker's analyses have since been verified by Martin (2004) using the computer program ABC.

Griffiths (1982) used the finite element method to study the bearing capacity for both rough and smooth footing, on undrained clay whose strength varies linearly with depth and the case of two layers of different strength but within each layer the strength is constant. Ukritchon et al., (1998) used the numerical limit analyses to evaluate the undrained stability of surface footings on nonhomogeneous and layered clay deposits under the combined effects of vertical, horizontal, and moment (V, H, M) loading.

In this paper, a series of numerical computations using the finite-element code PLAXIS (2012) are carried out to determine, the bearing capacity factor N_c for rough and smooth strip footing subjected to centered vertical loads and placed on a non-homogeneous undrainded clay. The numerical results are compared with those available in the literature.

2 PROBLEM PRESENTATION

The undrained bearing capacity equation has the following form:

$$q_u = c_{uo} N_c \quad (1)$$

where N_c is a bearing capacity factor, c_{uo} is the undrained shear strength at foundation level (soil surface); if the strength parameter c_{uo} is constant, the soil is described as homogeneous; if the strength parameter vary with position, the soil is non-homogeneous; for simplicity, the shear strength is assumed to vary linearly with depth according to:

$$c_u(z) = c_{uo} + k\,z \quad (2)$$

where k is the strength gradient with depth, z. The degree of non-homogeneity for a given foundation is represented by the non-dimensional ratio kB/c_{uo}.

Davis & Booker (1973) method gives a solution of bearing capacity for a strip foundation under vertical load where c_u increases with depth. The bearing capacity can be expressed by:

$$\frac{Q}{B} = F\left[(2+\pi)\cdot c_{uo} + kB/4\right] \quad (3)$$

where Q is the total load at failure and F is a dimensionless correction factor depending only in the ratio kB/c_{uo} (for rough base footing, $F=F_R$ and $F=F_S$ for smooth base footing)

The present paper addresses the effect of increasing the strengths with depth on the bearing capacity of strip footing on clay, as shown in Figure 1.

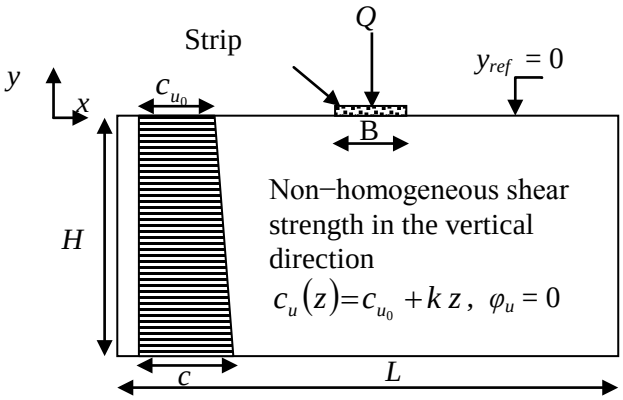

Figure 1. Problem geometry

3 NUMERICAL PROCEDURES

The two dimensional elastic-plastic finite element analysis (FEA) is conducted using PLAXIS 2D (2012) to reach the bearing capacity for strip footing.

The numerical evaluation of the bearing capacity is based on subdividing the soil into a number of elements. Because of the symmetrical nature of the problem, only half of the model is considered in the computations. The mesh adopted for all cases studied in this paper has a depth of B and $2B$ in large (B=footing width), the mesh in the footing neighborhood is refined to capture significant displacement gradients. The base of the model is constrained in all directions. The right and the left vertical sides are constrained in the horizontal direction only.

The soil was considered to be a linearly elastic-perfectly plastic material, obeying Tresca criterion. The cohesion at the soil surface c_{uo} is taken 1 kN/m^2; in the advanced settings of PLAXIS, the increase of shear strength with depth is defined by c_{incr} (k). A Poisson's ratio of υ=0.495 enforces the condition of undrained behaviour of clay. It is noted that the values of the elastic parameters had no effect on the value of bearing capacity (Edwards et al, 2005).

The strip footing was rigid, rough and smooth of width B = 1 m, subjected to a centered vertical load and located on the surface of a non-homogeneous clay. The loading of the rigid strip footing is simulated by imposing equal displacement at all nodes

representing the footing. The progressive displacement is accompanied by the increase of the pressure in the soil. Finally, the pressure under the footing stabilizes for a value that indicates a limit load; this load corresponds to the bearing capacity q_u.

4 NUMERICAL RESULTS

4.1 Bearing Capacity Factor N_c

For the case for rough strip footing on homogeneous, undrained clay (kB/c_{uo}= 0), the bearing capacity factor N_c has been obtained as N_c=2+π using the theory of plasticity (Prandtl, 1921). The numerical value of the bearing capacity factor N_c is 5.148, and the relative error is 0.15% when compared to the exact value of 5.14 kPa.

Figure 3 shows the bearing capacity factor, expressed as $N_c=q_u/c_{uo}$ versus kB/c_{uo}, where q_u is the ultimate unit bearing capacity and c_{uo} is the shear strength. As shown in Figure 3, the bearing capacity factor increases significantly with the increase of the kB/c_{uo} value.

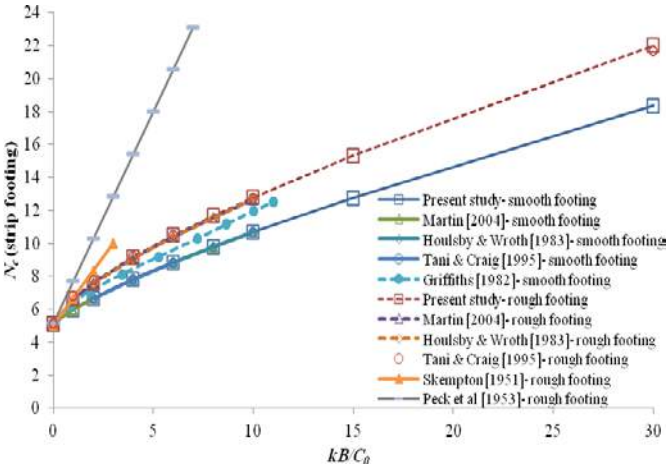

Figure 3. Comparison of obtained N_c with theoretical results for rough and smooth footing

The values of N_c obtained from the present study are in good agreement with the solutions reported by Houlsby & Wroth (1983), Tani & Craig (1995) and Martin (2004). The values of the bearing capacity factor N_c differ depending on whether smooth or rough conditions are assumed, the results for rough footing appear to be very high.

4.2 Correction Factor F_R

Figure 4 shows the bearing capacity correction factor F_R for rough strip footing. The numerical solution from the present study is compared with analytical results reported by Davis and Booker (1973) and with the numerical limit analyses by Ukritchon et al. (1998). For the homogeneous case (kB/c_{uo}=0), the obtained numerical value of F_R is 1.002, only 0.2% higher than the exact value and therefore the interface shear strength has no effect on the bearing capacity.

For non-homogeneous strength profile ($kB/c_{uo} \leq 20$), F_R increases with the increase of the rate of heterogeneity to a maximum value of 1.76, which means that the roughness increase the bearing capacity as strength heterogeneity increases. It can be seen that the numerical values of F_R obtained from this study are in good agreement with those obtained by Davis and Booker (1973) and are enclosed by the lower and upper bound solutions from Ukritchon et al. (1998) where a very good estimate of failure can be obtained by averaging the computed upper and lower bound loads Q_A=1/2(Q_L+Q_U).

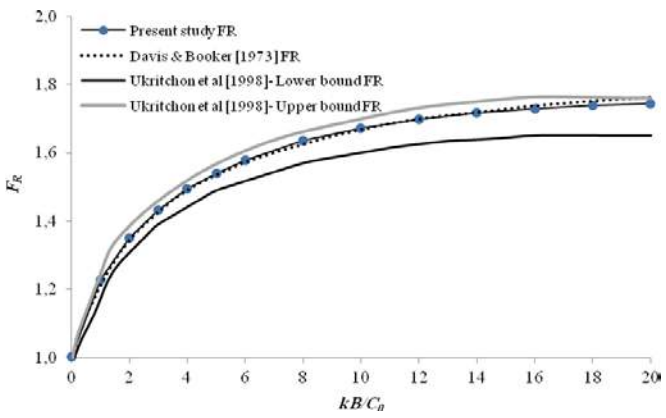

Figure 4. Correction factor for rough strip footing on a non-homogeneous soil.

4.3 Contact Stress Underneath the Footing

Curves of the normal stress σ_n acting on the smooth base of the footing loaded vertically, is plotted in Figure 5 with respect to the footing width, at different values of the ratio kB/c_{uo}. For the homogeneous case

(kB/c_{uo}=0), the analysis predicts uniform vertical contact stresses across the width of the footing. In contrast, calculations for non-homogeneous clay (kB/c_{uo}> 0) show that contact stresses increase toward the center of the footing (the results match with analytical solutions from Davis and Booker, 1973).

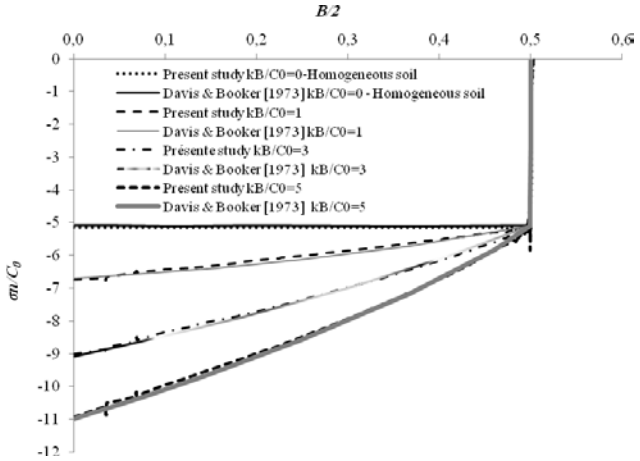

Figure 5. Distribution of normal stress underneath the smooth footing base.

5 CONCLUSIONS

The finite element software PLAXIS 2D was used to study the influence on the undrained bearing capacity of strength non-homogeneity. Results from a series of FEA have been presented and compared with data from other published studies and a good agreement has been obtained with available theoretical solutions for ultimate capacity. Various values of strength non-homogeneity ratio kB/c_{uo} from 0 to 30 have been explored for vertical loaded strip footing. The bearing capacity factor increases with the increase of the ratio kB/c_{uo}. The results show that the roughness increases the bearing capacity as strength heterogeneity increases.

ÖZET Bu çalışmanın amacı, Kastamonu İli Hanönü İlçesinde bulunan ve Asya Maden İşletmeleri tarafından işletilecek olan, açık ocak bakır madenindeki döküm sahasının tasarımının yapılmasıdır. Döküm sahalarının tasarlanması, tıpkı açık ocak basamak ve genel eğimlerinin dizaynında olduğu gibi, şev stabilite esaslarına dayandırılarak gerçekleştirilmelidir. Bu sebepten dolayı, öncelikle döküm malzemesinin ve dökümün yapılacağı bölgenin jeoteknik özelliklerinin tayin edilmesi gerekmektedir. Stabilite üzerinde etkisi olan, yeraltı su durumu, bölgenin depremselliği gibi konularda yine bu araştırmaların bir parçası olmalıdır. Sahada henüz döküm faaliyetleri gerçekleştirilmediği için, farklı tasarımlar gerçekleştirmek suretiyle, döküm sahasının stabilitesini etkileyen jeoteknik parametrelerin büyüklükleri, geri-analiz yöntemi ile elde edilmiştir. Bu uygulama, farklı genel eğime sahip tasarımlar için tekrarlanmıştır. Sınır – denge yöntemi esasına göre gerçekleştirilen stabilite analizleri sonucunda, her bir tasarımı stabil kılan jeoteknik parametrelerin büyüklükleri tayin edilmiştir. Bu aşamadan sonra ise, malzemelerin jeoteknik özellikleri ile döküm sahasının genel eğimi ve bağlı olarak sahanın döküm kapasitesi arasındaki ilişkiler ortaya çıkartılmıştır.

Anahtar Kelimeler: Şev stabilite analizi, döküm sahası, jeoteknik özellikler, sınır-denge yöntemi

ABSTRACT The main purpose of this study is to design waste dump area for an open pit copper mine owned by Asya Maden Inc. located in Hanonu, Kastamonu. Design studies can be carried out based on slope stability principles as per the design works of open pit bench and overall slope angle. Therefore, geotechnical properties of dump material as well as ground must be primarily determined. Hydrogeology as well as seismicity which have important effect on the stability should be also part of stability works. The values of geotechnical parameters for dump material controlled the stability of dump site determined from the back analysis method from different designs, because of the unavailability of dump material since dumping is not initiated at present. This application iterated for the other designs having different overall slope angles. As a result of the stability analyses based on limit equilibrium methods, the values of geotechnical parameters making the design stabile are determined. After this stage, relations among geotechnical properties and overall slope angle of the dump site as well as dump site capacity are presented.

Keywords: Slope stability analysis, waste dump, geotechnical properties, limit equilibrium method

1 INTRODUCTION

External waste dump area design is an important design issue of open pit mine design and planning concept. The aim of this study is to design the waste dump area for an open pit mine located in the Hanönü village of Kastamonu town. The copper mine will be operated by open-pit mining method, and the overburden material will be dumped to the site called as Corakoglu. The mine will be operated by Asya Maden Inc. Dump site area borders, digital topographical map, and information for the geology of the site were provided by the Company. Different designs were carried out to determine the relations between overall slope angle of the dump site and dump site capacity. Overall slope angle is an output of the stability analyses carried out for the dump site. Stability analyses, for this case study, were determined based on limit equilibrium methods. The required main geotechnical data for limit equilibrium stability analysis are cohesion, internal friction angle, and unit volume weight for each material at the site. During the design stage in this engineering project, it is not possible to obtain the actual values for geotechnical properties for dump material due to the unavailability of material at site. However, it needs to design the area of dump site according to the engineering point of view. In this situation, back analyses for stability investigations can be usable to understand the required values for geotechnical properties of dump material based on a certain limit of factor of safety (FoS). The details of these investigations as well as presenting a procedure for the design studies of dump site during the planning phase of a mining project are the main outputs of this research. The results proposed in this study are a part of a project completed by ITU Mining Engineering Department in 2014 (ITU Technical Report, 2014).

2 STUDY AREA AND GEOLOGY OF THE SITE

The copper mine deposit is located in northern Turkey close to the Hanönü town in the Kastamonu province (Fig.1).

Geology of the area is reported in Okay et al. (2006). A geological cross-section of the study area is given in Figure 2, while a cross-section prepared by the Asya Maden Geological Department is also given in Figure 3 to show the main geological formations in open pit mine and dump site.

3 GEOTECHNICAL PROPERTIES OF DUMP AND BASE GROUND

Material properties are one of the important input for slope stability investigations. Cohesion (c), internal friction angle (ϕ), and unit volume weight (γ) are geotechnical parameters used in limit equilibrium analyses of slope stability researches. In this case study, mainly two distinct material are defined. The first one is the dump material while the other one is called as base ground.

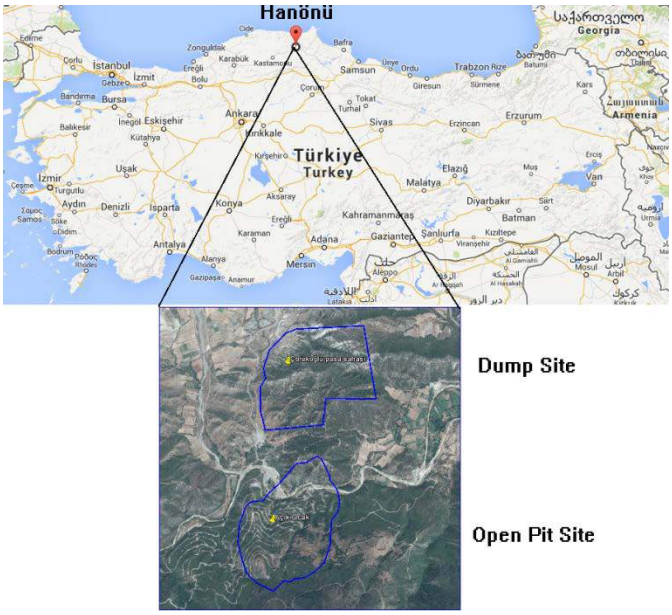

Figure 1. Location map and satellite image from Google Earth for the study area (IMC Technical Report, 2013).

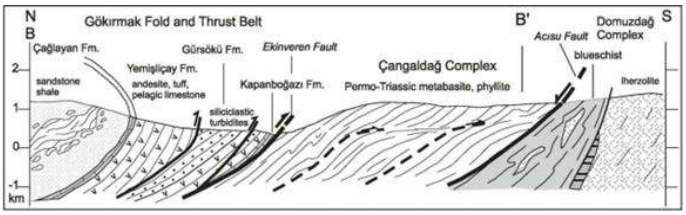

Figure 2. Cross-section for the site (Okay et.al., 2006).

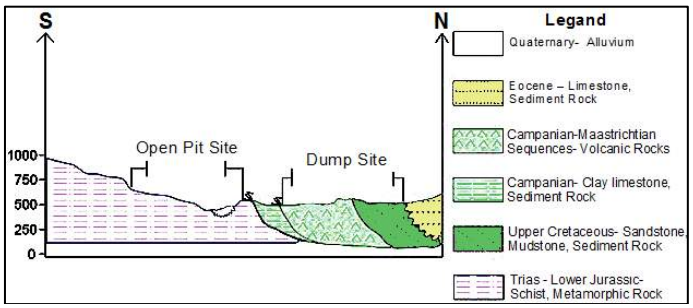

Figure 3. Geological cross-section of open pit and dump site.

3.1 Dump Material

The required geotechnical data should be determined by laboratory experiments on the samples taken from the site as well as in-situ tests. In this study, the excavation for overburden material has not been started, therefore it is not possible to obtain dump samples from the site. The unavailability of dump samples led to use the previous rock mechanics studies for open pit mine planning (ITU Technical Report, 2013). Waste dump material will be produced from the excavation of overburden material during the open pit mining activities. The original rock is mostly consist of mixed schist (MSCH), green schist (GSCH), and schist (SCH) based on the lithology of the open pit site geology. The values of geotechnical parameters for dump material are predicted from in-situ rock due to the unavailability of material at site. Triaxial compressive strength tests as well as direct shear strength tests were carried out in the existing rock mechanics project. The values of cohesion and friction angles are listed in Table 1. In order to make the most possible safe design, minimum values for geotechnical parameters are selected as design parameters which are 50 kPa for cohesion and 23.31^0 for friction angle.

Table 1. Material strength parameters for rock fill (ITU Technical Report, 2013).

Material		Stat.	Triaxial Compression Tests		Direct Shear Test - Residual	
			Cohesion (kPa)	Friction Angle (^{0})	Cohesion (kPa)	Friction Angle (^{0})
Mixed Schist	MSCH	Avg	2,270	53	220	23.31
		Min.	850	42	-	-
Green Schist	GSCH	Avg	1,750	62	50	30.67
		Min.	730	60	-	-
Schist	SCH	Avg	410	48	100	25.55
Design Parameters					**50**	**23.31**

3.2 Base Ground

Strength properties of the ground which waste will be dumped on, are also required for the stability investigations. The study carried out to determine geological and geotechnical properties for the site by DMT Corporation is used to obtain ground strength data (DMT Technical Report, 2013). The geology of the study area show that Corakoglu dump area consists of sandstone, mudstone, and sediments as well as volcanic members. Table 2 is prepared from DMT technical report to predict the strength parameters for the base ground. It should be noted that prior to dumping, the required strength tests must be carried out for the justification of the predictions for the ground geotechnical properties, as well.

Table 2. Natural ground geotechnical properties (DMT Technical Report, 2013).

Sr #	Material	Cohesion (kPa)	Friction Angle (^{0})
1	Sandstone	300-400	35-45
2	Mudstone	200-300	25-35
3	Limestone	200-300	25-35
Design Parameters		**200**	**25**

4 BENCH DESIGN

Initial study for the design of waste dump area is to decide the geometry of individual benches. A bench can be designed by selecting the value for height, width, and the slope angle (Fig. 4). First, the angle of the slope must be decided according to the type of the dump material, if there is no available site application. Common approaches can be used to decide the slope angle based on literature. Added to that, basic friction angle from site experiments or friction angle values from shear strength parameters can be also used to select the most proper slope angle.

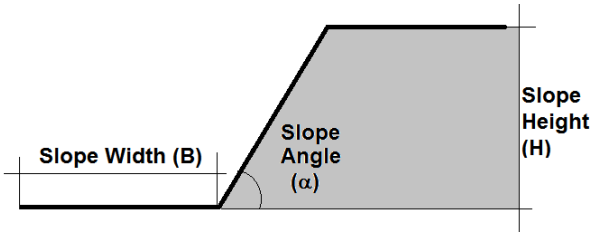

Figure 4. Slope geometry.

According to the classification proposed by Levy (2011), slope ratio between height and length can be taken as ¼:1 to ½:1 for dump material defined as mostly rock. In this study, several bench designs were considered and height is 10 m, angle is 60^0 is selected as bench design parameters for a safe and reliable design. The width of the slope is the only parameter to obtain alternative angles for overall slopes. In order to obtain different combinations of overall slope angle, different values for width are used for the design of dump site. The alternatives for slope width that make the designs for a safe overall slope angle are searched in the next section for the design of waste dump based on stability principles.

5 DUMP AREA DESIGNS

The size of the licensed area as dump site is nearly 135 hectares, while projection of the size is equal nearly 120 hectares. The elevation of the dump site ranges between 440 m and 630 m. The design of the waste dump area is carried out by considering slope stability principles. Limit equilibrium methods are used to decide the suitability of the design. Simplified Bishop multiple analyses are used during stability investigations due to the characteristic of the dump material. It is assumed that failure surface is circular.

As a result of slope stability analysis, a safety factor (FoS) value is calculated which is an indicator of stability consists of the ratio of forces resist the slippage to forces that cause slippage. When the safety factor value is 1 (FoS=1), the slope under investigation is in the limit of stable and unstable condition, and this condition is known as “Limit Equilibrium Condition”.

Back analysis is also used to determine valuable information regarding shear strength parameters such as cohesion and internal friction angle along a sliding surface as well as underground water conditions. The information of slope geometry before sliding, location of sliding surface, and underground water table level (UGWT) is important to increase the sensibility of back analysis. Unit volume weights of the material for the unstable condition shall be also known for the analyses.

There are numerous researches to define factor of safety in open pit mining as well as waste dump deposit. Huang (1983) proposed selection of safety factor in open pit mining. In this study, FoS takes as 1.30 without the effect of earthquake as the table from D’Appolonia Cons. Engnrs. Inc.

Due to the absence of the actual geotechnical data for natural ground and waste dump material, different alternatives for waste dump have been investigated based on different overall slope angle. The purpose of this study is to design the dump in a way that the amount of dumped material is not less than waste which will be excavated from open pit.

For the first design of the dump site, all waste material is considered to be dumped at the site and resulting overall slope angle is found. After determining the overall slope angle, the required strength parameters for dump material were calculated by using slope stability back analysis techniques. Back analyses can also be performed to obtain critical material strength parameters from known or assumed failure surface. Hence, it is possible to determine required cohesion and friction angle of waste dump material for the 1st design that is used to dump all waste material to the waste dump area.

Second, the reliable overall slope angle is determined where FoS is 1.30 after stability analyses. The predicted strength parameters for dump material given in Table 1 are used to for the 2nd design. Hence, it is possible to determine the slope width as well as the geometry of the waste dump. After design studies, the volume of total waste material could be dumped for the 2nd design is calculated.

When the overall slope angles for 1st and 2nd designs are determined, those are maximum and minimum values successively, 3 more designs were carried out to determine the relation between overall slope angle and total dump volume. The following figure shows the design procedures for the study.

The studies for the waste dump area design as outlined in Figure 5 were carried out by using an integrated mining and slope stability software. Micromine is used as integrated mining software to model existing topography and to draw the border of the dump. The designs numbered from 1st to 5th were also modeled by using Micromine. Cross-sections from these designs are taken from the software. Galena as a slope stability software is used to obtain the results of the stability analyses. Factor of safety for designed slopes as well as back analyses for material strength parameters determination can be handled by using Galena.

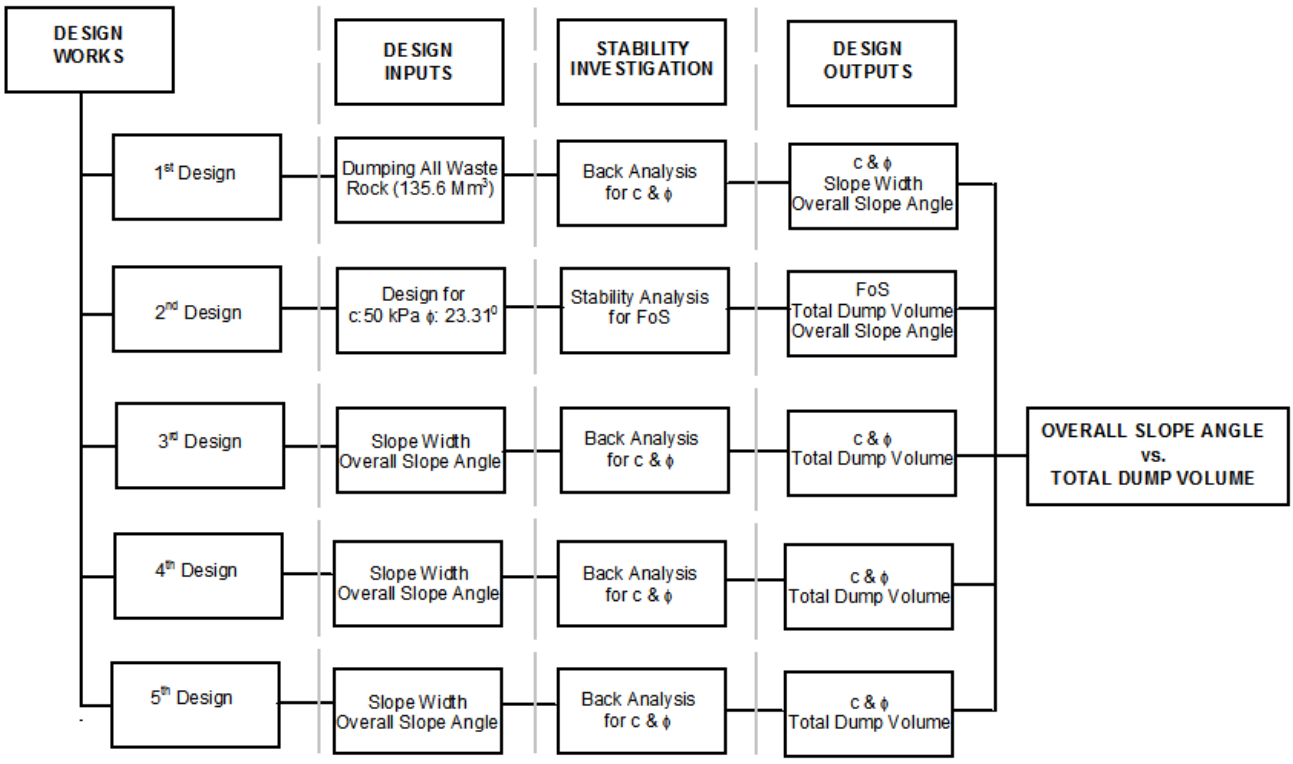

Figure 5. Design procedures based on stability principles in this project.

In order to avoid the mass presentation of figures, graphs and cross-sections used in the design studies, only 1st design outputs are presented in this study including the results of the each design in the following table.

In the 1st design, the value of bench width is selected as 5 m while the other parameters of the slope geometry is already fixed as 60^0 for slope angle and 10 m. for slope height.
The design of the dump site is given in Figure 6 as plan and views. Maximum overall slope angle is calculated as 42^0 in the 1st design with 143.5 million m^3 capacity. Cross-sections of the dump site can be seen in Figure 7.

Back analyses were carried out to find the material strength properties required for stability of this design. The output of the back analysis is given in Figure 8.

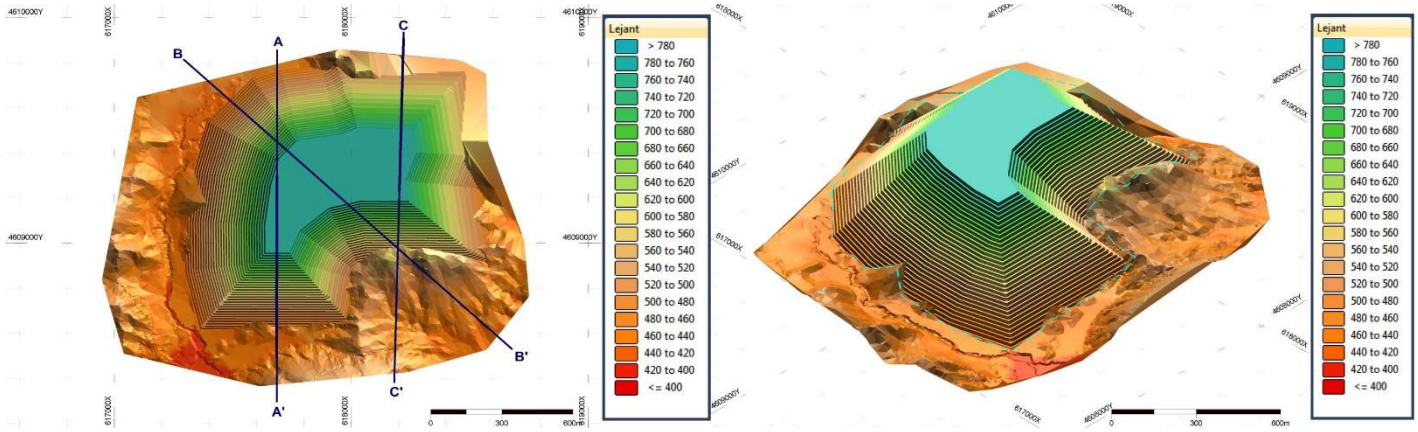

Figure 6. 1st - Design, plan and isometric view.

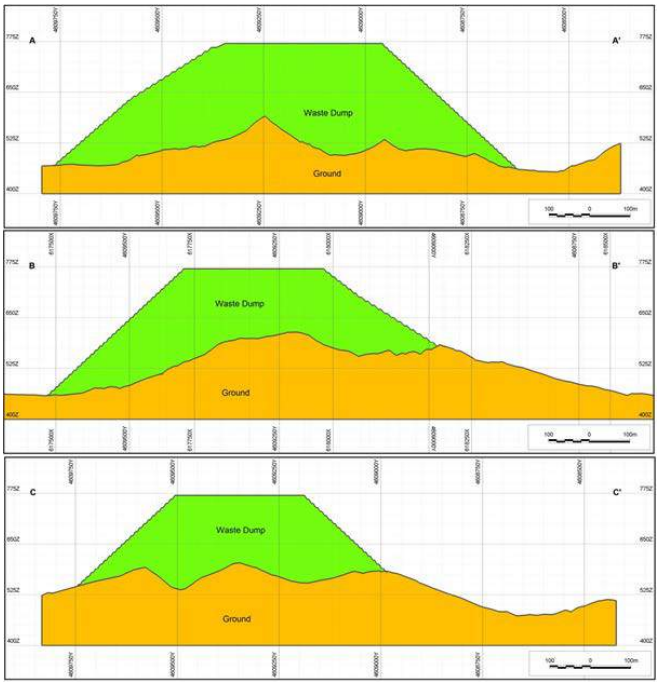

Figure 7. Cross-sections of the dump area.

The outputs of the back analyses studies are combined in a single graph given in Figure 9 for 4 designs performed as back analyses. The data obtained from this graph is used to set up a multiple linear regression model between cohesion, friction angle, and overall slope angle (OSA) for FoS=1.30. The equation determined from the multiple linear regression analysis is given below has 0.94 correlation coefficient and 1.34 standard error (Eq.1). This equation may be used to define overall slope angel after testing dump material and determining cohesion and friction angle values.

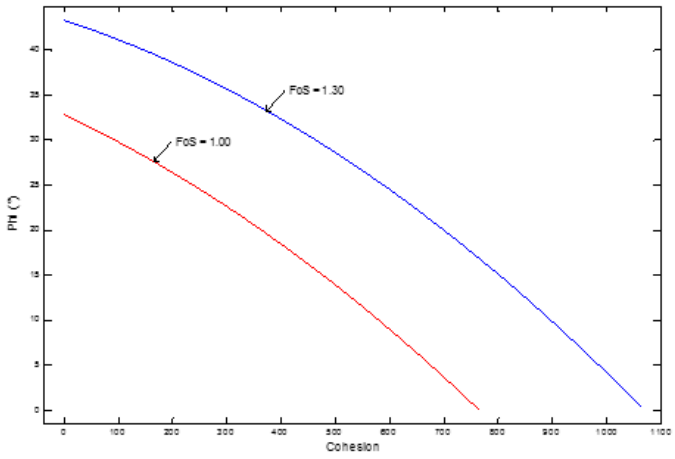

Figure 8. Back analyses results for 1st - Design.

$$OSA = 0.02xc + 0.44x\phi + 19.51 \quad (1)$$

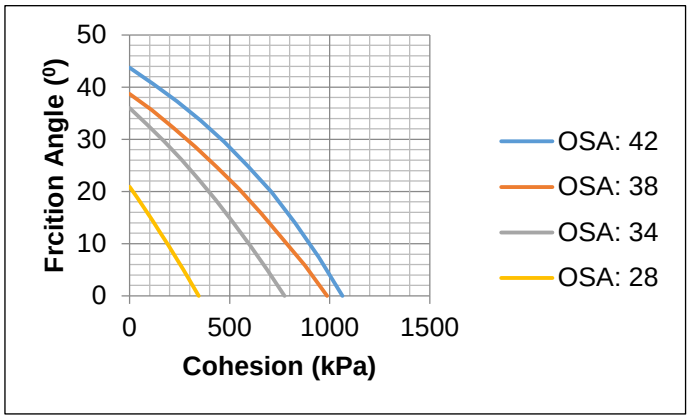

Figure 9. Results of back analyses from stability studies.

5 different designs are constructed for the dump site. The results for the geometry of dump sites as well as the individual slopes including the capacities of the damp areas are outlined in Table 3

.

Table 3. Summary of the design studies.

Sr #	Description	1st - Design	2nd - Design	3rd - Design	4th - Design	5th - Design
1	Overall Slope Angle (^{0})	42	23	28	38	34
2	Slope Angle (^{0})	60	60	60	60	60
3	Slope Height (m)	10	10	10	10	10
4	Slope Width (m)	5	17.5	13	7	9
5	Maximum Elevation (m)	890	670	730	830	780
6	Total Damp Volume (million m^3)	143.5	37.5	61.5	112.5	88.5

A relationship between overall slope angle and total dump volume that can be seen in Figure 10 is proposed as a result of these design works. The graph with a very high correlation coefficient, claims a relation between overall slope angle and dump capacity. The following arguments can be made from the graph.

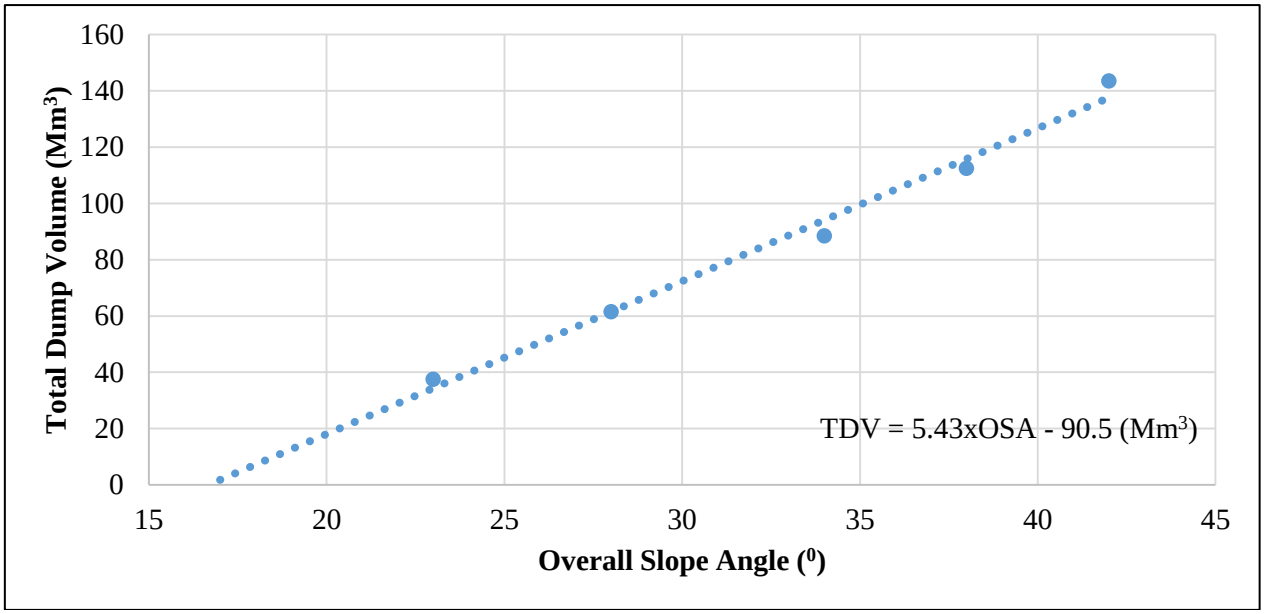

Figure 10. Correlation between OSA and total damp volume

After determining the actual material strength properties for dump material and ground, overall slope angle can be calculated from stability analyses and total dump volume will be achieved can be easily

computed from the equation in the graph based on the actual overall slop angle values.

6 HYDROGEOLOGY AND SEISMICITY

6.1 Effect of Water on Stability

The increasing level of underground water has an adverse effect on the stability of slopes. The stabilities of the designs proposed in this study were investigated under the dry condition of the slopes.

Observation well data is reported in hydrogeology report for the open pit mine prepared by Asya Maden Geological Department. According to this data, there exists an underground water table from the ground level between 3.65 m and 79 m. Average underground water table level is observed as 29.5 m from the surface (Asya Maden Technical Report, 2014).

Stability analyses by considering the underground water table level for 1st - Design is carried out to model the effect of underground water on the stability.

In the first stability analysis, underground water table elevates into the dump material. The FoS value is calculated as 1.20 which is below acceptable limit. In the second model, the rising of the UGWT into dump is prevented, and UGWT level is hold below surface. FoS value is calculated as 1.30 which is acceptable for stability.

The results of stability analyses considering water on stability show the importance of decreasing the underground water table level as well as controlling the surface water. Constructing proper drainage system to protect the dump against increasing water table level is important.

6.2 Effect of Earthquake

The effect of earthquake for the stability of dump slopes must be evaluated again by using the stability principles due to the importance of earthquake for Turkey. The scale of seismicity for Kastamonu Hanönü region is classified as 3rd degree according to the map prepared by "Turkish Republic Prime Ministry Disaster and Emergency Management Presidency, Earthquake Department Presidency"

Historical seismicity record map show that the closest earthquake bigger than magnitude of 5.0 happened in 1919, 20 km away from the Hanönü region (Özmen, 2001).

Due to the seismicity degree, magnitude of the historical earthquakes, and the distance between the biggest earthquake to the mine site, earthquake force is taken as 0.15g in this study.

In order to understand the effect of earthquake for 1st - Design and 2nd - Design, stability analyses were performed under earthquake condition. Cohesion is selected as 150 kPa while friction angle is selected as 40^0 from the result of back analyses. After applying the stability analyses, the value of FoS found as 1.03 that shows the suitability of the design under the earthquake condition for the 1st - Design. If FoS>=1.0 under earthquake condition the design is considered safe.

2nd - Design stability investigation under earthquake condition was also performed and FoS is calculated as 1.00 in this analysis that is also acceptable under stability concerns.

7 CONCLUSION

Waste dump area design is main purpose of this study. The most critical problem is having no actual material strength data for the dump material. Due to the absence of material strength properties of dump material, several different designs were performed in order to obtain a relation between overall slope angel and strength properties of dump material. Back analysis technique is used to understand value of cohesion and internal friction angle for a safe design, based on slope stability principles having factor of safety value more than 1.30.

As a result of the designs, two valid equations are determined as a main output of this research. In the 1st equation overall slope angle value can be determined from the cohesion and internal friction angle of dump material. In the 2nd equation, total dump capacity of the site can be calculated from the value of overall slope angle, so total

dump capacity of waste dump deposit area can be calculated, when the actual strength parameters of dump material are determined.

The procedure applied in this study for the design of waste dump deposit especially during the planning stage of a mining project can be applied for similar studies successfully according to the results of this study.

ACKNOWLEDGEMENTS

The Authors would like to appreciate the contributions of Ilbak Group, Asya Maden Inc. as well as the Managers and Engineers for their support to the research.

Performance Evaluation of Paste Backfill in Imiter Silver Mine, Ouarzazate Region, Morocco

K. Abdelhadi, O. Latifa, B. Khadija
3GIE Laboratory, Mohammadia Engineering School, Rabat, Morocco

ABSTRACT This work is part of topic of developing Paste Backfill technology in mining operations in Morocco. The silver mine of Imiter, Ouarzazate region, was chosen as case of study because of its commitment to implement PBF practice for the remaining life of the operation. Paste Backfill (PBF) is a combination of mine processing tailings, binder (cement and additives) and water mixing with specific recipe. It's generally used to fill in underground voids improving thus rock mass strength and allowing the maximization of ore recovery. The study of PBF introduction passes through several steps. The first element to define is the function which the backfill will ensure with underground works. Thereafter, chemical and mechanical characterization is done on the different components to determine optimal formulation ensuring the required mechanical strength of hardened paste. Actually, two PBF formulations are used in Imiter mine, one for slab separation of mining levels and one for underground voids filling. In this work we present a performance evaluation of the used PBF according to defined functions. The mechanical performance of PBF was evaluated in laboratory by the uniaxial compressive strength test. The conducted tests and analysis shows that actual PBF formulations are adequate with the associated functions in the extraction sequence.

Keywords: Underground mining, paste backfill, chemical and mechanical characterization

1 INTRODUCTION

Morocco is a country with important underground mineral resources. The main underground mining activity is located in the south and concern poly-metallic and precious metal deposit.

Mining operations use different kinds of backfill depending on the extraction method. The most used backfills are mechanical backfill (only waste material) and hydraulic backfill (cemented backfill).

More than 20 years ago, concentrator treatment discharges of mining plants were wholly stored on tailings parks on surface areas. The volume and chemical characteristic of these tailings, often rich of sulfurs, generate serious problem for storage requiring spaces and mainly environmental degradation due to Acid Mine Drainage.

The environmental legislation, increasingly requiring, leads mining societies to minimize as possible, the volume of tailings stored on the surface. Morocco is one of countries which going to make the environment preservation as the first preoccupation during and at the end of mining activities.

Paste backfill (PBF) is one of ingenious solutions to minimize the quantity of tailings to store. It's a mixture of total mill tailings generated during mineral processing, Portland cement or blended cement with supplementary cementitious material (lime, pulverized fly ash, and ground granulated blast furnace slag), and water (tap water, lake water or recycled and/or treated mine process water) (Belem et al., 2008).

The first introduction step of paste backfilling practice is already in progress for the silver mine of Imiter (Ouarzazate region) in southern of Morocco. Some characterization tests are done to evaluate chemical and physical characteristics of tailings and other used aggregates materials on the paste backfill fabrication.

The purpose of this paper, in addition to show PBF advantages, is to present a performance evaluation of the paste backfill mixture used by Imiter mine. Actually, two PBF formulations are used with underground works, one for slab separation of mining panels and one for stopes filling. The mechanical performance of these two recipe was evaluated by conducting uniaxial compressive strength tests.

2 PASTE BACKFILL TECHNOLOGY

2.1 PBF Advantages

Since their introduction in 1990, PBF technology has demonstrated advantages regarding economics factors, environment, geo-mechanics and safety (De Souza et al., 2001; Benzaazoua et al., 2005).

This success of PBF is explained first by the engineered character of the product which allows high quality in comparison with old backfill methods.

Actually, the economic and environment benefits of PBF have not to be approved. Costs due to tailings management in the storage areas and closing budget can significantly be reduced.

PBF technology is suitable for most mining methods because of its versatile characteristic which has allowed the increasing of resource extraction.

In term of safety, PBF is used as local and regional ground support and also help to reduce the number and exposure time of operators by fast filling rates. The fast filling increase in addition mine productivity with shorter stop cycle times.

2.2 Influencing Parameters

As showed in figure 1, the percentage and characteristics of each PBF component (tailings, binder, and water) affect directly the mechanical strength of hardened backfill.

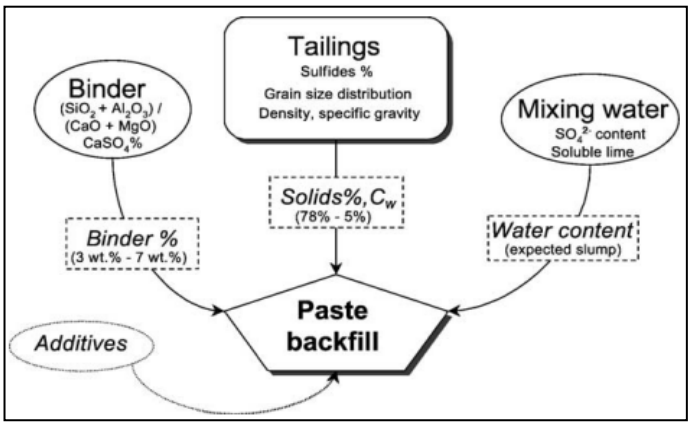

Figure1. Schematic diagram illustrating the different components of paste backfill (Benzaazoua et al., 2002).

Chemical composition of tailings: The sulfurs content is the most important parameter to verify in the chemical composition of tailings because of its direct influence on increasing the tailings density.

Morphology of grain and size distribution: Generally more spread is the grain distribution more quick is the PBF hardening. The morphology of tailings particles can also affect the quality of the final product mainly with phyllo-silicate material.

Binder and water chemistry: It's inefficient to choose paste backfill mixtures without testing first the tailings and mixing-water characteristics. The binder chemistry combined with the mixing-water chemistry affects the formation of primary and secondary hydrates during paste backfill strengthening. The cohesion of the paste backfill matrix is directly dependent on the nature of the precipitated hydrates (Benzaazoua et al., 2005).

Figure 2 shows the composition impact of each component of mixture on the backfill strength expressed with uniaxial compressive strength (UCS).

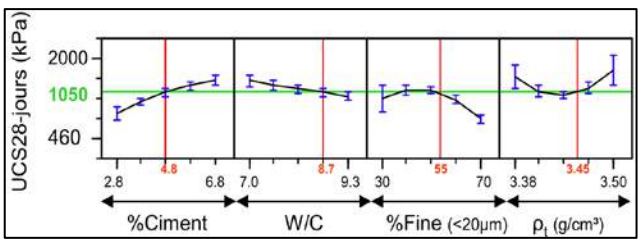

Figure 2. Example of component impact simulation curves (Fall et al., 2003).

2.3 PBF limit strength

The first step of PBF design is to calculate critical strength ensuring both stability of PBF and filled stope. The value of critical strength to reach depends on the function of the PBF in the mining method.

PBF can be used to support voids roof and then its design will be focused on rigidity and mechanical cohesion. In case where one side of PBF has to be exposed, the shear strength is the main parameter conditioning the backfill stability.

2.4 PBF Mixture Optimization

At this stage each proportion of tailings, binder (one or several cementation agents) and mixing water has to be defined in an optimized recipe.

The backfilling cost represents 2% to 20% from the total mining operation cost. Knowing that 75 % of backfilling cost corresponds to binder acquisition, it's important to optimize recipes to product backfill with a minimum cost (Belem et al., 2003).

The recipe optimization takes into consideration the mechanical and transportation exigencies thought a pertinent selection of type and binder content.

2.5 Flow Sheet Production

Generally, the PBF plant is located on the surface nearby the processing plant to facilitate the recovery of tailings at the end of the processing line.

The following present the classic procedure of PBF fabrication. Belem et al. (2003):

- Thickening of tailings slurry to about C_w = 55%. (Solid weight percentage),
- Filtration of tailings with disk filters or press filters to C_w between 70% and 82%,
- Binder addition with a proportion between 3% to 7 % from the total mass of dry tailings,
- Water addition (processing or fresh water) to generate an optimal slump comprised between 150 and 250 mm,
- Recipe mixing in a screw mixer with high power during 45 seconds to one minute.
- Underground delivery of PBF through transportation network.

2.6 Transportation

Several works were focused on the problematic of backfill transportation since their introduction (Landriault et al., 1987; Hassani et al., 1998; Li et al., 2002; Benzaazoua et al., 2004 ;…). PBF product must be delivered from surface to underground via boreholes and pipes at the highest practical density. Practically, it is not easy to have real proprieties of PBF rheology because of experimental dispositive complexity.

It makes difficult or even impossible determination or prediction of paste viscosity which depend on several factors (Benzaazoua et al., 2005).

Generally the slump test and flow-loop test are used to evaluate the paste consistence and pressures drop along the transporting network.

The prepared PBF should be pumped through pipelines reticulation network without causing any plugging. The pumpability of PBF is measured by the slump height. The fresh PBF behaves as a non-Newtonian fluid. That is, applied pressure is required to initiate flow (Belem et al., 2008).

2.7 Mechanical Behavior

Once the PBF is deposed in underground voids, it undergoes various transformations and interactions.

The PBF interactions with rock mass depend mainly on void dimension but also on pressure at the bottom and over the stope barricade.

In addition to hydration reactions which give the mechanical strength of hardened backfill, other phenomenons occur during the curing time of PBF, mainly:

- Drainage of excess water,
- Settlement and consolidation,

The strength of pastefill in the filled stope is related to the water flow which is a function of the paste properties (Belem et al.,

2001). Transformations and interactions of PBF have to be monitored in the short, middle and long term. This monitoring will show the impact of selected recipe and material characteristics on the mechanical strength of PBF. Adjustment can then be made to find the most appropriate recipe.

3 IMITER MINE OPERATION

Imiter mine is an operation located in Ouarzazate region, southern of Morocco. The exploitation concern a rich silver ore body. (Fig. 4)

3.1 Geological Overview

Imiter mine is located in NE edge of the Ouarzazate basin (Eastern Saghro, Anti-Atlas). The deposit is hosted in the volcano-sedimentary series of the Precambrian II and secondarily in volcano-clastic formations of the Precambrian III.

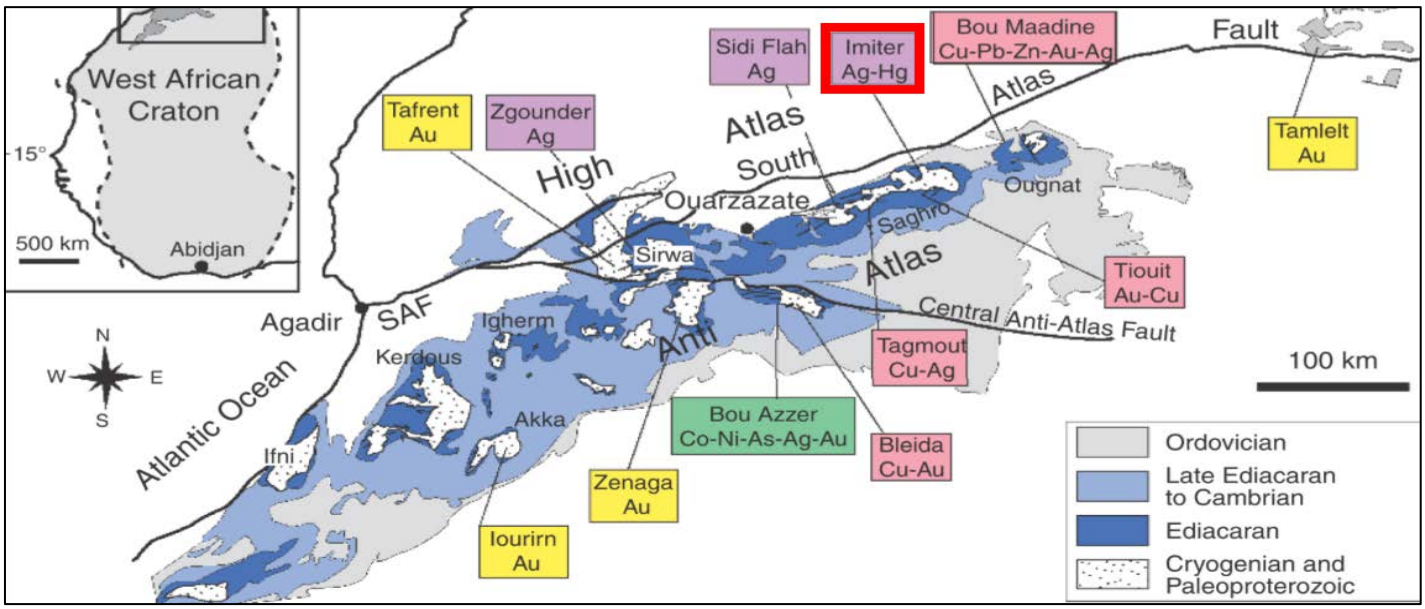

Figure 3. Location of the main ore deposits in the Anti-Atlas belt (Gasquet et al., 2005).

3.2 Ore extraction

In an old stage of the mine, the open pit was the principal extraction method. Actually the main extracted ore is coming from underground exploitation using two principal extraction methods: cut-and- fill and sublevel stopping. (Fig. 5)

Cut-and-fill method extract ore in horizontal tranches, starting from the bottom and advancing upward. Voids are backfilled with hydraulic fill or waste rock when the stope has been worked-out. Backfilling serves both to support walls and provide a working platform for equipment for the next tranche.

In sublevel stoping method ore is extracted in open stope (keep out for worker circulation). Ore body is generally large enough with an important vertical extension.

Pillars are normally shaped as vertical beams across the ore body. A specific extraction sequence is followed with primary and secondary stopes. Primary stopes are progressively filled to allow the ore extraction in secondary left ore parts.

In Imiter mine the cut-and-fill or sublevel stoping method is used depending on ore body extension and geometry. The sublevel stoping can also be longitudinal or transversal according to rock mass quality and geometry.

4 IMITER PASTE BACKFILL

4.1 PBF Components Characteristics

Imiter operation use a PBF recipe which combine crashed waste material (Gravel and sand), tailings and cement.
Mixing water come from local drilling pumping.

The following present Imiter PBF characteristics from conducted laboratory testing.

All tests was made according to Moroccan standards (NM) or French standards (NF) in case of need.

4.1.1 Gravel and Tailings

Table 1 present results of laboratory testing generally realized for conventional concrete aggregates.
These results confirm acceptable characteristics according to Moroccan standards.

Chemical composition and particle size distribution of tailing was identified respectively by XR and sedimentation technics.

Table 2 present the obtained chemical composition and figure 5 show particle size distribution curve for gravel, sand and tailings mixture.

Table 1. Laboratory characterization of Imiter paste backfill gravel.

Laboratory testing	Flatness coefficient (%)	Superficial cleanliness (%)	Los Angeles hardness (%)	Sand equivalent (%)
Testing results	23	0.3	15	56
Standard NM10.1.27	≤ 25	≤ 3	≤ 30	≥ 60

Table 2. Chemical composition of tailings.

Chemical Elements	AL_2O_3	CaO	Fe_2O_3	K_2O	MgO	MnO	Na_2O	P_2O_5	SiO_2	TiO_2	LOI	**Total**
%	13.86	2.81	6.33	3.59	3.96	0.18	1.61	0.19	57.37	0.72	8.47	**99.12**

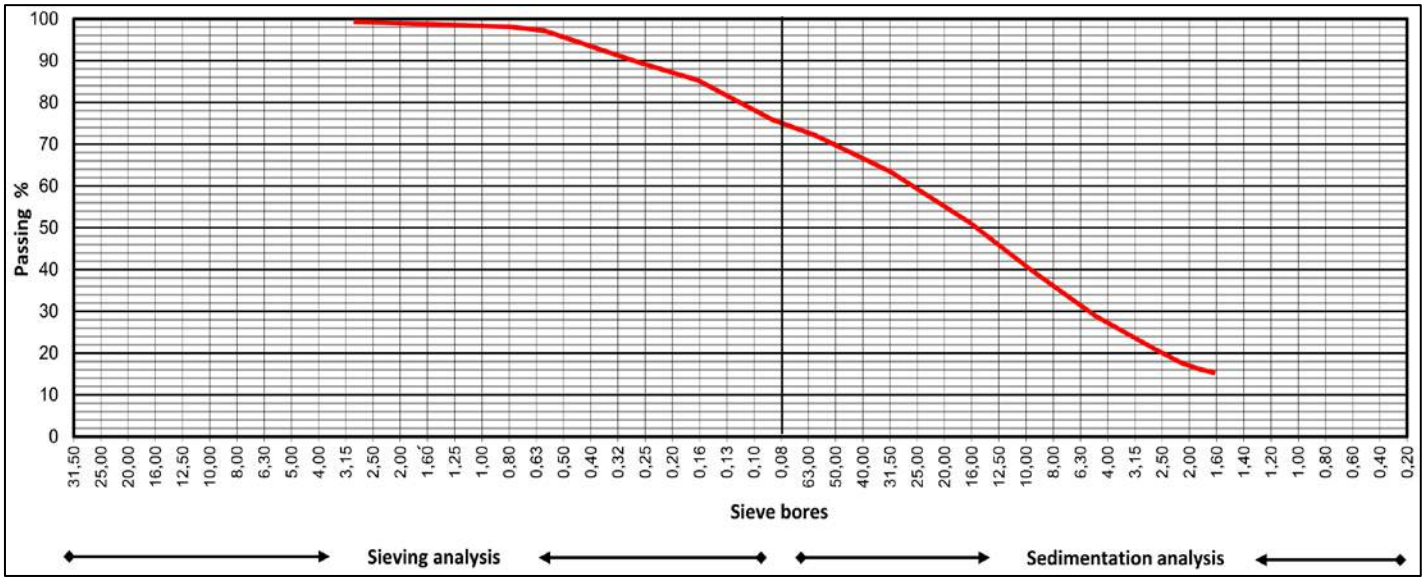

Figure 5. Imiter PBF particle size distribution

4.1.2 Binder

Table 3 and Table 4 present, respectively, physical and mechanical testing realized on cement (CPJ45 type) sampled from site stock. Results are presented in comparison with Moroccan standards NM 10-1-008 and NM 10-1-004.

Table 3. Physical testing – Cement CPJ45.

Physical parameter	Setting time	Expansion	Specific surface (BLAINE fineness)
Testing results	2h 00 min	1.7 mm	2470 cm^2/g
Standards NM 10-1-008	≥ 1h 30 min	≤ 10 mm	≥ 2200 cm^2/g

Table 4. Mechanical testing – Cement CPJ45

	Uniaxial compressive strength (MPa)		
	after 2 days	after 7 days	after 28 days
Testing results	18.7	27.3	39.5
Standards NM 10-1-004	-	≥ 20	≥ 32.5

4.1.3 Mixing water

Mixing water come from local drilling pumping. Table 5 present chemical composition obtained by laboratory analysis. Results are also presented in comparison with Moroccan standards NM 10-1-008.

Table 5. Chemical analysis of mixing water.

Chemical parameter	Ph	Material in suspension (mg/l)	Dissolved salt (mg/l)	Sulfates (mg/l)	Chlorides (mg/l)	Organic material mg/l
Testing results	6.60	0.5	617	153.60	194.70	0.00
Standards NM 10-1-008	≥ 4	≤ 2000	≤ 5000	≤ 2000	≤ 500	≤ 200

Table 6 present PBF mixtures actually used in Imiter mine and combining the above characterized materials. One formulation is for slab separation of mining levels with 7 % cement content and one for voids filling with 2 % cement content.

Table 6. Imiter PBF mixtures.

Cement %	7 %	2 %
Gravel (kg)	600	600
Sand (kg)	1000	1000
Tailings (kg)	340	340
Water (l)	500	500
Cement (kg)	160	40
Total weight (kg)	2600	2480

4.2 Prediction of PBF Strength

Typically stopes of 4 m width and 4 m height are mined with fill-and-cut instead 15 m height for sublevel stopping method.

The following present an estimation of required PBF UCS according to the assigned function.

4.2.1 PBF For Voids filling

The long term (> 90 days) UCS of filling backfill can be predicted by equation (1) whish consider a null friction angle: $\phi = 0$. (Mitchell et al., 1982).

$$\mathbf{UCS_{design}} = \mathbf{SF} * \left(\frac{\gamma_b H}{1 + \frac{H}{L}} \right) \quad (1)$$

Where FS = safety factor, γ_b = PBF bulk unit weight (KN/m^3), H = PBF height (m), and L = the stope width (m).

The required UCS was calculated for different safety factor based on Imiter ore geometry in case of each mining method. A PBF bulk unit weight of 18 KN/m3 was considered. Table 7 present the obtained results for UCS design prediction.

These results shows difference between the required UCS for each method. This difference is due to exposed PBF height face which depend on utilized method. This can be materialized by adopting two PBF recipe.

Table 7. UCS design calculation according to safety factor.

	UCS design (KPa)										
Safety factor	1.0	1.1	1.2	1.3	1.4	1.5	1.6	1.7	1.8	1.9	2.0
Cut-and fill	36.0	39.6	43.2	46.8	50.4	54.0	57.6	61.2	64.8	68.4	72.0
Sublevel stoping	56.8	62.5	68.2	73.8	79.5	85.2	90.9	96.6	102.3	108.0	113.6

4.2.2PBF For Slab Level Separation

Imiter ore body is divided into panel of 20 m height. Panel are separated by the implementation of slabs of 60 cm thick. This thickness is the minimum for verification of the non-tipping condition.

By assimilating the slag panel separation to a beam of two supports, we can use rules developed for beam calculation. By considering a non-recessed slab we can find the equation (2) giving the required thickness of the slab in terms of the admissible compressive strength σ_{ac}:

$$\mathbf{e} = \frac{\mathbf{6\,\gamma_p\,L^2} + \sqrt{\left(\left(\mathbf{6\,\gamma_p\,L^2}\right)^2 + \mathbf{32\gamma_b\,hL^2\sigma_{ac}(1-\beta)}\right)}}{\mathbf{16\,\sigma_{ac}(1-\beta)}} \quad (2)$$

Where γ_p = PBF bulk unit weight (KN/m3), L = mined tranche width (m), γ_b = backfill bulk unit weight (KN/m3), σ_{ac} = PBF admissible compressive strength (KPa), h = panel height (m), β = arbitrary coefficient $0 < \beta < 1$.

Using equation (2), we can find the admissible compressive strength of PBF considering a thickness of 0.6 m. The PBF UCS can then be calculated by equation (3).

$$\sigma_{ac} = \frac{UCS}{SF} \quad (3)$$

Where σ_{ac} = PBF admissible compressive strength (MPa), UCS: uniaxial compressive strength (MPa), SF: safety factor.

Considering a slag unit weight of 18 KN/m^3, a filling backfill unit weight of 17 KN/m^3, a height panel of 20 m and null β coefficient, we find a σ_{ac} = 1.7 MPa.

Generally a safety factor of 1.5 is associated with underground mining works, this give a required UCS of 2.55 MPa.

5 UNIAXIAL COMPRESSIVE STRENGTH RESULTS

PBF mixtures presented in chapter 4 was reconstituted in laboratory and crafted as cylindrical specimens of 10 cm diameter and 20 cm length. Mechanical performance of the analyzed PBF was evaluated by UCS testing. Tests was realized for different ages of specimens: 7, 14, 21 and 28 days after confection. UCS test is widely used as principal parameter for PBF backfilling system design because of its low cost and possibility to make correlation with other mechanical parameter.

Table 8 and 9 present respectively UCS results for PBF filling recipe (2% cement) and PBF slab recipe (7% cement).

Table 8. UCS results for PBF filling recipe (2% cement).

Age (days)	Mean unit weight (KN/m^3)	Mean UCS (MPa)
7	17.9	0.40
14	17.2	0.72
21	17.0	1.08
28	16.9	1.33

Table 9. UCS results for PBF filling recipe (7% cement).

Age (days)	Mean unit weight (KN/m^3)	Mean UCS (MPa)
7	18.5	0.49
14	18.0	1.03
21	17.9	1.59
28	17.8	2.01

6 DISCUSSION AND PROSPECTS

Table 10 present values of analytical prediction of the long term uniaxial compressive strength made in chapter 4 considering a safety factor of 1.5, and corresponding experimental laboratory testing after 28 days of curing time.

Table 10 shows that the 2% of cement recipe can be more optimized, laboratory testing give a high UCS value at 28 days of curing time compared to predicted values. This high experimental value can be explained by the mixture characteristics of Imiter PBF which combine in addition to plant tailing, crashed waste rock from mine development against an ordinary PBF combining only plant tailings, binder and mixing water.

Table 10. Predicted UCS design instead experimental values.

PBF function	Predicted UCS (KPa) Curing time > 90 days	Experimental Result (KPa) Curing time = 28 days
Void filling / Cut and fill	54	1330
Void filling / Sublevel stoping	85	1330
Slag level separation	2550	2010

For the slab recipe, experimental results gives a UCS value of 2.01 MPa against a predicted strength of 2.55 MPa. It's possible that slag PBF reach the required UCS value after a long curing time. Laboratory or in-situ testing must be done to evaluate the experimental long term strength of slag PBF.

Obtained result confirm that utilized recipes are adequate with the assigned functions of PBF. However PBF recipe for voids filling can be ameliorated to obtain an optimal mixture ensuring required mechanical strength.

The future works related to this topics will be focused on the recipe composition to find the optimal binder content ensuring required mechanical properties and evaluate the possibility to reduce or eliminate waste mine gravel from the mixture. The final objective is to determinate an optimal PBF recipe combining low possible cost and strength requirements.

Pit Slope Optimization Based on Hydrogeologic Inputs

G. Evin, F. Henriquez, V. Ugorets
SRK Consulting (U.S.), Inc., Lakewood, Colorado, USA

ABSTRACT With the variability of commodity prices and the constant increase of mining costs, it has become increasingly important to optimize pit slopes of mines, taking into consideration the complexity and the uncertainties presented by ground conditions. The variables in slope stability, geology, rock mass strength, structural defects, inherent and induced stresses, rock weathering, alterations, and groundwater, are well known, as are their impacts on slope performance. Most variables cannot be changed to optimize slopes. However, groundwater is one variable that can be managed during pit excavation, to reduce the effect of pore pressure on slope stability.

Hydrogeologists and rock mechanics engineers combine their efforts in order to quantify, simulate, and control the effect of groundwater pressures on pit slope performance. Based on comprehensive field hydrogeological data collection and interactive numerical groundwater and geotechnical modeling, it is possible to evaluate the water pore pressure effect on the pit slope, to provide an efficient depressurization strategy to meet the geotechnical engineering targets, and thus to develop cost-effective mine plans.

This paper discusses how proper management of groundwater conditions can contribute to mine planning and operations, through pit slope optimization. We show a complete approach from collection of hydrogeological data in the early stages of a project to design of an appropriate depressurization plan, taking into account the rock mass conditions, the mining plan, and the time to achieve an optimal pit slope.

Keywords: Hydrogeology, hydrogeological condition, pit slope, stability

1 INTRODUCTION

Groundwater water in open pit mines affects normal operations in many ways. Excessive water inflow into the pit can significantly impact the mine operations by reducing equipment performance and increasing loading and haulage time. Water in the pit could result in incremental increases in mining cost, reduction of mining performance, the need for special blasting products, increases in drilling time, and mechanical damage of mine equipment, etc.

A poor knowledge of the hydraulic parameters could also have a negative impact on the slope design and stability performance of the pit, which could result in an over or underestimation of the mine design; directly impacting, negatively, the net present value (NPV) of the business.

It is clear that a good understanding of groundwater conditions and their effects on the mine operation and mine design can help mining companies optimize their business.

Several authors have developed methods of data collection, interpretation and modeling of groundwater conditions to provide recommendations for pore pressure reduction and mine dewatering (Read & Stacey, 2009; Beale & Read, 2013; and others). This paper does not intend to review and comment about the current data collection and modelling technics, the objective of this paper is to discuss how the integration of the hydrogeology and geotechnical disciplines can optimize the mine operations. The paper intends to demonstrate the importance of good data collection, interpretation, and groundwater numerical modeling on slope stability as an optimization tool.

2 EFFECT OF GROUNDWATER ON SLOPE STABILITY

The literature lists different ways in which groundwater can affect open pit mine excavations, including (a) changes of effective stresses and/or (b) saturation, both contributing factors of slope stability.

2.1 Changes of Effective Stresses

In its simplest definition, the water pore pressure is the pressure of groundwater held within a soil or rock in gaps between particles (pores). Pore water pressure is used in calculating the stress state in the ground soil mechanics using Terzaghi's expression for the effective stress of a soil (below).

Soil or rock can be pictured as a frame of soil particles enclosing continuous voids containing fluids (water, air, gas etc.) as shown in Figure 1. In fully saturated soil, water is considered to be incompressible, so that a reduction in volume is possible only if some of the water can escape from the voids. In dry or partially saturated soil a reduction in volume is always possible due to the compression of air in the voids which allows the opportunity for the rearrangement of particles within the soil. In 1923, Terzaghi presented the principle of effective stress. The principle applies only to fully saturated soils and relates the following three stresses: (a) total normal stress σ_N, (b) pore water pressure (u) and effective normal stress (σ'), which represents the stress transmitted through the soil skeleton only. The Terzaghi principle is expressed by the following equation (Eq.1).

$$\sigma_N = \sigma' + u \quad (1)$$

Figure 1 shows a Normal force P applied on an area A, resisted by inter particle forces and the pressure located in the pore water. The physical model indicates that the forces at each point are in contact with the true plane XX, which can be split into two components; Normal Effective N' and tangential T forces, then the Effective Normal stress can be defined by the following equation (Eq. 2):

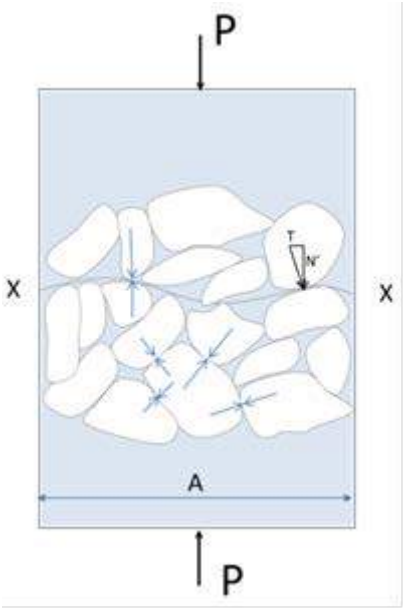

Figure 1. Interpretation of effective stresses.

$$\sigma' = \Sigma N' / A \quad (2)$$

Given the fact that the Total Normal stress is:

$$\sigma = P / A \quad (3)$$

Then the points in contact between the particles should have a total pore pressure acting on the plane (entire area A), reaching the equilibrium in direction normal to XX plane given by:

$$P = \Sigma N' + u \times A \quad (4)$$

or

$$P/A = \Sigma N' / A + u \quad (5)$$

Therefore,

$\boldsymbol{\sigma_N} = \sigma' + u$ or $\boldsymbol{\sigma'} = \sigma_N - u$

2.2 Shear Failure

In simple terms, failure occurs within the material when the shear stress becomes equal to the shear strength, expressed by Coulomb's principles (Das, Braja, 2011) in the lineal failure envelope, given in the following equation:

$$\tau = c + \sigma_N \times \tan \phi \quad (6)$$

where:

τ = shear stress;
c = material cohesion;
σ_N =normal stress; and
ϕ = internal friction angle of the material.

In other words, there are critical combinations between shear and normal stresses that produce failure. However, shearing resistance is developed by the inter-particle forces; therefore, if the effective normal stresses are zero then the shearing resistance must be zero (at least there is cementation between the particles) and the value of effective cohesion (c') would be zero.

The physical model indicates that each point in contact on the true plane XX, the Normal Effective N' and tangential T forces, will be reduced and potentially reach a critical combination of normal and shear stresses over the failure envelop establishing the failure.

2.3 Water Pore Pressure in Slope Engineering

The pore pressure in slope engineering is one of the contributing factors in slope stability. The groundwater changes, effective stresses, and increased density of the materials cause changes in hydrostatic loading (Read & Stacey, 2009). There are several different techniques to simulate water pore pressure in slope analyses; computer simulations can provide a good approach to analyze the groundwater effect on slope performance.

For saturated or partially saturated slopes, rock engineering experience establishes that a reduction of pore water pressure will improve the results of the slope performance parameters creating the opportunity to optimize slope designs. In practice, the time required to achieve the reduction of pore pressure must be considered, as well as the flexibility in the mining plan to allow enough time for getting the depressurization targets established by the pit slope engineer.

3 MINE DEWATERING AND PIT SLOPE DEPRESSURIZATION

One of first steps in pit slope stability analyses is to understand the water pore pressures in the pit slopes as the result of mining and planned dewatering. As soon as the pit floor reaches levels below the water table, natural drainage of the wall will usually occur due to seepage and with response to mining which induces relaxation of the rock mass (Beale & Read, 2013). The natural drainage in conjunction with active dewatering (if implemented) will cause a reduction of pore pressures in the rock walls. The second step is to evaluate an effect of additional pore pressure reduction on the pit slopes and the necessity of implementing a depressurization program. In some cases, the pore pressure dissipation achieved by passive and active dewatering is adequate for targeting the desired pore pressure goals. In other cases, to achieve the dewatering goals, a dedicated pit slope depressurization program is needed.

Pit dewatering is a necessary element of any mining that occurs below the water table. Pit slope depressurization is an optional method for additional reduction of pore pressure within pit walls if this is required for geotechnical reasons. Table 1 shows a comparison of general mine dewatering and pit slope depressurization.

Table 1. Comparison of mine dewatering and pit slope depressurization

Parameter	Mine Dewatering	Slope Depressurization
Material/rock	High permeability	Low permeability
Target	Lower water table	Decrease effective stress of the slope materials
Volume of water	Often high	Normally low
Area of implementation	Normally pit-wide	Often local to a specific slope sector
Most common method	By in-pit sump and vertical wells	By horizontal drain holes or gravity flowing drains in conjunction with general mine dewatering

The ability to reduce pore pressure to achieve the desired target depends on hydraulic parameters, on timing, and on the

effectiveness of dewatering and depressurization methods.

3.1 Depressurization Parameters

Major depressurization parameters and pore pressure reduction can be illustrated by a simple 1-D Flow (or Diffusivity) Equation:

$$\Delta h(x,t) = \Delta h_o erfc\left(\frac{4Kt}{S_s x^2}\right)^{-(1/2)} \quad (7)$$

where:
Δh = change in hydraulic head;
Δh_o = initial hydraulic head;
K = hydraulic conductivity;
S_s = specific storage;
t = time;
x = distance; and
erfc (α) – function which increases when α decreases and decreases when α increases.

This simple relationship (Eq. 7) indicates that slope depressurization depends on hydraulic parameters, time of dewatering, and distance from the dewatering (or depressurization) system. The hydraulic parameters need to be known. Time and distance are the only two variables which allow control of the pit slope depressurization.

Figure 2 indicates that for the given hydraulic parameters (K and S_s) the degree of depressurization increases with time and decreases with distance from the dewatering system. Figure 3 shows that more successful depressurization is potential for more permeable rock and shorter distances from the dewatering system. Equation (7) illustrates the mechanism for pore pressure reduction but it should be noted that it is based on various assumptions (linear flow, homogeneity, isotropy) that are unlikely to be met in practice, given the complex hydrogeological conditions surrounding many mine sites.

A key factor for designing a slope depressurization program in poorly-permeable materials is the time required to achieve the target pore pressure profile for the critical sector of the pit. Slopes excavated in higher-permeable rocks typically require less time for the depressurization to be effective.

In poorly-permeable weak rock environments, such as an operation with deep weathered zones or thick zones of argillic (clay) altered rock, it can take months to years to depressurize the slopes to desired targets (Beale & Read, 2013). Depending on the time available, it may be necessary to advance a general dewatering program to lower the water table and to provide additional time for drainage of less permeable pit sectors.

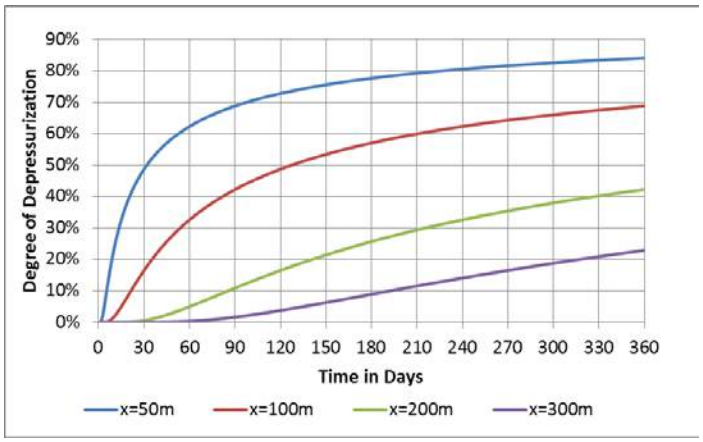

Figure 2. Pore pressure reduction vs. time and distance from dewatering (K=10^{-8} m/s, S_s=10^{-5} 1/m)

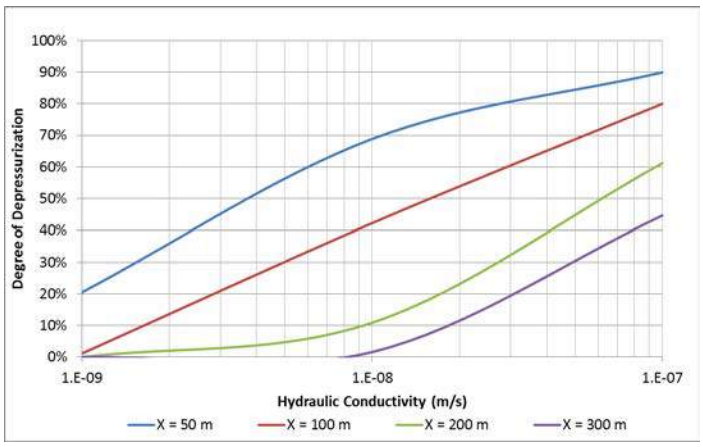

Figure 3. Pore pressure reduction as function of hydraulic conductivity and distance for 90 days of dewatering

3.2 Depressurization Methods

There are different methods of pit slope depressurization, which include:

1. Seepage from face and pumping from sumps.
2. Horizontal drain holes.
3. Gravity-flowing vertical drains.
4. Pumping wells.
5. Drainage tunnels with sub-vertical drain holes.

The first method is very common and used for passive dewatering or as part of active dewatering to intercept residual passive groundwater inflow coming to the open pit. The other methods allow for the addition of the reduction of pore pressures in the pit slopes to achieve the desired depressurization target. The choice of the best depressurization option, or a combination thereof, depends on the site specific hydrogeological, geological, structural, and geotechnical conditions which define the depressurization targets.

The use of horizontal drains or sub-horizontal drain holes (second method) is the most commonly applied method worldwide for locally reducing pore pressures behind open pit slopes. To install the drain holes, specific targets need to be identified. These targets may include:

- The water contained in low permeable material.
- Water trapped in permeable but compartmentalized fractures behind the pit slope.
- Water "dammed" behind geological structures.
- New geological units which will be encountered in pushbacks as the pit is expanded.

The effectiveness of the depressurization system from horizontal drain holes depends on the success of intersecting the defined targets and, in case of a low permeable pit slope, timing, distance between drain holes and their depth, hydraulic parameters, and the ability to discharge more water than recharged from precipitation and surface-water bodies.

3.3 Hydrogeological Characterization and Data Analysis

Hydrogeological parameters affecting pit slope stability include:

- Water levels;
- Distribution of hydraulic conductivity of rock within pit slope;
- Groundwater storage parameters; and
- Recharge from precipitation and surface-water bodies.

These parameters need to be determined during hydrogeological studies. Where it is possible, hydrogeological data should be collected during the early stages of the project and in conjunction with geotechnical studies. Table 2 summarizes content of hydrogeological studies for different stages of the project and targeted level of data confidence.

Table 2. Hydrogeological study and targeted level of data confidence

Project Stage	Hydrogeological Study	Targeted Level of Data Confidence
Conceptual	Regional groundwater survey; water level data collection in exploration holes; identification of hydrogeological units based on Geological Model	>20%
Pre-Feasibility	Mine scale airlift, pumping, packer testing and piezometer installation; initial hydrogeological parameters and groundwater flow understanding; initial hydrogeological database and conceptual model established; preliminary groundwater model and sensitivity analysis; initial assessment of dewatering and depressurization requirements	30-50%
Feasibility	Targeted pumping and airlift testing; piezometer installation; enhancement of hydrogeological database and 3D model; advancement of assessments of dewatering and depressurization requirements	40-65%
Design and Construction	Installation of dewatering wells and piezometers; refinement of hydrogeological database, 3D model, depressurization and dewatering requirements	65-75%
Operations	Ongoing management of piezometers and dewatering well network; continued refinement of hydrogeological database and 3D model	>75%

Note: Table modified by authors from Read and Stacey (2009)

4 GROUNDWATER MODELING AS A TOOL TO PREDICT PORE PRESSURES

Numerical groundwater modeling is widely used to simulate groundwater inflow to open pits for relatively complex hydrogeological conditions. The modeling process includes development of a conceptual hydrogeological model, grid discretization, assigning of hydraulic parameters and boundary conditions, model calibration, and prediction. Predictions very often include two scenarios:

- Passive inflow (or how much water will enter into the pit during its excavation without active dewatering/depressurization).
- Active dewatering to reduce residual passive inflow to the pit or active depressurization to reduce pore pressure for pit slope stability.

The active dewatering scenario is used when the rock within the pit slope is permeable and the amount of passive inflow cannot be managed safely during the mine operation. The active depressurization scenario is used when the rock within the pit slopes has low permeability, and high seepage face and pore pressures that are causing slope stability problems. The numerical groundwater models used for dewatering predictions are typically 3-D and developed at the regional scale with additional discretization around the pit both laterally and vertically. The discretization of regional dewatering models very often is not sufficient to precisely predict pore pressure distributions within the pit slopes. Therefore, 2-D cross sectional or 3-D (strip or asymmetrical) and more detailed pore pressure models are used along critical pit sections as “windows” within the regional groundwater model. These models use the hydraulic heads from the regional model to incorporate boundary conditions (sometimes variable in time) within pore pressure models. It should be noted that pore pressures in pit slopes and their changes as a result of depressurization should be predicted in time due to the fact that steady state calculations tend significantly to over predict dewatering and depressurization effects.

To evaluate the effect of depressurization parameters on pit slope stability through the calculation of the Factor of Safety (FoS), the authors developed a series of 3-D strip models. These models assume excavation of a 45 degree open pit to depths of 300m, 600m, and 1000m, in 3, 6, and 10 years (Figure 4 shows the finite-element mesh for the 1,000m pit).

Hydraulic conductivity values were varied from 10^{-9} m/s to 10^{-5} m/s (with an increase by a factor of 10; a total of 5 values were evaluated). Specific yield and specific storage were kept constant and equal to 0.05 and 10^{-6} 1/m, respectively.

The initial hydraulic heads were assumed to be 50m below the ground surface with constant-head boundary conditions at a significant distance (6km), from the center of the pit. Depending on the time and geometry of the excavations, different water levels can be predicted. Figure 4 shows the predicted water table (P=0 kPa curve) at the end of 10 years of excavation of the 1,000 m open pit, for different hydraulic conductivity values.

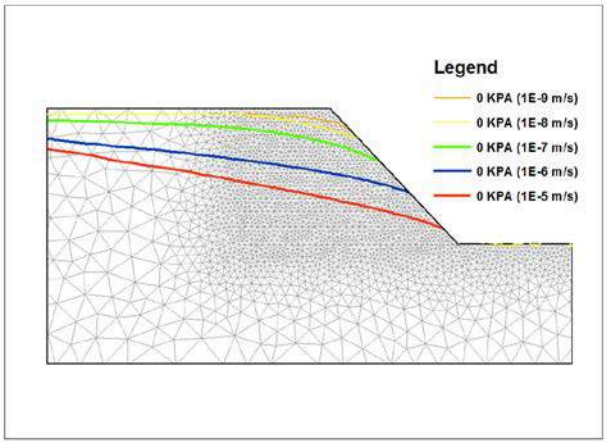

Figure 4. Predicted water table (P=0 kPa) at end of open pit excavation used for slope stability analysis

The numerical simulation provides the pore pressure distribution in the slope, which easily can be used for the slope stability analysis, as showed in Figure 5.

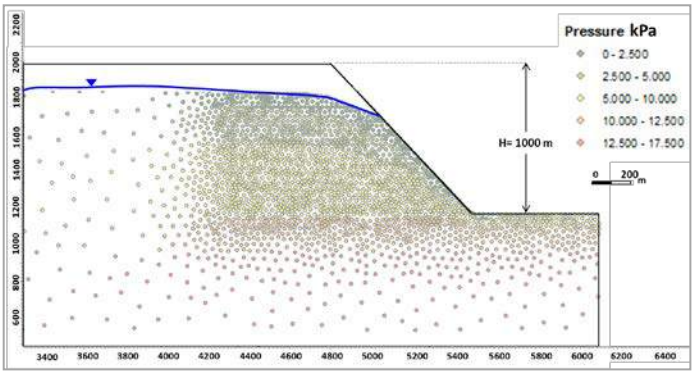

Figure 5. Pore pressure distribution at year 10 of pit excavation, K=10^{-8} m/s

Based on these models, the FoS of each pore pressure distribution was determined in order to demonstrate the effect of the hydraulic conductivity on pit slope stability. For this exercise, the simplified stability models considered the single rock mass medium to be continuous, isotropic, and lineally elastic, and assumed the lineal Mohr & Coulomb failure criteria to be valid and a good estimation of the rock mass strength.

Even though the described rock mass conditions are rarely found in the real world, this condition will be assumed valid for the purpose of this exercise.

Changes of hydraulic conductivity have a strong effect on the FoS. Figure 6 shows the FoS for 300m, 600m, and 1,000m pit slopes (excavated in 3, 6, and 10 yrs., respectively) as function of hydraulic conductivity. The geometry and the rock mass strength parameters were fixed for this example and a variable range of the hydraulic conductivity values were used to simulate the pore pressure field for each case.

This example does not intend to discuss the acceptability of the FoS given different pore pressure conditions; the chart, rather, shows the impact of the water pore pressure field, based on a large range of hydraulic conductivity, on the slope performance.

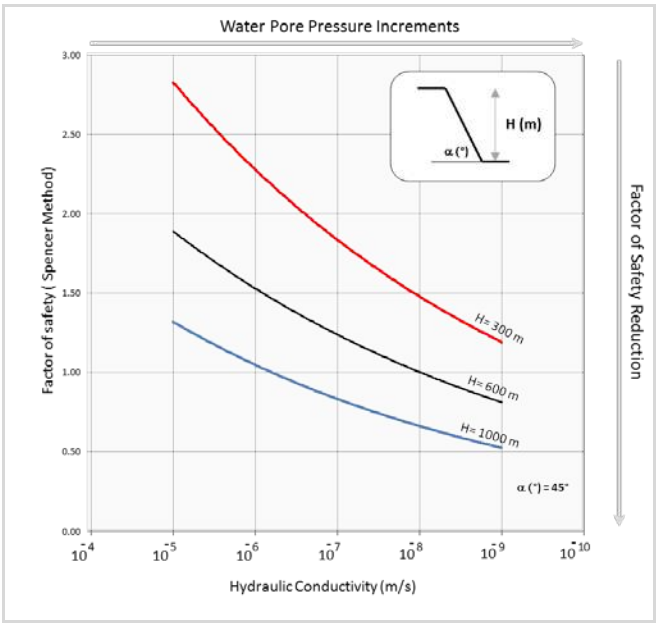

Figure 6. Relationship between FoS and hydraulic conductivity, obtained by using a test model.

The results of the test model indicate:

- Reduction of the hydraulic conductivity results in incremental increase of pore pressure within pit slopes. Therefore a reduction of the FoS is expected.
- Slopes less than 300m could be considered stable for rock with any hydraulic conductivity values, median pits (H is about 600m) requires additional depressurization for K<10^{-7} m/s, however for deep slope (1,000m) the FoS could be reduced to values below the limit of equilibrium (it should be noted that this statement is valid for only the test model used).
- In low permeable rock (*K* from 10^{-8} m/s to 10^{-9} m/s) increasing of FoS by additional pore pressure reduction could be not achievable due to required timing of depressurization and change of slope angle might be required, and should be reviewed in more detail.
- Figure 6 shows that the stability of the slope could depend upon the hydraulic conductivity at different heights. This example shows, for a medium size slope (H>600m), that a wrong assignment of the hydraulic conductivity can over or under estimates the slope angle, resulting in

extra capital cost, NPV of the project and/or safety issues, mining difficulties, negative impact on the mining plan and could jeopardize the mine reserves and the business.

5 HYDROGEOLOGICAL AND GEOTECHNICAL INTEGRATION

The success of an open pit mine design is based on quality, quantity and distribution of the geotechnical and hydrogeological data. Also, interpretation and modeling plays a "key" role in the final results. Today, mining companies have a clear understanding of the importance of data requirements, and extensive budgets are assigned to this task during different stages of the project. Unfortunately, there can be disconnection between the geotechnical and hydrogeological disciplines, affecting the final results. For example, hydrogeologists very often focus on dewatering and not on water pore-pressure modelling, placing more attention on high permeability units and not considering, in detail, the low permeable units, which might present problems for slope stability. Another example of this disconnect is reflected in the geotechnical design constraints; sometimes the geotechnical engineer's design assumes certain hydrogeological conditions, which are not achievable in reasonable time.

The disconnect between disciplines normally results in extra cost for drilling, opportunities lost for data collection, misunderstanding of the geotechnical requirements, use of non-achievable assumptions, missuses of the hydrogeological models, over or under estimation of the slope designs or excessive costs for missed selection of appropriate slope depressurization systems.

To minimize the negative impacts, it is important to recognize the need for the integration of both disciplines during each stage of the project.

Figure 7 below shows an integrated chart of geotechnical and hydrogeology processes for slope stability analysis recommended by the authors.

6 CONCLUSIONS

Integration of geotechnical and hydrogeological studies during different stages of the mining project can provide required hydrogeological input for slope stability analysis and pit optimization. At early stages of the project the Geotechnical Engineer needs to identify potential effects of pore pressure on slope stability, allowing the Hydrogeologist to characterize geotechnically important hydrogeological units. Data collected in the field need to be sufficient to develop reliable conceptual hydrogeological and numerical groundwater flow models to predict pore pressures in pit slopes during excavation and dewatering. At late stages of project development, these models should be sufficient to predict additional pit slope depressurization options (if they are necessary) and to define the required time for pore pressure reduction. These models, along with comprehensive sensitivity analysis of remaining uncertainties, should provide an input for cost-benefit analysis of implementation of pit slope depressurization. Numerical test modeling completed for this study indicates that for a medium- and high-permeable rock in a medium size slope (200 – 500 m height), there is significant impact of hydraulic conductivity on slope performance. This indicates that the accuracy of the hydrogeological inputs, and the interpretation and the modelling of the hydrogeological conditions are essential during the geotechnical investigation.

For saturated or partially saturated slopes, rock engineering experience establishes that a reduction of water pore pressure will improve the results of the slope performance parameters, creating the opportunity to optimize slope designs. Unfortunately, in some cases the slope depressurization requirements are not properly assessed due to lack of hydrogeological understanding, hydrogeological modelling objectives and, in some cases, due to miscommunication between the Hydrogeologist and rock mechanics Engineers. This disconnection between the hydrogeological and rock

mechanics teams results in a potential of over or under estimation of slope designs. In order to avoid this, it is useful to consider the following questions:

- What will pore pressures be in the ultimate pit slope and how will they change in time during planned mining/dewatering?
- What would be the effect of pore pressure reduction on slope stability?
- How much time is required to reduce pore pressure?

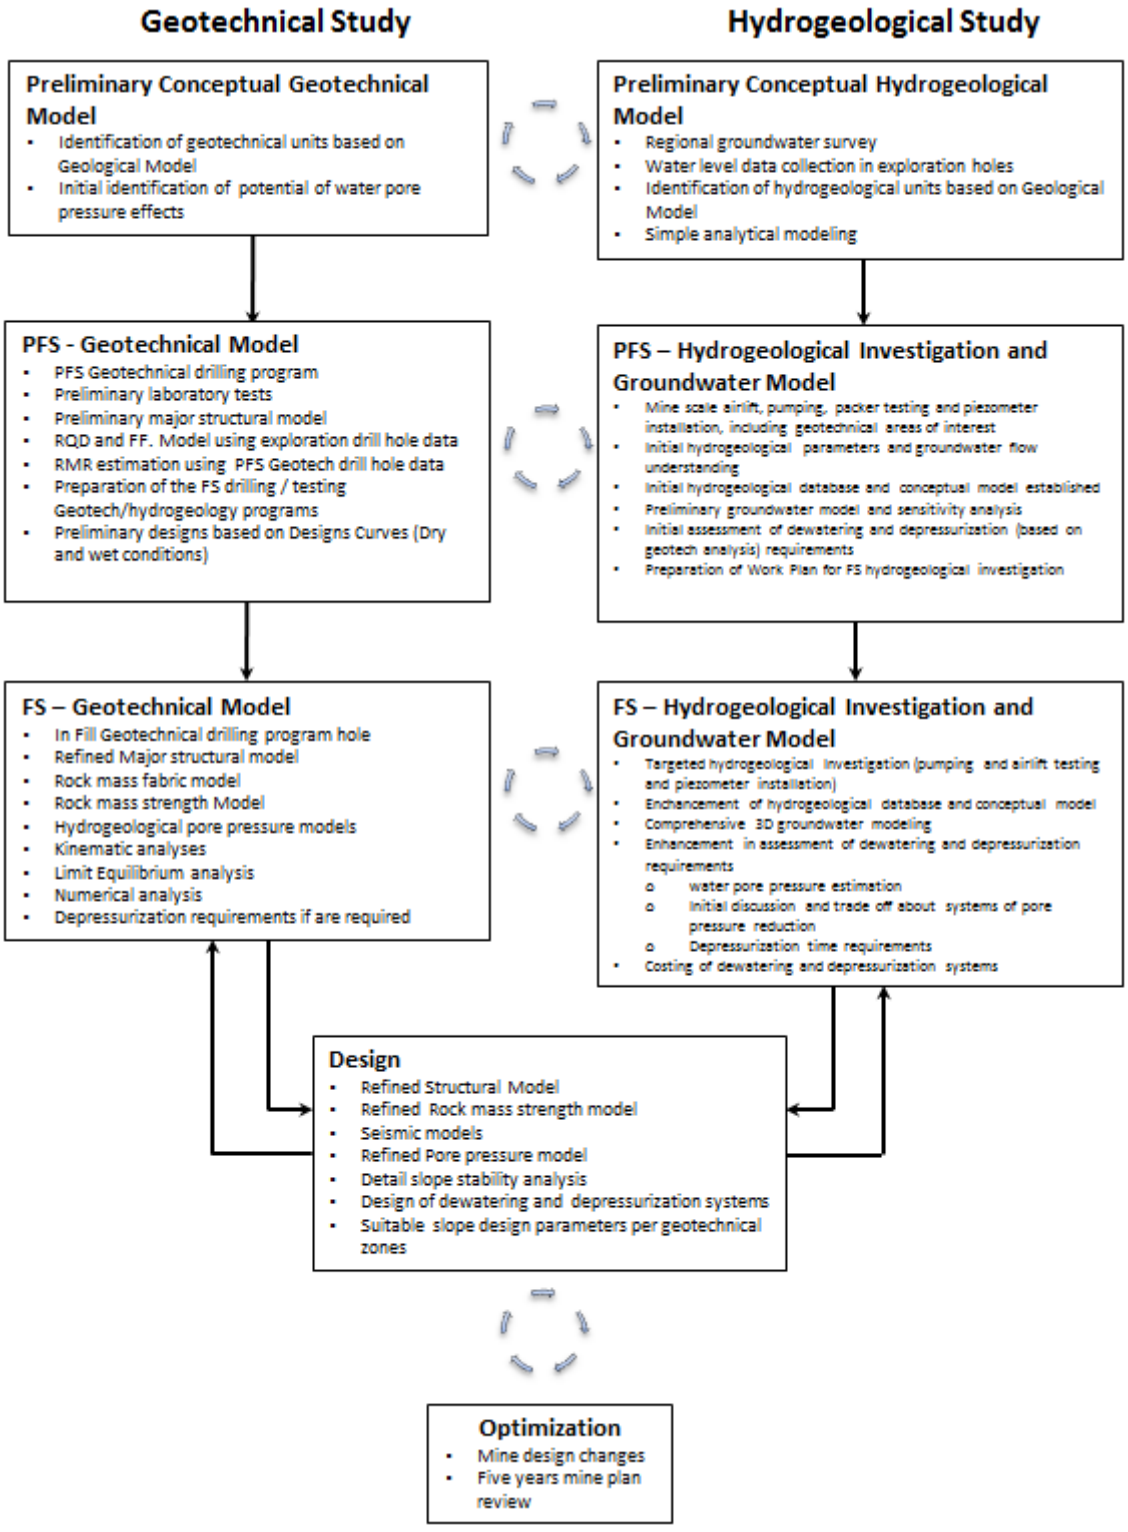

Figure 7. Integration of geotechnical and hydrogeological studies during different stages of the project (PFS: Prefeasibility Study, FS: Feasibility Study)

- Is the time required for depressurization in alignment with the mine plan and life of the mine?
- Is the knowledge regarding the hydraulic parameters sufficient for constructing a detail model to simulate the depressurization requirements?
- Does the mine plan have the flexibility to develop a proper depressurization plan?
- What depressurization method is the best for site specific hydrogeological conditions?
- What is the cost-benefit of implementation of pit slope depressurization?

These questions must be addressed in detail before moving forward to more detailed engineering.

Slope engineering is a common effort between different disciplines, and the understanding of each of the disciplines is critical in determining the final results. Also, the design process should be considered as an iterative process, where the integration between Geotech - Hydrogeology and Mine plan areas is a key in the mining cycle

Prediction of Open Pit Mine Slope Variation Based on Geo-Mechanical Uncertainty using Artificial Neural Network (ANN)

A.R. Kamrani, M. Osanloo, M.Minaei Mobtaker
Amirkabir University of Technology, Tehran, Iran

ABSTRACT This paper develops a model to predict open pit's slope under uncertainty condition using artificial neural network (ANN) and the defect of probabilities method is solved. Due to high cost for data collection and lack of sufficient and accurate data for ANN training, conditional random simulation is used for generating random geomechanical parameters data. Then for each group of random numbers, the stable slope angle is calculated based on specified factor of safety (FOS). In final stage, using artificial neural network, stable slope angle based on variety of geomechanical parameters is predicted. This method was applied to collected data from the great wall of Sungun copper mine in Iran. The outputs of ANN i.e. the stable slope angles, demonstrate that cohesion and internal friction angle are the most sensitive parameters respectively. It also shown that change in unit weight do not change the stable slope more than 1 degree. These results which was obtained from ANN fitted on what's conventional methods proof, completely.

Keywords: Artificial neural network, open pit slope, geomechanical uncertanity

1 INTRODUCTION

Open pit mine slope is one of the major parameter which influence on determination of ultimate pit limit. Nowadays due to metal's price increment and mineral consumption, depth of open pit mine is going to increase. On the other side, slope instability is a reason of several problems in open pit mining. Cost imposing, losing whole or some part of available ore, human safety problems and losing whole or some equipment and facilities may be forced mine to close prematurely. Consuming time to separate ore from waste and repairing the roads is another consequence of slope failure. These situations lead to additional dangerous and risk for open pit mine slope determination. So the outcome of slope failure like the huge mass of rock fall from high altitude similar to what's happen for Palabora (2003) and Bingham Canyon (2013) mines, can be divided into three principal issues: social/safety, economic and environment (Read & Stacy, 2009). Regarding to mentioned factors, studying on stable slope in open pit mines is important even during exploitation stage.

Rock's geomechanical uncertainties exist as a comprehensive system with all physical and mechanical properties changes in a non-fixed manner and dynamic process, during the project's life time (Ghanem & Spanos, 2003). In fact being randomness and uncertainty in the rock mass properties are the most important factors which affect reliability of safety factor (Peng & Jian, 2011). With respect to high sensitivity of stable slopes to geomechanical parameters, uncertainty play major role in pit slope design. Geomechanical uncertainties come from three sources: (1) lack of sufficient number of samples, (2) error on calculation of rock mass properties and (3) in most of the cases the laboratory measurement of rock property has no consistency with rock insitu condition. By decreasing 20% in strength parameters of rock mass, failure probability grows 8.4 times more than previous mode (Dianqing et al. 2011).

Pit slope influence on stripping ratio (waste/ore) and on quality of mineable reserve. Depend upon on types of ore, hanging wall and footwall material, open pit slope is ranged between 30 up to 55 degrees.

Highest pit slope will cause lower W/O and more mineable reserve exploitation. But it must be stable according to uncertainty and unreliability of the strength and mechanical rock or soil parameters. There is also some correspondence between the steepest and highest stable slopes for both natural and man-made slopes (Wyllie & Mah, 2005). In other words one of the important parameter on slope stability is height of wall or depth of mine. There are several methods have been developed during last decades to estimate pit stable slope. Probabilistic method is one way to design stable slope without uncertainty and overcome this difficulty.

Tobutt (1982) uses Monte Carlo simulation to calculate the probability of failure and Bishop simplified formula used to determine the most critical slip circle. He proposed using this method rather than conventional method for probability calculation. From that time, many researches have been carried out with Monte Carlo simulation and the stability of slopes were analyzed in probabilistic method (Griffiths & Fenton, 2004; El-Ramly & Morgenstern & Cruden, 2005; Xu & Low, 2006; Afrapoli & Osanloo, 2014). But the main disadvantage of this method is how the probabilities will change with variation of input parameters. If the system is changed, the procedure must be repeated in order to determine the effect on response statistics and probabilities (Fenton & Griffith, 2008). For that reason ANN has been applied to satisfy the need for stable slope predictability.

Application of artificial neural network (ANN) in rock mechanic as a pattern recognition or non-linear function prediction with quantity or quality parameters are vast. As an example Erzin & Cetin (2013) predicted the critical FOS for a limited slope with multiple-regression and ANN. They show that ANN have more accurate results compared to multiple-regression. Also ANN was used in probability slope stability analysis conjugated with Monte Carlo simulation (Sung, 2009). Creating qualitative index for open pit mine slope instability based on fully coupled model and various case studies from all around the world is presented by Naghadehi, et al. (2013). The author uses ANN in order to find out the relation between each couple.

2 METHODOLOGY

Figure 1 shows the algorithm of the developed model.

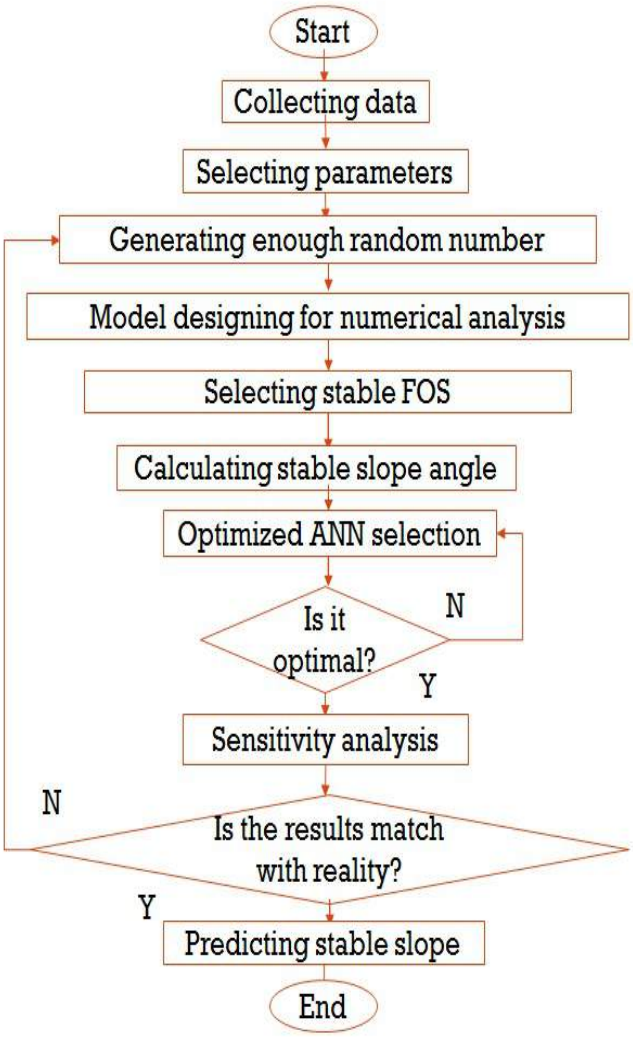

Figure 1. Algorithm of the proposed model

2.1 FOS Calculation

The first effort to provide a stable slope is measurement of resistance and disturbance forces and calculating FOS. There are several methods for FOS calculation such as limit equilibrium method or failure surface determination like Janbu and Bishop Methods or strength reduction method (SRM) which is used by numerical analysis software (e.g. FLAC, 3DEC, PHASE2). Despite of these discrepancies between methods, the logic which governing them is same: if the resisting and disturbing forces is

equal, the FOS will be 1. In this case, slope is in the state of slip and reduction in slope angle or stabilization is needed till FOS gets bigger than 1. However the amount of this growth is the biggest challenge and it depends on risk acceptance of decision makers and depth accessibility. In comparison with all FOS determination methods, Hoek suggested the SRM. Because it includes all benefits of limit equilibrium analysis and it allows the user to study slope displacements that are critical in the evaluation of open pit stability (Hoek, 2009).

The basic concept of strength reduction method (SRM) is:

1- The strength parameters of a slope are reduced by a certain factor (SRF), and the finite element/finite difference stress analysis is computed.
2- This process is repeated for different values of SRF, until the model becomes unstable (the analysis result do not coverage).
3- This determines the critical strength reduction factor (critical SRF) or safety factor of the slope (Rocscience Inc, 2010).

FLAC uses the SRM and the FOS is calculated according to 1, 2 and 3 equations:

$$C^{trial} = \frac{1}{F^{trial}} C \quad (1)$$

$$\varphi^{trial} = arc\ tan(\frac{1}{F^{trial}}\ tan\varphi) \quad (2)$$

$$\sigma_t^{trial} = \frac{1}{F^{trial}}\ \sigma_t \quad (3)$$

Which:

C is cohesion (MPa)

φ is friction angle (degree)

σ_t which is tensile strength (MPa)

By reducing C, φ and σ_t and using trial values of F_s^{trial} continuously, failure occurs. If the slope is initially unstable, C, φ and σ_t will be increased until the limiting condition is found. Note that using σ_t relation is optional, but in this study is considered.

As mentioned before, FOS is an uncertain parameter itself and this study focuses on uncertainty of geomechanical parameters so an appropriate amount of FOS should be selected and the stable slope angle evaluated.

2.2 Artificial Neural Networks

A typical structure of ANNs consists of a number of processing elements, or neuron, that are usually arranged in layers: an input layer, an output layer and one or more hidden layers (Figure 2).

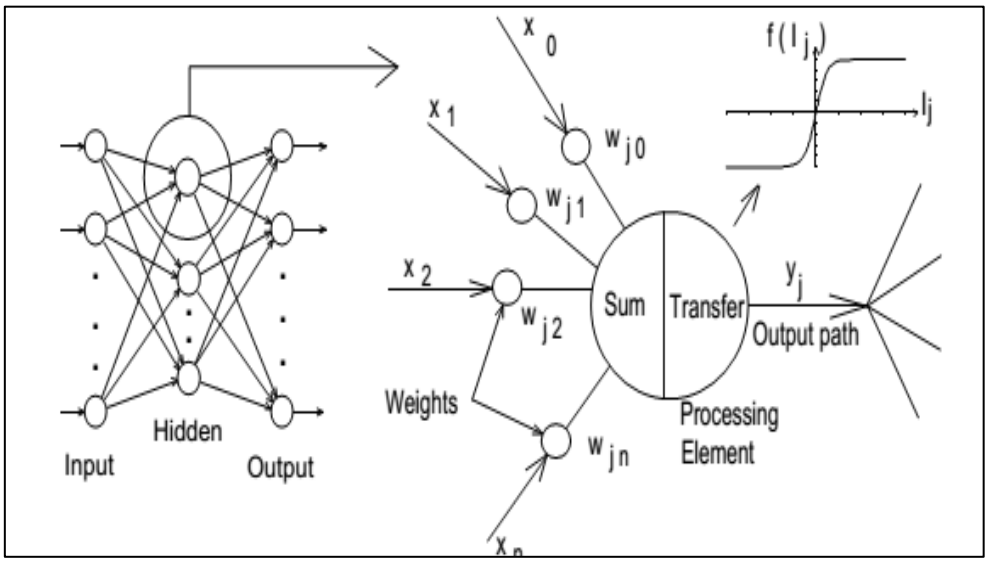

Figure 2. A typical ANN structure (Shahin, et al., 2001)

The input from each neuron in the previous layer (x_i) is multiplied by an adjustable connection weight (w_{ji}). At each neuron, the weighted input signals are summed and a threshold value which is called bias (B_j) is added. This combined input (I_j) is then passed through a non-linear

transfer function (f (.)) to produce the output of the neuron (y_j).

The output of one neuron provides the input to the neurons in the next layer. This process is summarized in Equations 4 and 5 and illustrated in Figure 2 (Shahin, et al., 2001).

$$I_j = \sum w_{ij}\, x_i + B_j \quad (4)$$

$$y_j = f(I_j) \quad (5)$$

The number of required data for ANN training should be far enough. Providing adequate data needs having enough case analysis. Otherwise to provide data, generating random numbers considering its statistical distribution will be used.

3 CASE STUDY

Sungun copper mine locates in northwest Azerbaijan province of Iran. The mine is near to the boundary of Azerbaijan and Armenia as shown in figure 3. Sungun copper mine is one of the biggest open pit mines in Iran. The history of exploitation in Sungun back to 200 years ago. Old evidence across the Sungun River shows that underground mining method was used for ore extraction.

Figure 3. Sungun copper mine location

One of the critical pit wall of Sungun copper mine is wall RS03 which is located in southwest of mine and its height is 700 meter. This wall is the biggest mine wall in Iran which is used as case study in this paper. Figure 4 shows the location of this wall in Sungun copper mine.

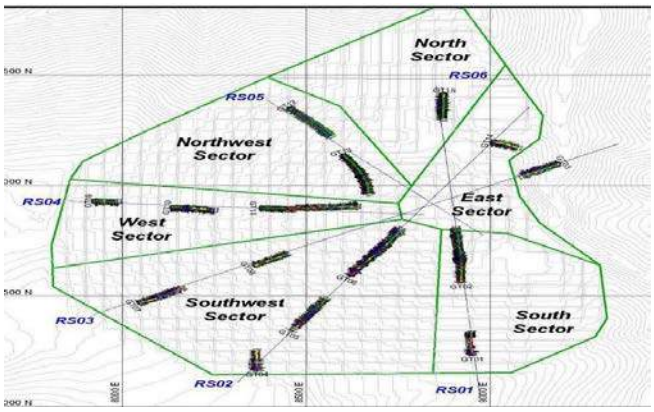

Figure 4. Location of RS03 in Sungun copper mine of Iran

4 MODEL APPLICATION

The RS03 pit wall of Sungun open pit mine was selected for application of the model. Table 1 shows the five geomechanical parameters that were tested, and their mean and standard deviation. According to the latest studies, the selected slope angle for this wall is 30 degrees and its FOS is 1.3 (srk consulting, 2008). The slope is stable only when drainage is performed.

Table 1. Mean and standard deviation of Sungun geomechanical parameters

	σ_t (MPa)	E (MPa)	phi	C (KPa)	Unit Weight (KN/m^3)
Mean	0.039	3061.167	36.285	662.142	24.466
Standard deviation	0.053	3790.032	12.592	320.790	2.059

Figure 5 shows the model which is designed by FLAC3D 5.0. Point A display where slope angle changes till the FOS of 1.3 is achieved.

In case of ANN training due to lack of experimental information, 00 group of parameters were generated randomly and for this operation conditional simulation was used.

A random field which takes on certain known values at specific points in the field is

called a conditional random field $Z_c(x)$. It takes on specific values $Z(x_a)$ at the measurement locations x_a, a = 1,2,…,n_k, where n_k is the number of measurement locations. Mathematically,

$$Z_c(x) = \{Z(x) \mid Z(x_a), a = 1,2,\ldots,n_k\}$$

To accomplish the conditional simulation, the random field will be separated into two parts spatially: (1) x_a , a = 1, 2, …, n_k, being those points at which measurements have been taken, and at which the random field takes on deterministic values $Z(x_a)$, and (2) x_η, η = 1,2,…, N-n_k , being those points at which we wish to simulate realization of their possible random values. The conditional random field is simply formed from three components in equation 6:

$$Z_c(x) = Z_u(x) + [Z_k(x) - Z_s(x)] \quad (6)$$

$Z_c(x)$ = desired conditional simulation
$Z_u(x)$ = unconditional simulation
$Z_k(x)$ = best linear unbiased estimate of field based on known (measured) values at x_a
$Z_s(x)$ = best linear unbiased estimate of field based on unconditional simulation values at x_a (Fenton & Griffith, 2008).

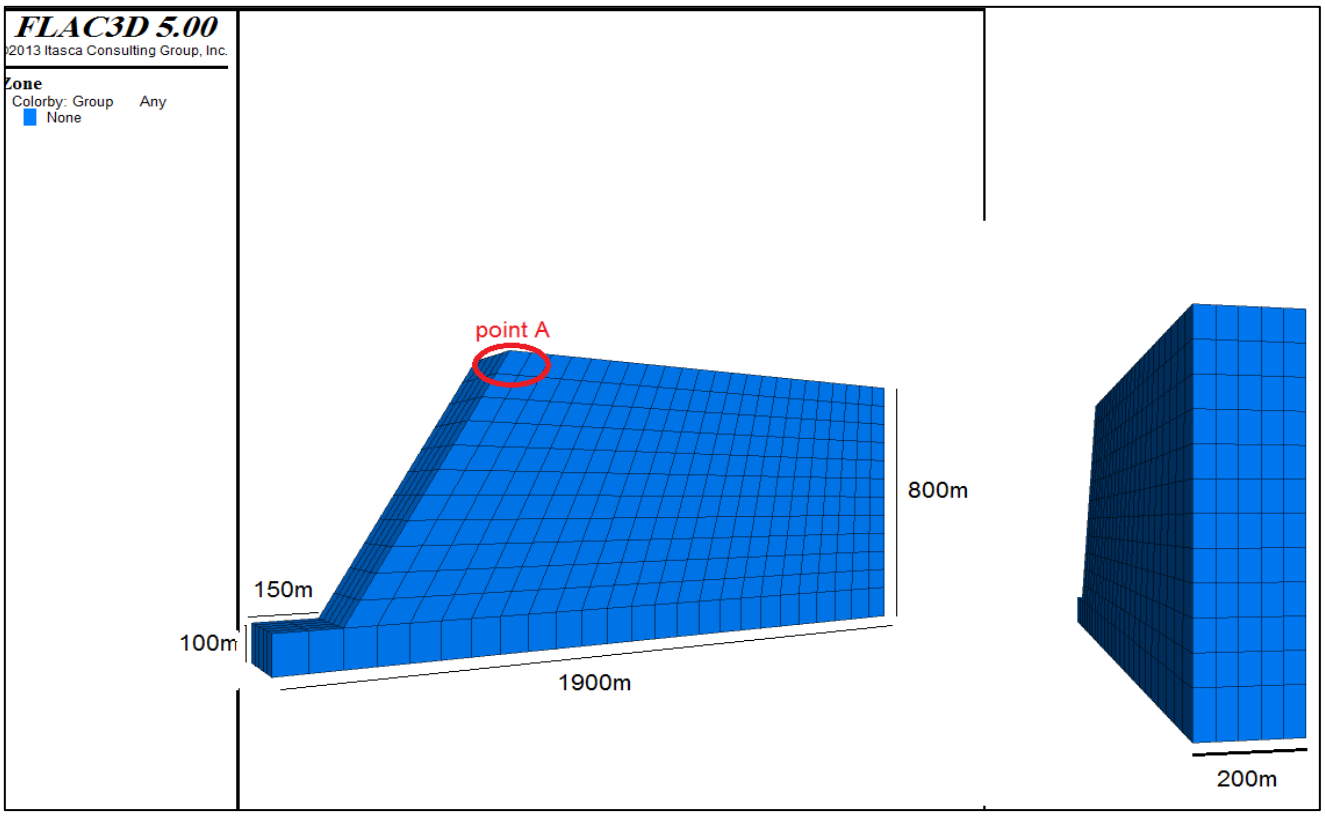

Figure 5. Slope model in FLAC

4.1 **ANN** optimization

Selection of the suitable type of network from a variety of neural networks is the first step for using ANN. Determining the application of neural networks in the problem, can be solution of this option. Back propagation error networks is capable of approximating any function with limited discontinuity points. The next step is selecting training method. Here to prevent the occurrence of over-fitting due to the low numbers of data, Bayesian framework method was used.

Bayesian framework has a simple concept. The typical performance function used for training feed forward neural networks is the Figure 6. Comparison between ANN predicted angle and FLAC calculated angle mean sum of squares of the network errors that is obtained from equation 7.

$$F = mse = \frac{1}{N}\sum_{i=1}^{N}(e_i)^2 = \frac{1}{N}\sum_{i=1}^{N}(t_i - a_i)^2 \quad (7)$$

Where **F** is error function, **mse** is sum of mean square error, **N** is the number of samples, **t** is the target value and **a** is obtained value.

It is possible to improve generalization if the performance function is modified by adding a term that consists of the mean of the sum of squares of the network weights and biases. Equation 8 shows this relation:

$$msereg = \gamma mse + (1-\gamma)msw \quad (8)$$

Where: **msereg** is modified performance function, γ is the performance ratio and **msw** is sum of mean square weights and its formulation is equation 9.

$$msw = \frac{1}{n}\sum_{j=1}^{n} w_j^2 \quad (9)$$

Where: **n** is total samples and **w** is the weight of each sample.

Bayesian framework assigns random values for the modified performance function (msereg) to find a more accurate weights and biases for the network and optimize it more efficiency.

Using this performance function causes the network to have smaller weights and biases, and this forces the network response to be smoother and less likely to over fit.

Transfer function and number of hidden layer and neurons should be selected in a way that optimized network obtained. Many researchers believe that these values can be catch only with trial and error (Zhou & Wu, 1994; Sung, 2009; Erzin & Cetin, 2013). The efficient amount of hidden layer is ranged between 2 or 3 (Zhou & Wu, 1994). So a program was written that determine the best network. Table 2 shows the optimized network which was calculated by the program. Also figure 6 shows the comparison between ANN predicted angle and FLAC calculated angle.

Table 2. The optimized ANN parameters

No.layer	**1**	**2**	**3**	**4**	**Output layer**
No.neuron	8	14	18	19	-
Transfer function	logsig	logsig	logsig	logsig	tansig

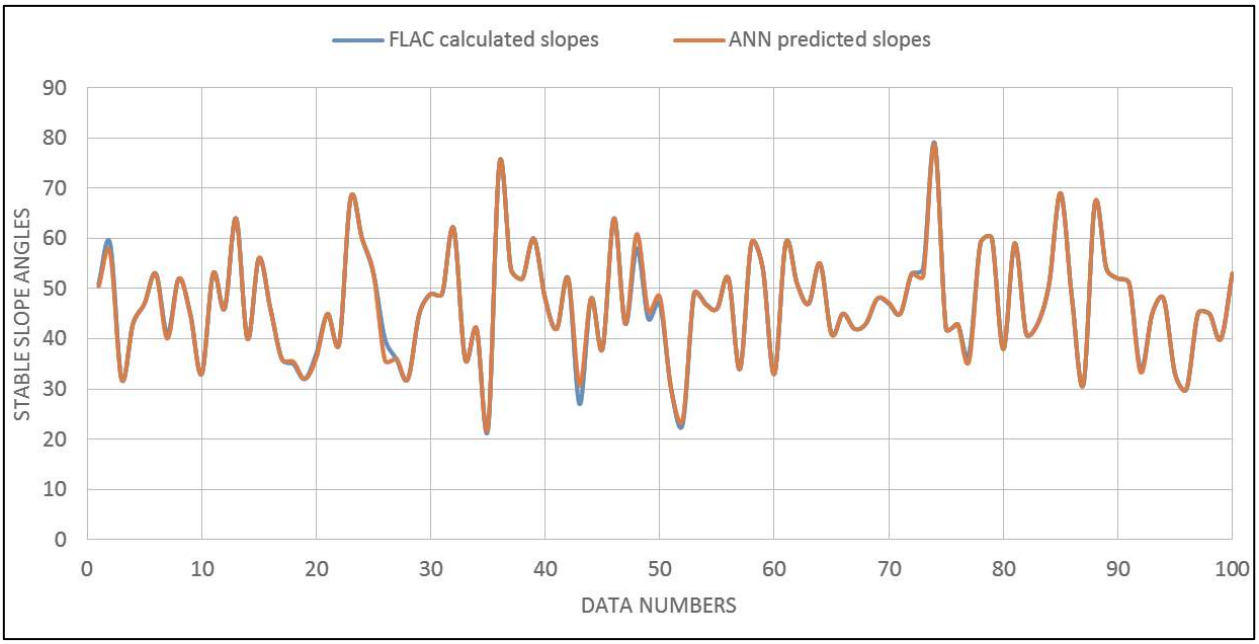

Figure 6. Comparison between ANN predicted angle and FLAC calculated angle

4.2 Sensitivity Analysis of Parameters

For training network in Bayesian framework the inputs and outputs data converted into [-1,1] range. The error of optimized network became 0.000632838. A sensitivity analysis was executed on geomechanical parameters of Dyke 1A (DK1A) lithology. With changing in parameters the predicted stable slope of different properties is compared with each other to find the most effective parameter. Table 3 shows the properties of

DK1A which was used for sensitivity analysis.

In this sensitivity analysis some of the parameters doubled (e.g. E,σ_t,C) and for some others the maximum amount were placed (e.g. φ, ρ). Table 4 shows the results of this sensitivity analysis.

Table 3. Geomechanical parameters of DK1A lithology

Lithology	E_m (MPa)	σ_t (MPa)	Phi (φ)	C (KPa)	Unit Weight (ρ) (MN/m^3)	UCS mean (MPa)
DK1A	854	0.006	34	572	0.024	50

Table 4. Sensitivity analysis results

	DK1A parameters	High unit weight	Double bulk and shear modulus	Double cohesion	High friction angle	Double tensile strength
unit weight (Kg/m^3)	2400	2640	2400	2400	2400	2400
Bulk modulus (MPa)	711.67	711.67	1423.33	711.67	711.67	711.67
shear modulus (MPa)	328.46	328.46	656.92	328.46	328.46	328.46
Cohesion (KPa)	572	572	572	1144	572	572
Internal friction angle	34	34	34	34	58	34
Tensile strength (MPa)	0.006	0.006	0.006	0.006	0.006	0.012
Slope angle (degree)	33.59	31.96	34.62	46.21	56.35	34.62

5 CONCLUSION

The objective of this study is to develop a model that uses ANN to predict stable slope and overcome to uncertainty of geomechanical parameters. Accordingly FOS calculation based on SRM was described and for compensation of lack of data in the model application, conditional simulation was used. About the ANN optimization some technique like Bayesian framework was applied. Then geomechanical parameters as an input and stable slope angles as an output were trained to an optimized ANN. The following results were obtained from sensitivity analysis

- The cohesion and friction angle (C, φ) have the greatest effect.
- The tensile strength has the lowest effect but it can't be ignore at all.
- The negative impact of unit weight with respect to height of wall was not significant and can be neglected.

Agreement of sensitivity analysis with facts shows that ANN training process performed successfully. It also indicates that the network estimates function very well. The uncertainty problem is solved with prediction capability of neural network respectively. So with the new data will be treated in two ways: 1st, the stable slope is predicted. 2nd, the new data retrain to the network to provide the network with greater precision.

M. Ozyurt
Bilfer Mining Inc., Ankara

ABSTRACT With an increase in the overall slope height of open pit mines, stability analysis and amount of stripping waste rock becomes progressively difficult. It is necessary to optimize the overall slope angle by increasing it as much as possible with ensuring the mining safety. After comprehensive geotechnical investigation and rock mechanical laboratory tests, the combined use of limit equilibrium and numerical modeling analysis methods increases reliability and accuracy of the stability analysis. With the optimum slope design in Bizmişen iron ore mine, there will be a significant decrease in production cost and in the amount of stripping.

Keywords: Open-pit mining, rock slope stability, overall slope angle, limit equilibrium method, numerical modeling, factor of safety

ÖZET Açık ocaklarda genel ocak derinliğinin artması, stabilite analizlerini ve pasa miktarını artan bir biçimde zorlaştırmaktadır. Madencilik güvenliğini sağlayarak, genel ocak eğim açısını mümkün olduğunca büyük tutmak optimum ocak açısı tasarımı için gereklidir. Jeoteknik incelemeler ve kaya mekaniği laboratuvar testleri sonrasında, limit denge ve numerik modelleme analiz yöntemlerinin birleşik kullanımı duraylılık analizinin güvenilirliğini ve doğruluğunu arttırır. İdeal şev tasarımı ile Bizmişen demir ocağında, üretim maliyetini ve dekapaj miktarını önemli bir derecede azaltacaktır.

1 INTRODUCTION

Huge amount of minerals are exploited from the ground by open pit mining activities. With an increase in mining operations, the depth of open pit mines are getting deeper so that pit slope stability has become significant for long term sustainability. Since mining excavations are getting more difficult due to higher slope angle, stability and safety evaluations are essentially considered from the economic point of view. However, increasing overall slope angle as steep as possible is a crucial way to minimize the amount of stripped waste rock and reduce the production cost providing that the mining operations are carried out under safe conditions. Therefore, it is necessary to make optimum slope angle design for deep open pit mines. The height of final slope of a planned iron ore mine in Bizmişen region reaches its peak value of 400 m at the deepest side. The mine will be one of the deepest open pit mines in Turkey. For a large scale open pit mine which is case in point,

increasing the overall slope angle by 1° will reduce approximately 3 million m^3 of waste rock and results an economic benefit around 10 million American dollars. Hence, slope design is supposed to be optimized by increasing the economic efficiency without endangering safety conditions.

2 GEOTECHNICAL SITE CHARACTERIZATION

In the present work, overall slope angle optimization studies were carried out for the intended Bizmişen open pit mines, situates in the Eastern Turkey. To determine quality of the rock mass, geotechnical site survey around the region and geotechnical borehole core logging were conducted. Additionally, in order to determine the physico-mechanical properties of the rock materials with the help of laboratory tests, core samples from the logged drill holes and rock blocks were taken directly from the mine site.

2.1 Geotechnical Survey

In the region, according to the reserve estimation studies, multiple open pit requirement is decided to extract the orebody. Thus, field geological investigations for each planned open pits were carried out and some technical visits were conducted. Slope faces in which prior and present mining activities carried out were investigated to determine the rock mass characteristics around the site. During investigations, geological strength index (GSI) values were assigned for the dominating rock masses. The rock mass properties required for numerical analysis were assigned as suggested by Hoek *et al.* (2005).

Besides field investigations, geotechnical logging was performed with representative drillholes. To increase the accuracy and reliability as much logging study as possible was carried out and plenty of samples were taken for laboratory experiments. To designate the rock mass quality, Rock mass rating (RMR) proposed by Bieniawski (1989) and Q-system proposed by Barton *et al*., (1974) values for all dominating lithology around the region were also determined as a result of geotechnical logging. The average RMR and Q values for footwall, ore and hangingwall are presented in Table 1.

With the combined work of field observations and geotechnical logging, rock mass properties and rock quality characterization were constituted for Bizmişen region prior to stability analysis and optimization of slope angle. Regarding the characteristics of dominating rock formations, the assigned average GSI values for footwall, ore and hanging wall are given in Table 1.

Table 1. Assigned average RMR, Q and GSI values.

	RMR	**Q**	**GSI**
Footwall	60	4.28	57
Ore	55	3.22	55
Hanging wall	48	2.57	48

Additionally, since the hydrologic studies assist to gain a general comprehension of regional groundwater trends, during the technical investigations around the mine sites, hydrologic information was obtained and implemented into numerical modeling.

2.2 Laboratory Studies

For stability analysis of the slope and optimum design of the slope angle, comprehensive laboratory tests with 426 rock specimens taken from the cored exploration drillings were carried out. Based on the laboratory experiment results, rock material properties were determined. Unit weight (γ), Poisson's ratio (ν), Young's modulus (E), indirect tensile strength (σ_t), uniaxial compressive strength (σ_c), and mi constants were obtained by means of conducting the related laboratory work and the results are shown in Table 2.

Table 2. Rock material properties of slope rock masses dominating in the region

Lithology	γ (kN/m^3)	ν	E (GPa)	σ_t (MPa)	σ_c (MPa)	m_i
Footwall	26.90	0.08	36.05	13.19	123.9	37
Ore	39.48	0.10	26.68	14.30	58.3	27
Hanging wall	25.00	0.14	7.81	3.46	17.1	10

3 ROCK MASS PROPERTIES AND MODELING METHODOLOGY

Since the mine slope presents a closed-oval shape and its range is very large, the ultimate slope depth differs due to topography. The most appropriate way to carry out stability analysis is to choose the critical section including the deepest level of the open pit mine. For convenient and reliable optimum design of the slope, critical cross-section is schemed with respect to 7 various overall slope angle, between 36° and 42°.

To carry out stability analysis by using the Mohr-Coulomb failure criterion, design input parameters such as cohesion (c) and internal friction angle (Ø) were calculated as suggested by Hoek et al., (2002). Since harsh climate conditions and atmospheric actions around the region may lead to occur alteration for the shallower slopes, rock mass quality characterization was adjusted with respect to the mining depth. According to the laboratory experiment results and geotechnical site characterization studies, equivalent cohesion and friction angle (Hoek *et al*., 2002) for the hanging wall in which slope would be constructed are determined as 715 kPa and 19.6° respectively.

4 STABILITY ANALYSIS AND OPTIMUM DESIGN OF THE SLOPE

Different options are available to investigate the slope stability analysis. Limit equilibrium method is a conventional approach, it can provide information about the potential for slope failure. Numerical modeling is another one, it may assist further analysis of a more complex mechanism. Optimum design can be achieved with the combined use of limit equilibrium method and numerical modeling.

4.1 Stability Analysis by Limit Equilibrium Method

The traditional limit equilibrium method depends upon the force and moment equilibrium method. Factor of safety (FOS) value, a ratio of resisting forces to driving forces, can be determined by means of this method. As a principle, a possible failure surface is assumed and the rock mass above the surface is considered as a free body. The critical factor of safety is determined by ensuring that the rock mass can maintain the stability on the assumed possible failure surface (Read and Stacey, 2010). Although, the method provides a fast computation time, the application of the method is greatly restricted since it cannot analyze the indication of instability mechanism. Determination of displacement or deformation is not possible due to not taking into consideration the in-situ stress-state.

Several approaches based on method of slices were proposed by some researchers for limit equilibrium method. Spencer (1967), simplified Bishop (1955), and GLE/Morgenstern-Price (1965) are the most widely used techniques for stability analysis and optimum design of the slope.

Computation results of the stability analysis of optimized slope angles made by Slide v6.0 (2014) are shown in Table 3. Based on the safety requirement of the engineering, the minimum value of factor of safety is considered as 1.2 (Hoek and Bray, 1981).

It can be seen from Table 3, the factor of safety decreases as the overall slope angle increases. The results obtained using different techniques are close to each other and range from 1.106 to 1.283 depending on

the overall slope angle. As mentioned above the required FOS value is considered as 1.2 and it can only be obtained for overall slope angle of 36°.

Table 3. Factor of safety (FOS) computation results by limit equilibrium analysis for critical section with various overall slope angle

Overall slope angle	GLE/Morgenstern-Price	Bishop	Spencer
33	1.278	1.283	1.281
33	1.257	1.261	1.259
34	1.233	1.236	1.235
35	1.217	1.219	1.218
36	1.202	1.204	1.204
37	1.193	1.196	1.193
38	1.168	1.173	1.169
39	1.152	1.156	1.152
40	1.135	1.138	1.135
41	1.120	1.124	1.118
42	1.106	1.111	1.108

The relationship between factor of safety, overall slope angle and the approximate amount of stripping is given in Figure 1. The minimum suggested FOS value 1.2 is only obtained for overall slope angle of 36° or lower. On the other hand as the overall slope angle decreases, the amount of stripping material increases. Therefore for safe working conditions with minimum stripping 36° seems to be optimum overall slope angle for the Dönentaş open pit mine in Bizmişen region.

4.2 Stability Analysis by Numerical Modeling

Although limit equilibrium methods of analysis such as the method of slices are simple to use, the assessment of displacement or the development of failure surface are not possible. By considering the slopes composed of formations having complex material properties, limit equilibrium method can be found insufficient

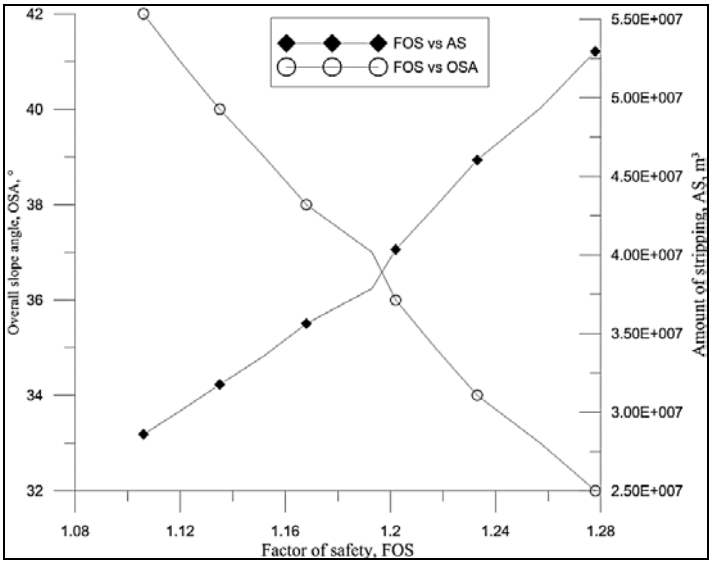

Figure 1. Overall slope angle factor of safety and amount of stripping relations.

For models with geological complexity, numerical modeling provides an insight by using the theoretical system of stress-strain relations considering the actual conditions. In order to estimate the shape of failure surface and the corresponding stability coefficient of the rock mass strength reduction method is mostly used. Strength reduction factor (SRF), which is equal or slightly less than FOS, is determined by reducing the cohesion and friction angle gradually when the non-convergence of nonlinear finite element appears, the slope is considered as unstable state and the reduction factor is determined (Zienkiewicz *et al.*, 1975). Moreover, since failure surface does not need to be assumed, the distribution of stress and deformation which has a significant influence on the initiation and growth of the failure surface can be obtained by using this method.

According to the preliminary analysis by limit equilibrium method, the ultimate slope angle is considered as 36° which meets the production requirements. Numerical modeling is carried out only for this plan, the progress of which is shown in Figure 2.

From Figure 2, it can be seen that failure surface is created automatically with the strength reduction method with respect to the stress-strain relation by using the Phase2 v9.0 (2014).

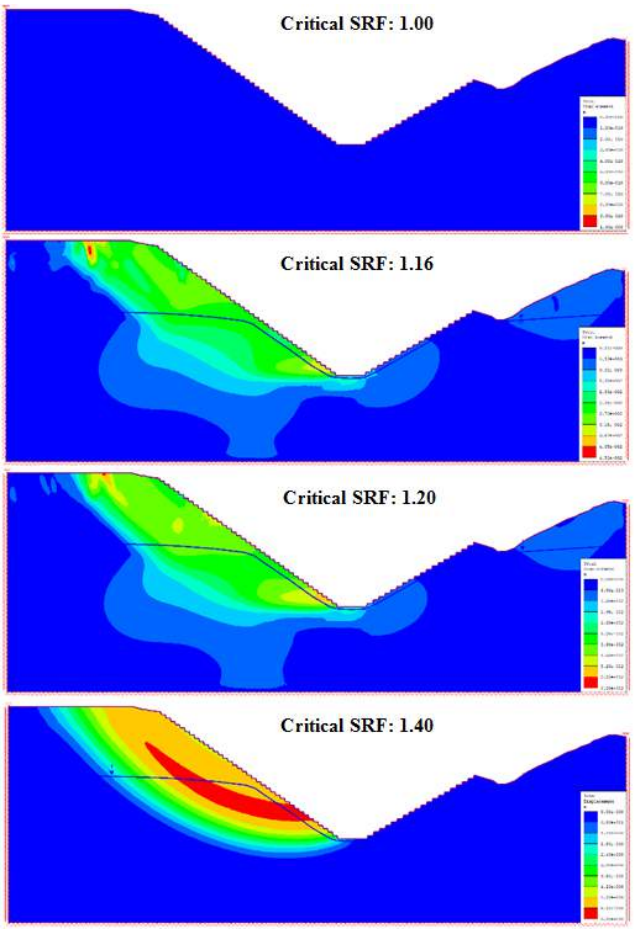

Figure 2. Progress of strength reduction method showing the SRF and related displacements.

Based on the numerical modeling computation results, strength reduction factor is determined as 1.20 with a maximum displacement of 0.287 m for the critical section. Moreover, the critical failure surface is developed with respect to the shear strain localization. Figure 3 illustrates the shear strain condition at the critical SRF and shows the plot of maximum displacement corresponding SRF.

The SSR solution procedure using model convergence as an indicator of slope stability is given in Figure 3. As the strength decreases the maximum displacement increases, at a certain point slope fails and analysis does not converge, displacement increases rapidly. The SSR value at the point is called as critical SRF.

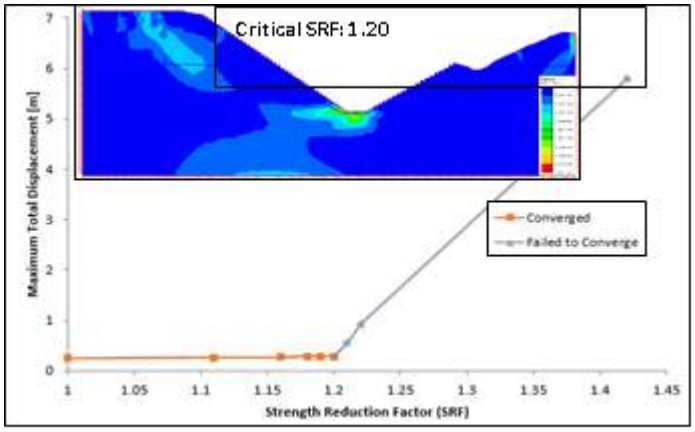

Figure 3. Maximum shear strain condition at SRF and plot of total displacement corresponding SRF

The obtained both SRF and FOS values are consistent with each other and higher than 1.2 and the result obtained from numerical modeling are coherent with the limit equilibrium results.

5 CONCLUSION

This paper presents a general description of studies conducted for stability analysis and optimum design of the open pit slope. For deep open pit mines making the overall slope angle as steep as possible can reduce the amount of stripped waste rock and diminishes the production cost under a prerequisite safety conditions.

An iron ore open pit mine in Bizmisen region, Erzincan intended to be 400 m final slope height, is the case in point for the geotechnical optimization attempt. Within this purpose, geotechnical site characterization and comprehensive laboratory studies were conducted. Rock mass and material properties were determined for stability analysis. The FOS and SRF values obtained from the limit equilibrium method and numerical modeling are higher than 1.2. This study shows that combined use of limit equilibrium and numerical modeling analysis techniques is an effective and practical way to optimize the overall slope angle by increasing the reliability and accuracy. With the optimum design, the slope angle of the iron ore mine with 400 m final slope height is proposed to

be adjusted to 36° satisfying both safety conditions and economic considerations.

Study of The Bench Slope Stability By Numerical Method, Case of Ouenza Mine Algeria

R.Adil, M.L.Boukelloul
Laboratory of Mineral Resource Development and Environment -LAVAMINE- BadjiMokhtar University-Annaba

K. Talh
Laboratory of Metallurgy, Materials and Physical Properties- BadjiMokhtar University-Annaba

ABSTRACT Mine slope stability remains a key issue that arises when operating open pit deposits. Slope stability has a direct influence on work safety in the mine, technological operating principles, the total depth of mine drainage problems, etc.

Too high slope angles can lead to destabilization, landslides development and flows over the edges of the mine. These accidents cause a lot of damage to businesses and hinder the normal cycle of operations, not to mention they can be dangerous to the lives of personnel.

The definition of slope angles that ensure stable operations requires a detailed study of all geological and geotechnical factors of rock mass: lithology, tectonic conditions, physical and mechanical properties of rocks, discontinuities of the rock mass, the hydrogeological conditions, etc.

To prevent slippage in the Ouenza mine, it was proposed to study the bench slope stability by numerical method based on finite elements (implemented in PLAXIS software). To better understand the bench slope stability problem, we modelled the mine bench slope to the study of the structure in two dimensions. For the calculation of the stability, plane strain assumption is adopted. The mechanical behaviour of rocks follows the Mohr-Coulomb criteria.

Keywords: Ouenza mine, stability, slope slippage, bench

1 INTRODUCTION

Raw materials, as well as building materials metalliferous ores, are the basis for supplying and meet the various branches of the national economy. Since the independence, Algeria has initiated a broad program aimed at:

1. The exploration of new deposits of useful minerals and substances.
2. The re-opening of mines and abandoned quarries.
3. The modernization and mechanization of mining and quarrying activity.
4. The training of national personnel who will be responsible and responsibility to properly manage and according to the required standards, the production process the financial return of the equipment used and that, to meet the demand of the consumer public and / or private.

It should be noted that the operation of a given deposit must consider the characteristics of the rock mass and to wisely choose the method of slaughter rocks, the most appropriate method of operation, and mechanization of processes loading and transportation of the blasted rock.

Not to mention the evaluation of bench slope stability of the open pit or intended quarry.

In this context, it was proposed to study the stability of slopes (bench slopes) mine of Ouenza. And, to draw conclusions regarding landslides or no slope of the studied mine.

2 GEOLOGICAL AND GEOMORPHOLOGICAL OF THE OUENZA MINE

Above the shelves that extend between Oued Mellègue and the mountains of Tebessa

appear isolated reliefs, whose highlights range from 1,200 to 1.400 meters.

Jebel Ouenza belongs to this series of links located on both sides of the Algerian-Tunisian border. Consisting of Aptian limestone collapsed affecting domed cut holes, this massive contains significant iron ore deposit, whose existence has been known since antiquity.

2.1 Geographic Context

The Ouenza deposit is located in the extreme NE of Algeria near the Tunisian -Algerian border; 120 Km of El Hadjar steel complex (Annaba) which is connected by a railway line and 90 km from the capital of the Wilaya of Tebessa. It is part of the Algerian-Tunisian border, Figure 1, which are geologically known by almost exclusively sedimentary character.

2.2 Morphology and Deposit Structure

The Ouenza deposit is located in the Jebel Ouenza which is a large anticlinal direction SW- NE, Figure 2. If one moves away from the SW periclinal part that presents a spectacular field as you see the enormous mass of reef limestones of the Aptian which forms the backbone of the mountain. Chain R. (2006).

3 RESEARCH METHODOLOGY

3.1 Slope Stability of Open Pit Mines

3.1.1 Factors affecting slope stability

Analysis of the deformation process in open pits must take into account the joint influence of natural and technical factors. These can be divided into three natural factors:

- **Geographical and climatic:** Site relief, precipitation, temperature regime, specific conditions of freeze-thaw.
- **Geological:** lithology massive, tectonic setting, structural and textural characteristics of rocks and massive, mechanical properties of rocks, etc..;
- **Hydrogeological**: surface water passing through the territory of the farm or are nearby, groundwater in the massif, the presence of water in the contacts between the rocks or the tectonic discontinuities etc.

Among the technical factors include the geometry of the mine and waste rock, the slope angles of the mine and waste rock, the excavation method and slaughter of the rock, the structure of the mechanization of work, the presence near the mine underground excavations, methods and pumping parameters, etc.

From a general point of view, the rock mass can be considered as both geological objects and mechanical objects. The study of the stability of rock masses requires having knowledge of structural geology and rock mechanics.

Geologically a wide variety of rock masses based on observed:

• The nature of the rock matrix and petrographic and mechanical characteristics.
• Discontinuities at all levels and of all types, affecting the massif.
• Variability in space of the couple rock matrix / discontinuities.

3.1.2 Classifications deformations

The many classifications of natural slope movements and mining slope are very diverse and complex. Varnes D.J. (1978), NemcokA. (1972),Goulakian A.T.(1980**)** .

We can divide all the deformations in four groups based on the movement of the mechanisms:

• **Creep:** Slow movement of the masses without defining sliding surfaces
• Slip: mass movement in one or more well defined sliding surfaces
• **Slip - casting:** the dynamics of this movement is similar to that of a liquid Viscous.
• **Landslide:** sudden movement of rock masses with momentary loss of contact between the moving mass and massive.

3.1.3 Rockslide

Called rockslides moving a well-defined mass field with shear failure resistance defect following a well-identified area where the deformations are localized. Cojean R. (1985,1991). The displaced rock materials usually break and the initial slip turns into a landslide. One distinguishes rock slides with translational movement (on a stratigraphic seal a gap , a surface foliation or cleavage) , the following shifts associations discontinuities (forming dihedral, jagged surfaces, etc.) , slides with rotational movement (in highly fractured rock masses) slides with monolithic movement . Multiple combinations of different families discontinuities lead to a variety of disruptions mechanism.

For a bank, it is said that there is a risk of rupture for an association discontinuity and a given failure mechanism, if the geometric configuration formed by all elements (slope and discontinuities) supported the break. It is said that the break is cinematically possible.

Hoek E. (1981) proposed to distinguish five types of movements according to the configuration of the discontinuities and the orientation of the slope and of the kinematic motion.

• **Rupture plane simple:** the mass out is limited by a discontinuity plan; movement occurs in the direction of the dip vector of this discontinuity.
• **The dihedral out along a plane:** the mass out is bounded by two intersecting discontinuities movement occurs in the direction of the vector dip in one of two ways; there detachment without mechanical action along the other plane.
• **Breaking into true dihedral:** the mass out is bounded by two intersecting discontinuities movement occurs in the direction of the vector dip of the intersection of two planes; the mass is pressed simultaneously on both fronts during sliding.
• **The block switching by breaking:** the mass is cut out into blocks resulting from the combination of two discontinuities repeating a finite number of times, and forming, at the base, a stepped surface; the movement takes place in the direction of one of the planes; it combines the tilt of a set of upper blocks and sliding a set of lower blocks along the fracture surface.
• **Fracture on one staircase surface:** the mass out is restricted by a stepped surface resulting from the combination of two discontinuities repeating a finite number of times; the movement takes place by sliding in the direction of the dip vector of one of the two plans.

4 CASE OF STUDY

4.1 Numerical Modelling of the Stability of Benches Embankments

To better understand the bench slope stability problem, we modeled the mine bench slopes to the study of the structure in two dimensions. The bedrock is composed of layers of limestone and iron. For the calculation of the stability, plane strain assumption is adopted. The mechanical behavior of rocks follows the Mohr - Coulomb criteria. The mechanical and physical properties of rocks are determined by tests in the laboratory of Ouenza mine.

Table 1. Physical properties of rocks.

Parameters	Iron	Limestone
Permeability horizontal (K), m /s	10^{-5}	10^{-11}
Permeability vertical (K), m /s	10^{-5}	10^{-11}
Dry density (γ), g/cm^3	2.70	2.60
Saturated gravity (γ), g/cm^3	2.90	2.65

Table 2. Mechanical properties of rocks.

Parameters	Iron	Limestone
Modulus of Elasticity (E), GPa	21	19.84
Poisson's ratio (V)	0.25	0.22
Internal friction angle (ϕ),	45	50
Cohesion (C), MPa	3.20	3.50

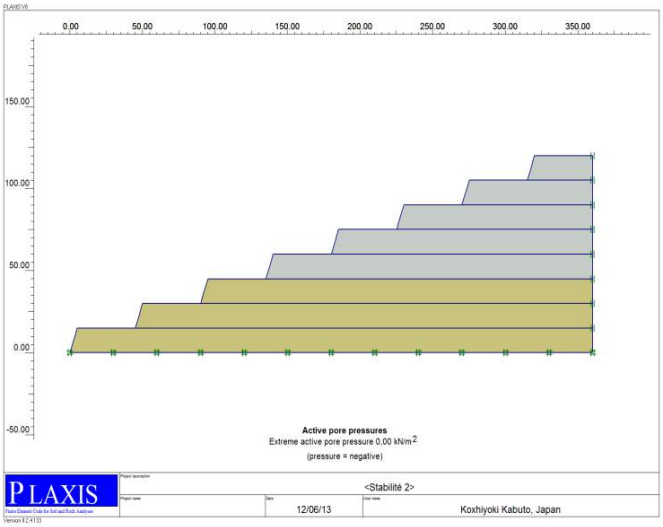

Figure 3. Geometric Model of mine slope

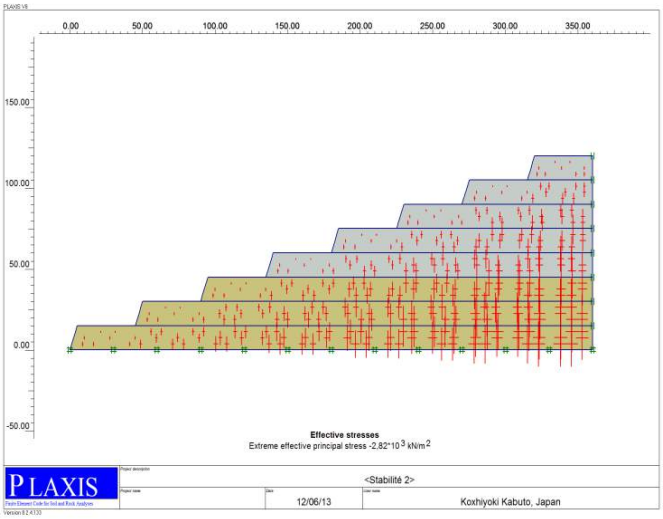

Figure 4. Maillage of mine slope

5 CONCLUSIONS

The obtained results, according to the numerical method based on finite elements and implemented in the software PLAXIS show that the movements and deformations are very low (Dh = 243.76 10^{-6} m) , which means that the bench slopes are stable.

Assessment of Engineering Behavior of Foliated Rocks Using Some Index Tests

D. Fereidooni
School of Earth Sciences, Damghan University, Damghan, Iran

G.R. Khanlari, M. Heidari, A.A. Sepahigero
Geology Department, Bu-Ali Sina University, Hamedan, Iran

ABSTRACT In this research, different experimental techniques have been used to determine the strength of five types of anisotropic foliated rocks, selected from the Hamedan Province, west of Iran. For this purpose, after sample preparation and assessment of mineralogical and physical properties, selected samples were subjected to Cylindrical Punch, Point Load and Brazilian tests and their strengths were evaluated with respect to different angles between anisotropy planes and the major loading directions. Data analyses show that the types and amounts of minerals have an influence on the physical and mechanical properties of the tested anisotropic rocks. Porosity and water absorption also have a dominant control on the mechanical indices such as cylindrical punch index (CPI), point load index ($I_{s(50)}$) and Brazilian tensile strength (BTS). On the basis of the test result, two empirical equations are proposed for calculating CPI and $I_{s(50)}$. Other empirical equations relating studied indices are also presented.

1 INTRODUCTION

The most important factors influencing the strength and deformation behaviors of intact rocks are mineral composition, crystal size, rock fabric, alteration degree, weathering and anisotropy (Saroglou et al., 2004). Some rocks of the earth's crust show well-defined fabric elements in the form of bedding, stratification, layering, foliation, fissuring or jointing. In general, these anisotropic rocks have physical, mechanical and hydraulic properties that are varied in different directions. Anisotropy can be found at different scales from intact specimen to rock masses. This property plays a significant role on the rock behavior in engineering projects. For example, in civil and mining engineering, anisotropy affects the stability of underground excavations, surface excavations, foundations, drilling, blasting and rock cutting (Chen et al., 1998).

Out of the three generic categories of rocks, metamorphic rocks usually show the highest degree of anisotropy (Ramamurthy et al., 1993). The anisotropic nature of some metamorphic rocks is mainly due to the presence of a single set of discontinuity or weakness planes such as cleavage, foliation, schistosity, joint or microfissure (Al-Harthi, 1998).

In recent years, different methods and testing techniques have been developed and implemented to determine geotechnical properties of anisotropic rocks. Standard procedures for measuring various geotechnical properties of rocks were suggested by ISRM (2007) that provides an excellent review of many available techniques in both laboratory and field environments. In laboratory testing, mechanical properties of intact anisotropic rocks are usually determined from specimens prepared at different angles with respect to the apparent planes of anisotropy. The most important laboratory static tests include uniaxial and triaxial compression, punch, point load and Brazilian tests.

Literature review shows that performing direct static laboratory tests in order to evaluate rock strength and deformation is mostly expensive and requires considerable time due to preparation of rock specimens. Therefore, different indirect testing methods were developed and used to interpret the engineering properties of anisotropic rocks. These tests are relatively easy to perform, cheap, and take short testing time (Shalabi et al., 2007). Hence, indirect index test results are often used to predict strength parameters of anisotropic rocks. For this reason, in the present research, some of the most important laboratory tests such as cylindrical punch, point load and Brazilian tests were used. Based on the results, their applications are strongly recommended for determining strength parameters of anisotropic rocks.

2 SAMPLE SELECTIONS

Suitable sampling locations of rock types were selected from the 1:250,000 scaled geological map prepared by the Geological Society of Iran (G.S.I., 1977). During field investigations, lithological characteristics of rocks were considered. Samples were obtained from quarries, road and railway cuttings and excavated foundations. Observations of hand specimens indicate that these samples are heterogeneous so that different foliation planes could be identified by their light and dark colors. The studied rock samples were selected from different parts of the Hamedan Province, west of Iran. The sampling locations include Avarzaman (AVZ), Heydareh (HDR), Malayer (MLR), Varkaneh (VRK) and Zagheh (ZGH). Five examined rock types are phyllite, sillimanite garnet hornfels, slate, andalusite garnet hornfels and staurolite andalusite schist. All selected samples are fresh rocks obtained from depths of about 5m.

3 EXPERIMENTAL STUDIES

3.1 Specimen Preparation

A total of 1050 specimens were prepared for block punch, Brazilian and point load tests (350 specimens for each test) at seven different anisotropy angles (β = 0°, 15°, 30°, 45°, 60°, 75° and 90°). Diameters of prepared specimens were about 54 mm. Specimen thickness of cylindrical punch tests (CP-test) was kept between 5-15 mm as proscribed by Ulusay et al. (2001). Length to diameter ratios of the point load test specimens and ratios to diameter of Brazilian test specimens were kept in accordance to the ISRM (2007) stipulations.

3.2 Petrographical and Mineralogical Studies

In order to identify the mineral composition and texture of the rock samples by optical microscopic observations, thin sections were prepared in two directions; parallel and perpendicular to the rock anisotropy planes. These orientations were studied by using a modern polarizing microscope as proscribed by ISRM (2007). The mineralogical studies indicated that the metamorphic rocks were commonly composed of quartz, biotite, feldspar, muscovite, garnet, sillimanite, staurolite, andalusite, graphite and other tiny cryptocrystalline matrix materials. The textures were different in the parallel and perpendicular orientations for the rock anisotropy planes. The anisotropy planes were clearly seen when the thin sections were prepared perpendicular to the rock anisotropy.

Textures of the rocks were found to be porphyroblastic and lepidoblastic. In the porphyroblastic fabric, the rock texture could be divided into two components: porphyroblasts and matrix. Andalusite, staurolite and garnet porphyroblasts were found to be dominant types of minerals with sizes of 0.2 to 1 mm (Fig. 1). The matrix was characterized by quartz, feldspar, biotite and muscovite (50-100 μm). These patterns defined a fabric characteristic of both regional and contact metamorphic rocks. Table 1 presents a summary of the average modal abundance of the minerals and the mineral compositions of the rock samples. Fig. 1 shows microscopic images of the sample of AVZ as representative sample.

Table 1 Mineral composition of tested samples

Rock mark	Rock type	Mineral content (%)									
		Qtz.	Fld.	Bt.	Mt.	Gt.	Ad.	Slt.	St.	Chl.	Other minerals

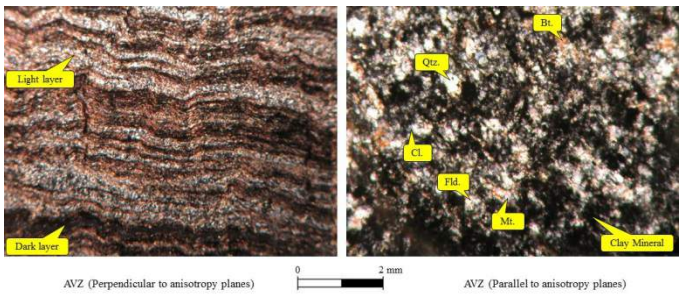

Figure 1. Photomicrographs of the sample of AVZ (The left image is perpendicular to anisotropy planes and the right image is parallel to anisotropy planes).

3.3 Physical Properties

Physical properties of different intact rocks depend on their mineral compositions and microstructures. Irfan (1996) indicated that the physical properties of the intact rocks are highly influenced by the type, texture, fabric and the minerals forming the rocks. Physical properties of the rock samples, such as dry and saturated unit weights (γ_d and γ_{sat}), specific gravity (G_s), porosity (n) and water absorption (W_a) were determined using standard testing methods suggested by ISRM (2007). For this purpose, five sets of tests were performed on the core specimens prepared in different directions of anisotropy planes (β = 0°, 15°, 30°, 45°, 60°, 75° and 90°). On each type of anisotropic rocks 35 tests were performed. Therefore, a total of 175 tests were performed for calculating physical properties. Table 2 shows the values of the parameters for the tested samples. The dry unit weight ranges between 2.55 and 2.81 gr/cm^3 with an average of 2.72. The saturated unit weight ranges between 2.64 and 2.82 gr/cm^3 with an average of 2.75. The specific gravity ranges between 2.77 and 2.84 with an average of 2.81. The porosity ranges between 1.13 and 8.99% with an average of 3.36%. The water absorption ranges between 0.40 and 3.55% with an average of 1.27%.

Table 2. Physical properties of tested samples

Rock mark	γ_d (gr/cm^3)	γ_{sat} (gr/cm^3)	G_s	n (%)	W_a (%)
AVZ	2.73	2.74	2.77	1.74	0.64
HDR	2.81	2.82	2.84	1.13	0.40
MLR	2.71	2.75	2.82	3.76	1.33
VRK	2.79	2.80	2.82	1.16	0.41
ZGH	2.55	2.64	2.80	8.99	3.55
Average	2.72	2.75	2.81	3.36	1.27

3.4 Cylindrical Punch Test

Probably, the earliest reference to the punch test is reported by Lacharite (1960). In this article, this test was used to assess the shear strength of a rock type. To this time, different researchers used the punch test to determine rock shear strength (Mishra and Basu, 2012). They placed the apparatus with a rock disc specimen in a compression machine. The compressional loading induces double shear failure planes in the specimen.

Their studies were extended in 1982 for the development of the block punch test and its index (Schrier, 1988). In his article and references, the effect of specimen size on the block punch index (BPI) was not considered. Later, a comprehensive study was carried out by Ulusay and Gokceoglu (1997) in order to investigate the specimen size effect on BPI. They proposed an empirical equation to calculate the corrected block punch index (termed as BPI_c) which considers the specimen size effect. This equation was later modified by Sulukcu and Ulusay (2001) based on additional test results. Ultimately, after considering the findings of the previous investigations, Ulusay et al. (2001) suggested a new method for the block punch test. On the basis of their suggestion, the corrected block punch index (BPI_c) can be calculated as follows:

$$BPI_C = 3499D^{-1.3926}t^{-1.1265}P \quad (1)$$

where D and t are diameter and thickness of the disc specimen in mm and P is the failure load in KN. In the case of anisotropic rocks, the BPI would change depending on the anisotropy angle. For this reason, a strength anisotropy transformation factor (K_a) was introduced for normalizing BPI of anisotropic rocks in the strongest direction (i.e. BPI_{c90}, when the loading direction is perpendicular to the weakness planes) (Ulusay et al., 2001). Based on additional test results, strength anisotropy transformation factor (K_a) was modified by Karakul et al. (2010).

In this study, instead of the block punch test (BP-test), the cylindrical punch test (CP-test) was used in order to determine the cylindrical punch index (CPI) for anisotropic rock samples. The CP-test apparatus was made in a welding laboratory from steel plates and 10×10 box profile, and the same apparatus has been used by Jafari et al. (2010). The dimensions of the CP-test apparatus used in this research are about 15×15×15 cm. This apparatus consists of an upper piece, a lower piece and a punching cylinder which are connected to each other by two connecting screws. Specimens were placed between the two pieces before the testing. This fabricated frame can be placed within a uniaxial compression or a point load machine. In order to perform this test, each specimen was placed in the apparatus, and the axial load was applied at a rate of 0.05 KN/s. Specimen loading must be axial, and each specimen must fail between 30 and 60 seconds (Ulusay et al., 2001). The process of specimen placement in the apparatus is shown in Fig. 2. Failures should be such that the traces of shear failure can be seen on both sides of specimen (Fig. 3). After performing the cylindrical punch test, cracks in specimens tend to propagate parallel to anisotropy planes. These types of failures occurred at all anisotropy angles except specimens at β=90°. For example, Figs. 4 and 5 show failures of ZGH specimens at β=0° and VRK specimens at β=90°.

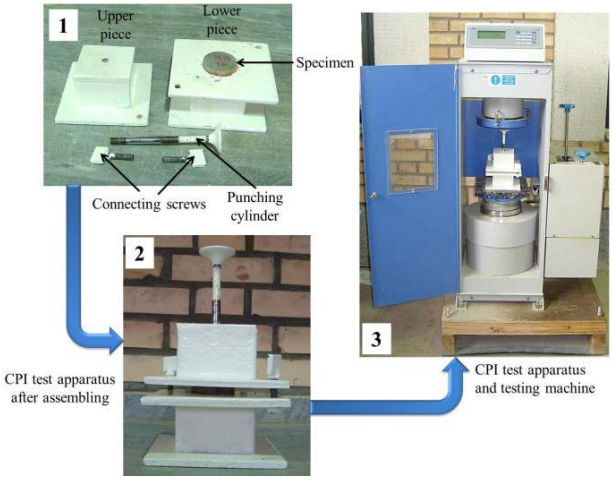

Figure 2. Cylindrical punch test apparatus and performance process of this test

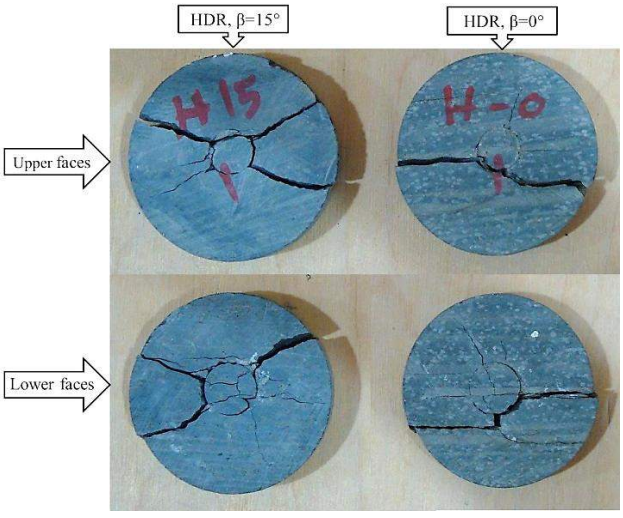

Figure 3. Trace of failure in upper and lower faces of two tested specimens

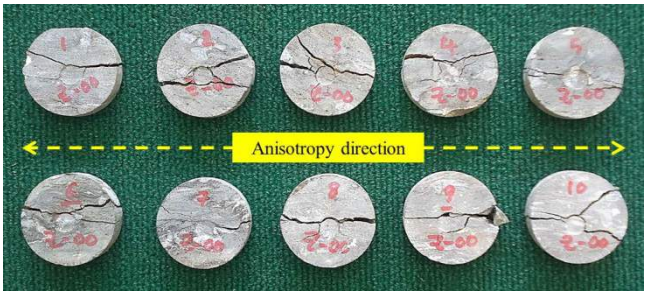

Figure 4. Crack propagation parallel to anisotropy directions at β=0°

Figure 5. Crack propagation not parallel to anisotropy directions at β=90°

On the basis of the experimental results achieved from this research, the most important advantages of cylindrical punch test (CP-test) in comparison to the block punch test (BP-test) are as follow:

1. In the CP-test, distance of the shear surface is equal from the edge of the specimen, whereas, in the BP-test the distance is not equal. These differences may affect the test results (Fig. 6).

2. Stress distribution on specimen surface in the CP-test is more uniform than in the BP-test.

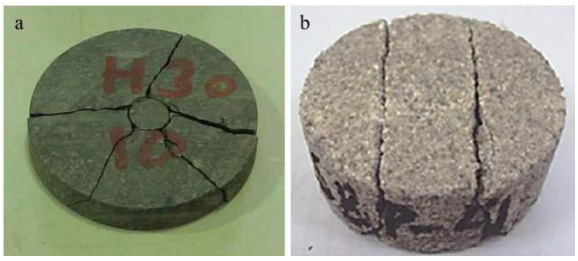

Figure 6. Comparison between failure mechanism in a) CP-test and b) BP-test(a: this research, b: Mishra and Basu, 2012)

Evaluation of CPI in MPa is possible using the following equation:

$$CPI = \frac{P}{\pi D t} \qquad (2)$$

where P is the failure load in N. D and t are the diameter and thickness of the sheared cylinder in mm.

In anisotropic rocks, the values of CPI are affected by the anisotropy angle (β). In this research, 350 disc specimens with thickness of about 10 mm were tested. Average CPI values of each sample at different β angles are presented in Table 3. For all tested samples, CPI values at β=0° are at a minimum but, at β=90° are maximum. Also, in this table the values of punch anisotropy index (PAI) were calculated from the ratio of (CPI_{90}/CPI_0).

Fig. 7 shows the correlation between CPI and β for the tested samples. The curves presented in this figure indicate a direct relationship between the parameters. In other words, with increasing anisotropy angles from 0° to 90°, the values of CPI increase. Variation rates of CPI in anisotropy angles between 0° and 15° are maximum. In other words, the slopes of the curves are maximum between β=0° and β=15°. But, with increasing anisotropy angles from 15° to 90°, variation rates of CPI decrease; especially, for the samples of AVZ and HDR (Fig. 7).

Table 3. The values of CPI and PAI for tested samples at different β

β (Deg.)	CPI (MPa)				
	AVZ	HDR	MLR	VRK	ZGH
0	13.47	18.34	9.04	27.11	11.22
15	13.99	22.16	9.35	27.94	11.83
30	14.29	23.91	9.58	28.17	12.11
45	14.50	24.30	9.71	29.60	12.90
60	14.65	25.60	10.18	30.05	13.82
75	14.75	26.46	10.20	30.04	13.63

PAI	1.12	1.45	1.13	1.11	1.26

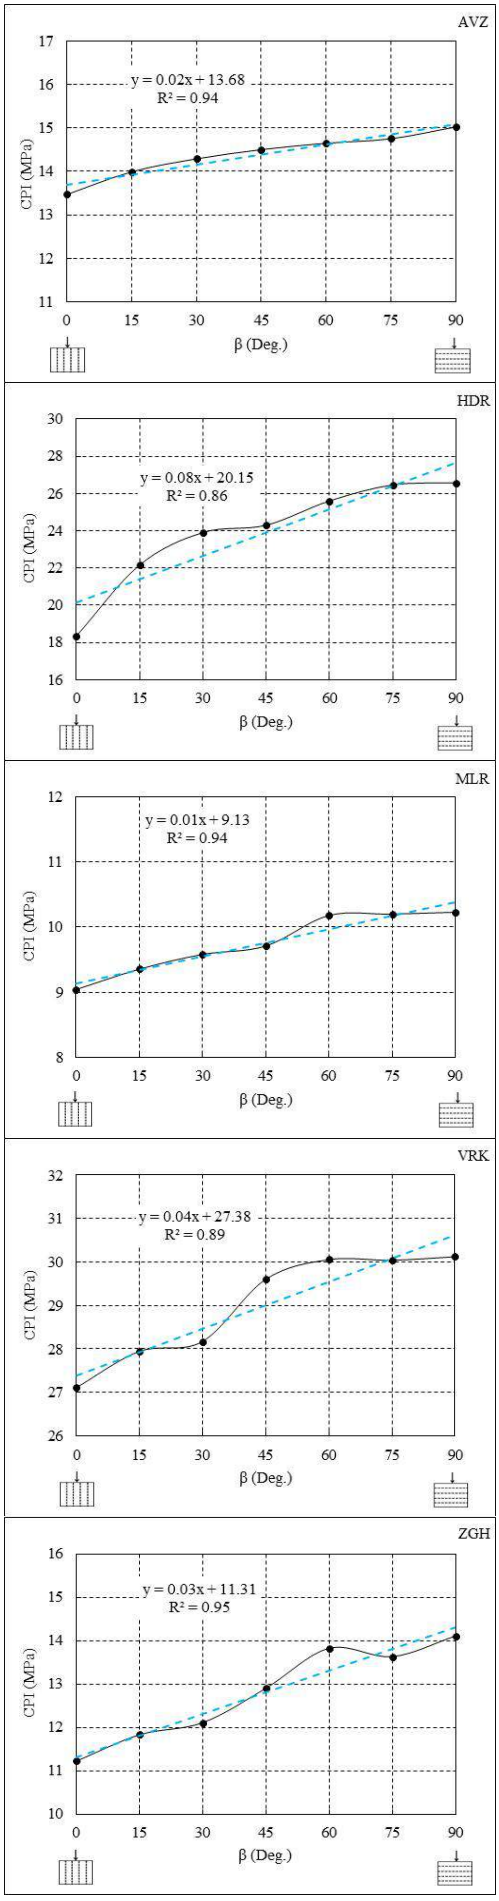

Figure 7 Correlations between CPI and anisotropy angles (β) for tested samples

After analysis of the results, Equation 3 is proposed in order to determine cylindrical punch index at different anisotropy angles ($CPI_{\beta=i}$). The importance of this equation is that by performing CP-tests only at β=90°, it is possible to determine CPI in different anisotropy angles from 0° to 90°. This equation was obtained from the trial-and-error method using the CPI data obtained at different anisotropy angles.

$$CPI_{\beta=i^\circ} = CPI_{\beta=90^\circ} - K(1-\sin\beta) \quad (3)$$

where K (difference between CPI at β=90° and in other degrees of β) is a function of β that can be achieved by Equation 4. This equation was obtained by curve-fitting between K and β.

$$K = 2.35 - (0.03 \times \beta) \quad (4)$$

where β is anisotropy angle in degrees. The calculated values of K at different anisotropy angles based on the above equation are presented in Table 4. A reverse linear relationship occurs between K and β.

Table 4. The values of K at different β

β (Deg.)	K
0	2.35
15	1.90
30	1.45
45	1.00
60	0.55
75	0.10
90	0.00

The relationship between experimented results and calculated values of CPI using Equation 3 for all tested samples at seven different β is shown in Fig. 8. For comparison of the results, the 45° line (y=x) has been plotted in this figure. It is clear that the two lines are nearly fitted to each other.

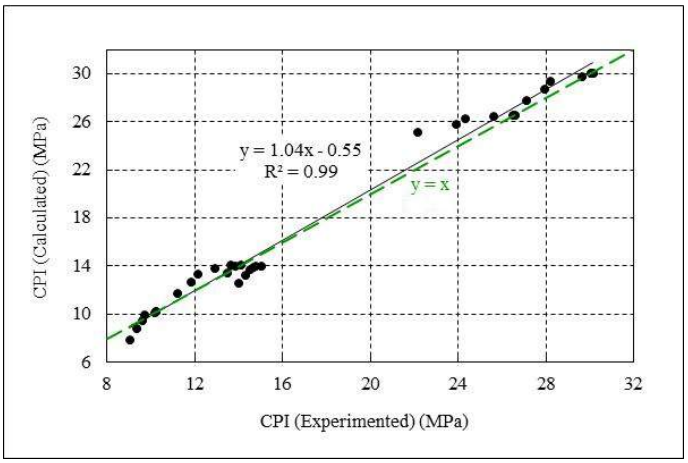

Figure 8. Correlation between experimented and calculated results of CPI for tested samples

3.5 Point Load Test

The point load test is commonly used in practice because of the ease of testing, simplicity of specimen preparation and possible field application (Kahraman and Gunaydin, 2009). The method of point load test was standardized by ISRM (2007) and ASTM (2001).

In anisotropic rocks, foliation planes are characteristics of the rocks, and it is expected that mechanical behaviors of these rocks will be controlled by these planes under a certain state of stress. If the merit of the point load test, its success, and wide use are kept in mind, the following two issues emerge to be absolutely important in rock engineering (Basu and Kamran, 2010): (1) to check feasibility of utilizing the point load test (with weakness planes at an angle with loading direction) for strength evaluation of anisotropic rocks and (2) to evaluate predictability of UCS by point load strength for these rocks.

On the basis of the literatures (Broch and Franklin 1972, Tsidzi 1990, Ajalloeian and Lashkaripour 2000), point load strength anisotropy index ($I_{a(50)}$) is reported to be a good index for anisotropic rocks. This index is defined as the ratio of $I_{s(50)}$ values measured in the strongest and weakest directions ($I_{a(50)}= I_{s(50)max}/ I_{s(50)min}$). Because the strongest and weakest directions are perpendicular and parallel to planes of foliation, respectively, the point load strength anisotropy index ($I_{a(50)}$) is close to 1.0 for quasi-isotropic rocks and are at higher values for anisotropic rocks (ISRM, 2007).
In this research, the required specimens for point load test (350 cylindrical specimens with L/D=0.3-1.0) were prepared and tested at seven anisotropy angles. On the basis of our laboratory experiments, the use of axial point load tests are easier to do and give better results than other point load tests for anisotropic rocks. A total of 10 axial point load tests were carried out in each direction of foliation planes and the mean values were calculated. The minimum and maximum values of anisotropy ratio (1.81 and 5.72) were measured for ZGH and AVZ samples, respectively (Table 5).

Table 5. The values of $I_{s(50)}$ and $I_{a(50)}$ for tested samples at different β

β (Deg.)	$I_{s(50)}$ (MPa)				
	AVZ	HDR	MLR	VRK	ZGH
0	0.64	2.80	0.69	5.46	1.01
15	0.67	4.19	0.76	4.41	1.10
30	1.50	7.15	0.89	5.53	1.25
45	1.55	5.35	1.38	6.88	1.39
60	1.33	8.68	1.56	8.08	1.72
75	2.60	9.05	1.95	9.03	1.71
90	3.66	9.80	2.51	9.51	1.83
$I_{a(50)}$	5.72	3.50	3.64	2.16	1.81

Fig. 9 shows the correlations between $I_{s(50)}$ and anisotropy angles (β) for tested samples. The curves in this figure indicate linear relationships between $I_{s(50)}$ and β with high correlation coefficients. In other words, with increasing anisotropy angles from 0° to 90°, the values of $I_{s(50)}$ increase. Therefore, the value of $I_{s(50)}$ at β=90° is maximum for all samples.

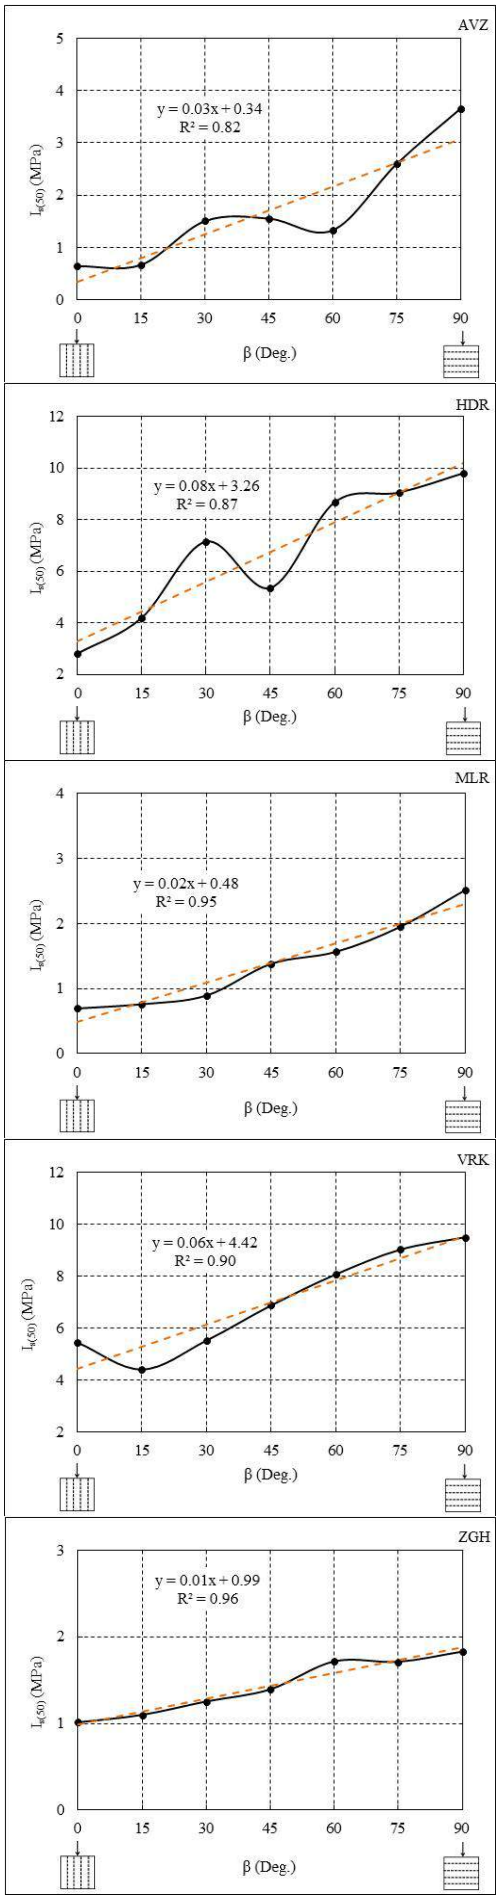

Figure 9. Correlations between $I_{s(50)}$ and anisotropy angles (β) for tested samples

Our laboratory studies show that the core preparation of anisotropic rocks can be difficult because the cores may break along their weakness planes. Therefore, in the present research a suitable method was proposed to determine point load index ($I_{s(50)}$) in different anisotropy angles (β). In our suggested method, preparation of core specimens is not necessary because it is possible to use natural specimens that that have broken along their foliation planes. By using this method and after calculation of $I_{s(50)(\beta=90°)}$, the estimation of values of $I_{s(50)}$ is possible for anisotropy angles from 0° to 90°. Estimation of the $I_{s(50)(\beta=i°)}$ is possible as follows:

$$I_{s(50)(\beta=i^\circ)} = [(0.71 \times \sin\beta) + 0.20] \times I_{s(50)(\beta=90^\circ)} \qquad (5)$$

where β is anisotropy angle in degrees. Equation 5 was obtained from the correlation between the ratio of $I_{s(50)(\beta=i°)}/ I_{s(50)(\beta=90°)}$ and β (Fig. 10).

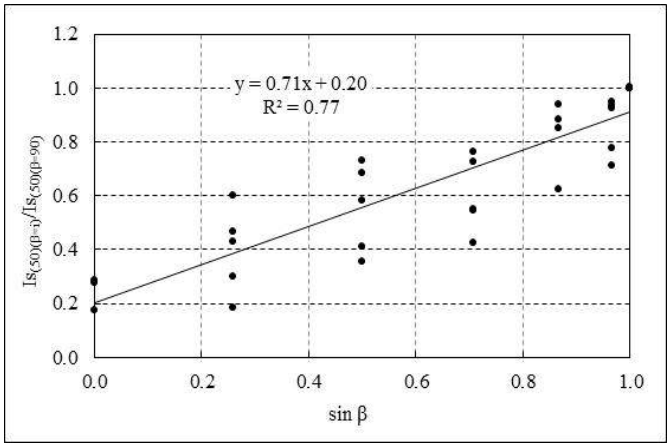

Figure 10. Relationship between $I_{s(50)(\beta=i°)}$ / $I_{s(50)(\beta=90°)}$ and β for tested samples

Relationships between experimented and calculated values of $I_{s(50)}$ using Equation 5 in seven different β are shown in Fig. 11. For comparison of the results, the 45° line (y=x) has been plotted in this figure. It is clear that the two lines are nearly fitted to each other.

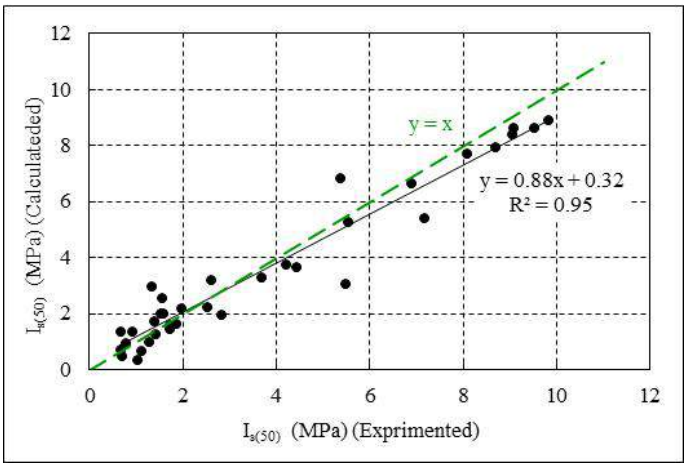

Figure 11. Correlation between experimented and calculated of $I_{s(50)}$ for tested samples

3.6 Brazilian Test

The Brazilian test is a simple indirect testing method for determining tensile strength of brittle materials such as concrete, rock, and rock-like materials (Li and Wong, 2013). This test can be carried out on rock specimens with lengths to diameter ratios from 0.5 to 0.75 according to ISRM (1978) and ASTM (2001). In this research, at least 10 tests were undertaken for each rock type. The Brazilian tensile strength (BTS) was determined by the following equation (ASTM, 2001):

$$BTS = \frac{2P}{\pi Dt} \quad (6)$$

where P is the maximum load recorded during the test. D is the diameter and *t* is the thickness of specimen.

The effect of anisotropy on indirect tensile strength determined by the Brazilian test has been investigated by many researchers such as Hobbs (1963), Barla and Innaurato (1973), Chaberlain et al. (1976) and Behrestaghi et al. (1996). In such studies, the tensile strength of anisotropic rocks was approximated by an equation based on the theory of isotropic elasticity, in spite of the anisotropic character of the rock. Brazilian tensile strengths (BTS) of anisotropic rocks increase as β increases from 0° to 90°. The tensile strengths corresponding to foliation planes oriented at other orientations are between these two values (Zhang et al., 2011).

In this research, the specimens were placed in a Brazilian test machine with different anisotropy angles of loading directions (β=0°, 15°, 30°, 45°, 60°, 75° and 90°). The correlation between Brazilian tensile strength (BTS) and anisotropy angle (β) for all tested samples are shown in Fig. 12. The resulting data are summarized in Table 6. The maximum value of BTS (21.90 MPa) was obtained for VRK sample at β=90° and the minimum value of 1.03 MPa for AVZ sample at β=45°.

The Brazilian anisotropy index (BAI) for indirect tensile strength was obtained from the ratio of tensile strength at strongest and weakest directions. The BAI varied between 1.53 and 5.59 for HDR and MLR samples, respectively.

Table 6. The values of BTS and BAI for tested samples at different β

β (Deg.)	BTS (MPa)				
	AVZ	HDR	MLR	VRK	ZGH
0	2.03	5.67	2.27	8.63	3.95
15	1.11	5.58	1.71	10.95	3.48
30	1.23	6.32	1.33	12.83	3.27
45	1.03	7.12	1.94	13.55	3.38
60	3.94	7.76	2.20	16.56	3.94
75	3.97	8.24	3.06	19.48	4.74
90	5.46	8.56	7.43	21.90	5.09
BAI	5.30	1.53	5.59	2.54	1.56

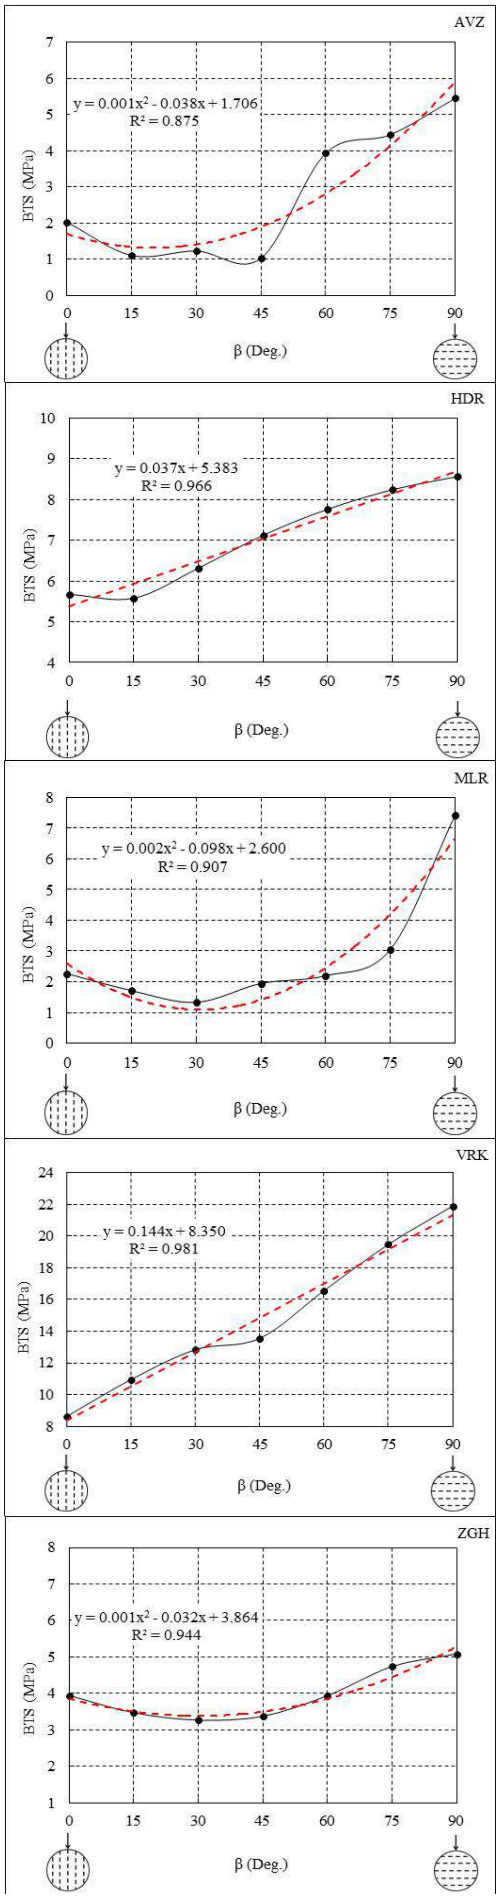

Figure 12. Relationships between BTS and anisotropy angles (β) for tested samples

Fig. 12 shows good linear correlations between the measured indirect tensile strength and angles of anisotropy (β) for the samples of HDR and VRK. A binominal-linear relationship was obtained for the samples of AVZ, MLR and ZGH. In other words, semi U-shape curves were obtained between BTS and β for these samples. These results match with those of Chen et al. (1998).

The highly foliated rocks, such as the regional metamorphic samples of AVZ, MLR and ZGH, have both weak and strong sequenced anisotropy planes in their structures (see Fig. 2). When these rocks are loaded at β=0°, the applied load is subjected to the strong anisotropy planes. This leads to increase failure load (P). Therefore, BTS at β=0° is higher than other anisotropy angles such as 15°, 30° and 45° and creates semi U-shape curves (Fig. 12). The contact metamorphic rocks, such as the samples of HDR and VRK, have been re-metamorphosed forming porphyroblasts in some places. Therefore, their textures are poorly foliated, and they do not develop semi U-shape curves. Therefore, the correlation curve between BTS and β for these rocks is linear.

4 RELATIONSHIP BETWEEN CPI, $I_{s(50)}$ AND BTS

Relationships between cylindrical punch index (CPI) and point load strength index ($I_{s(50)}$) for tested samples are presented in Fig. 13 and produce linear correlations. With performing point load test at β=90° on an anisotropic rock type, the $I_{s(50)}$ at different angles of anisotropy were obtained using Equation 5. Therefore, CPI values in different β are calculated using Equation 7:

$$CPI_i = 2.24 I_{s(50)_i} + 9.78 \qquad (7)$$

where CPI_i and $I_{s(50)i}$ are cylindrical punch index and point load strength index at different anisotropy angles (β=i°), respectively.

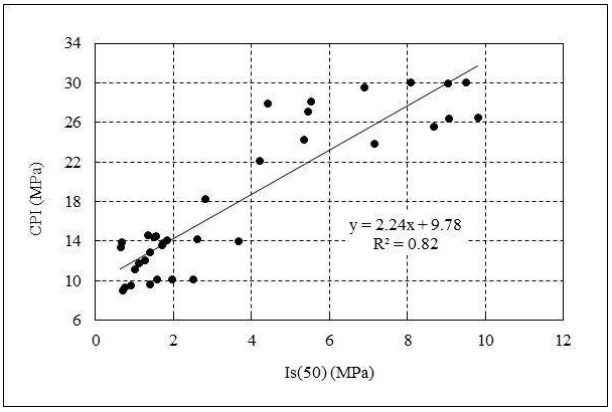

Figure 13. Relationship between CPI and $I_{s(50)}$ for tested samples

Relationships between Brazilian tensile strength (BTS) and point load strength index ($I_{s(50)}$) for tested samples are presented in Fig. 14. A power relationship exists between these two mentioned parameters. With performing point load test at β=90° on an anisotropic rock sample, the $I_{s(50)}$ in different angles of anisotropy was obtained from Equation 5. Therefore, Brazilian tensile strength for the sample can be achieved from the following equation:

$$BTS_i = 2.20 \times I_{s(50)_i}^{0.79} \quad (8)$$

where BTS_i and $I_{s(50)i}$ are Brazilian tensile strength and point load strength index in different anisotropy angles (β=i°), respectively.

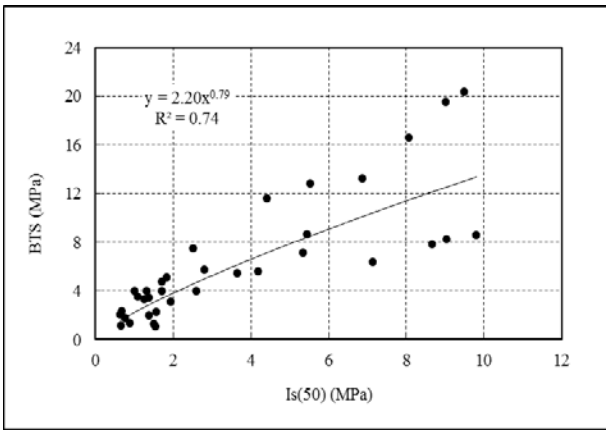

Figure 14. Relationship between BTS and $I_{s(50)}$ for tested samples

Relationships between Brazilian tensile strength (BTS) and cylindrical punch index (CPI) for tested samples are presented in Fig. 15. Here a linear relationship exists between the mentioned parameters. Therefore, Brazilian tensile strengths (BTS) in different directions of anisotropy are calculable using Equation 9:

$$BTS_i = 0.05CPI_i^2 - 1.47CPI_i + 13.06 \quad (9)$$

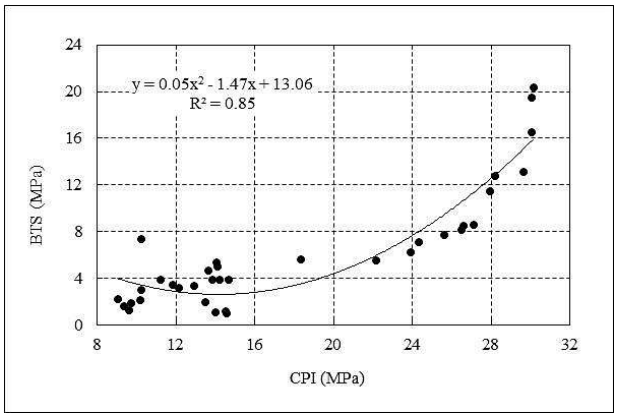

Figure 15. Relationship between BTS and CPI for tested samples

5 DISCUSSIONS AND CONCLUSIONS

The petrographic and mineralogic studies of the samples show that the HDR and VRK samples were affected by re-metamorphism. They have a high degree of metamorphism, and some contain porphyroblasts of garnet, andalusite, sillimanite and staurolite. Therefore, dry unit weight of these samples is higher than for the other samples because of their re-metamorphism, presence of dense metamorphic minerals, and decreased porosity (Table 2). The decrease of porosity causes the decrease of water absorption which increases the cylindrical punch index (CPI), point load index ($I_{s(50)}$) and Brazilian tensile strength (BTS) as can be seen in HDR and VRK samples. On the other hand, with increasing porosity and water absorption, the mechanical properties of the studied rocks decrease as can be seen in ZGH sample. The presence of metamorphic minerals in porphyroblastic texture reduces the influence of anisotropy and decreases anisotropy indexes in mechanical tests (PAI, $I_{a(50)}$ and BAI) as can be seen in HDR and VRK samples. Contrary to these observations, in the samples that the metamorphic minerals are not present as porphyroblasts but occur in lepidoblastic texture, the influence of

anisotropy is high as can be seen in microscopic images of the samples. This high influence increases the PAI, $I_{a(50)}$ and BAI as can be seen in AVZ and MLR samples. The comparison between PAI, $I_{a(50)}$ and BAI values show that these indexes have good agreement with each other in different tested rocks.

In the present research, a new empirical equation is proposed in order to calculate CPI of anisotropic rocks in different anisotropy angles (β) using CPI at β=90° (Equation 3). This equation helps to determine CPI in different anisotropy angles from 0° to 90°. Similar to CPI, a new empirical equation is proposed in order to determine the point load strength index in different anisotropy angles (β) using point load strength index at β=90° (Equation 5). This equation helps to determine $I_{s(50)}$ in different anisotropy angles.

The review of the Brazilian test results show that the maximum value of BTS is obtained at β=90° for all tested samples. On the other hand, the minimum value of BTS is obtained at β=0°, 15°, 30° and 45° in different tested samples.

In this research, the equations proposed between different parameters help to determine various index strength parameters of anisotropic rocks, such as CPI, $I_{s(50)}$ and BTS.

The Relation between Uniaxial Compressive Strength and Block Punch Index for Pyroclastic Rocks

S. Kahraman
Hacettepe University, Mining Engineering Department, Ankara, Turkey

M. Sarıbıyık
Graduate School of Natural and Applied Sciences, Nigde University, Nigde, Turkey

ABSTRACT Because preparing the desired smooth specimens from pyroclastic rocks is difficult for some standard tests, the development of some equations is important for predicting the uniaxial compressive strength (UCS) of these rocks. In this study, the relation between the UCS and block punch index (BPI) for pyroclastic rocks was investigated. Twenty eight different samples of pyroclastic rocks collected from the Cappadocia Region were tested in the laboratory. The linear regression analysis shows that the UCS-BPI conversion factor for the tested rocks is 3.0. On the other hand, the correlation coefficient of power law function is higher than that of the linear function. Concluding remark is that the UCS-BPI conversion factor for the pyroclastic rocks is lower than the suggested general conversion factor of 5.5 and the UCS-BPI relation is best represented by power law function.

Keywords: Pyroclastic rocks, UCS, BPI

1 INTRODUCTION

The uniaxial compressive strength (*UCS*) of rock is commonly used in civil and mining engineering projects performed in rock environment. However, the test for determining UCS is time consuming and expensive. On the other hand, it requires well-prepared and high quality core samples. For this reason, some indirect tests such as point load, block punch index test, Schmidt hammer, and ultrasonic velocity tests have been frequently used to predict *UCS* for preliminary studies (Broch and Franklin, 1972; Gunsallus and Kulhawy, 1984; Gaviglio, 1989; Sachapazis, 1990; Katz et al., 2000; Kahraman, 2001; Ulusay et al., 2001; Yasar and Erdogan, 2004; Fener et al., 2005; Basu and Kamran, 2010; Kohno and Maeda, 2012 ; etc.). However, the core length may be too short to allow the preparation of specimens long enough even for point load testing, if rock cores are divided into small discs due to the presence of thin bedding or schistosity planes. Block punch index (BPI) test is suggested by Ulusay and Gokceoglu (1998) to solve the above problems

A wide range of rocks were tested and a linear correlation with a conversion factor of 5.1 was suggested by Ulusay et al. (2001) for the prediction of UCS from BPI. In this study, the relation between UCS and BPI was investigated for pyroclastic rocks to check whether the suggested conversion factor is valid and the relation is linear for these rocks.

2 PREVIOUS STUDIES

There are several studies on the relation between the UCS and BPI of rocks in the literature. Available studies are briefly explained and suggested regression equations are given following:

van der Schrier (1988) were tested a total of 1150 specimens pertaining to nine rock types (breccia, calcarenite, calcilutite, dunite, gneiss, limestone, marble, mudstone, and sandstone) and found a high correlation between UCS and BPI. The equation of the correlation as follows:

$$UCS = 6.1BPI - 3.3 \quad (1)$$

where UCS is uniaxial compressive strength (MPa) and BPI is block punch index (MPa).

Ulusay and Gokceoglu (1997) performed BPI and UCS tests on twenty-three different rock types including igneous, volcanic, sedimentary, and metamorphic rocks. They analyzed data by using both linear and non-linear regression method and derived following relations between UCS and BPI:

$$UCS = 5.51BPI_c \quad (2)$$

$$UCS = 5.29BPI_c^{1.01} \quad (3)$$

$$UCS = 9.82e^{-0.108BPI_c} \quad (4)$$

$$UCS = 40.48\ln BPI_c - 13.4 \quad (5)$$

where UCS is uniaxial compressive strength (MPa) and BPI_c is the size corrected block punch index (MPa).

Gokceoglu and Aksoy (2000) presented new approaches for the characterization of clay-bearing, densely jointed and weak rocks such as marl, mudstone, sandstone, and schist. They also correlated UCS with BPI and found following relation:

$$UCS = 5.25BPI_c \quad (6)$$

Sulukcu and Ulusay (2001) carried out BPI and UCS tests on twenty-three different rock types. After combining their data with the data from previous studies (Ulusay and Gokceoglu, 1997; Ulusay and Gokceoglu, 1998; Ulusay and Gokceoglu, 1999), they evaluated the data of forty one different rock types and suggested following equation:

$$UCS = 5.1BPI_c \quad (7)$$

Mishra and Basu (2012) investigated the applicability of BPI test for estimating uniaxial compressive and Brazilian tensile strengths of granite, schist and sandstone samples from India. They derived following equations:

For granites

$$UCS = 4.02BPI_c + 36.16 \quad (8)$$

For schists

$$UCS = 1.35BPI_c + 10.89 \quad (9)$$

For sandstones

$$UCS = 4.99BPI_c + 10.69 \quad (10)$$

For all tested rocks

$$UCS = 4.93BPI_c \quad (11)$$

Yesiloglu-Gultekin et al. (2013) aimed to develop some estimation models by using for the UCS of six different granitic rocks from Turkey. They used tensile strength, BPI, point load index, and P-wave velocity in their analysis and found following logarithmic relation between UCS and BPI:

$$UCS = 47.106\ln BPI_c - 17.589 \quad (12)$$

A very detailed study was carried out on a wide range of rock types and a linear relation (Eq. 7) between UCS and BPI with a conversion factor is 5.1 was suggested in 2001 (Sulukcu and Ulusay, 2001). However, recent studies (Mishra and Basu, 2012; Yesiloglu-Gultekin et al., 2013) show that the relation between UCS and BPI may differ from the suggested relation or may not be linear for individual rock types.

3 SAMPLING

The sampling area is the Cappadocian Volcanic Province (CVP) located in the central Anatolia (Fig. 1). The CVP extends as a belt in NE-SW direction with a long axis of about 300 km and is in large part situated within the Anatolide tectonic belt. The main units in the province are basement rocks, Yeşilhisar Formation, Ürgüp Formation, and Quaternary deposits.

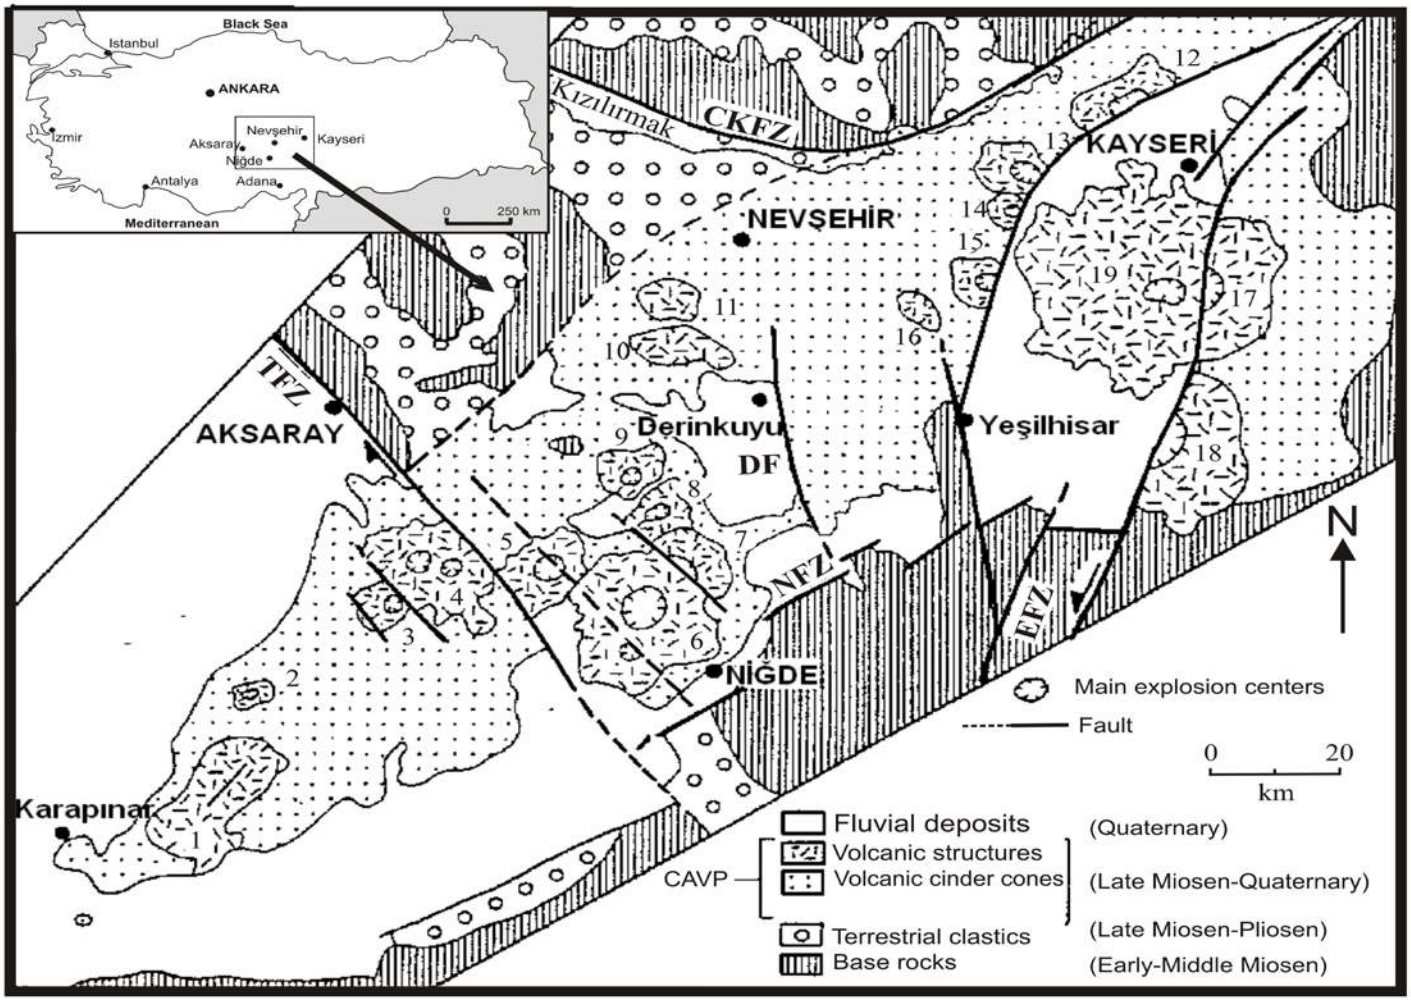

Figure 1. Simplified geological map of Cappadocian Volcanic Province (CVP). Numbers show the major volcanic complexes: 1. Karacadag volcanics, 2. Kotudag volcanics, 3. Kecikalesi volcanics, 4. Hasandag volcanics, 5. Keciboyduran volcanics, 6. Melendiz volcanics, 7. Tepekoy volcanics, 8. Cinarli volcanics, 9. Golludag volcanics, 10. Acigol volcanics, 11. Kizilcin volcanics, 12. Erkilet volcanics, 13. Hamurcu volcanics, 14. Seksenveren volcanics, 15. Tekkedag volcanics, 16. Hoduldag volcanics, 17. Kocdag volcanics, 18. Develidag volcanics, 19. Erciyes volcanics (Toprak et al. 1994).

The Ürgüp Formation corresponds to Mio-Pliocene ignimbritic volcanoclastic rocks intercalated with sediments of lacustrine and fluvial facies. It has a thickness of more than 400 m and extends throughout the CVP. It consists of seven ignimbritic members (Kavak, Zelve, Sarımaden Tepe, Cemilköy, Tahar, Gördeles and Kızılkaya), two lava flows (Damsa and Topuzdağ) intercalated with sedimentary rocks (Çökek Member).

Block samples of pyroclastic rocks were collected from the 28 different sites in the CVP. Each block sample was inspected for macroscopic defects so that it would provide test specimens free from fractures, partings or alteration zones. The sites of the samples and some properties are given in Table 1.

4 EXPERIMENTAL STUDIES

4.1 Density test

Dry and saturated densities were determined by using trimmed core samples according to ISRM (2007) standards. The specimen volumes were calculated from the average of several calliper readings. The dry and saturated mass of the specimens were determined by a balance, capable of weighing to an accuracy of 0.01g of the sample mass. The density values (ρ) were obtained from the ratio of the specimen

Table 1. Sampling areas and some properties of samples.

Rock code	Location	Colour	Dry density (g/cm^3)	Saturated density (g/cm^3)	Porosity (%)

weight to the specimen volume. At least three samples were tested for each rock type and the results were averaged (Table 1).

4.2 Porosity test

The effective porosity values were calculated by using the saturation and calliper techniques (ISRM, 2007). Pore volumes were determined from dry and saturated weights, and sample volumes were obtained from calliper readings. The porosity values (n) were obtained from the ratio of pore volumes to specimen volume. The test was repeated at least three times for each rock type and the results were averaged (Table 1).

4.3 Uniaxial compressive strength (UCS) test

UCS tests were carried out on trimmed core samples, which had a diameter of 38 mm and a length-to-diameter ratio of 2.0-2.5 (ASTM, 1986). The tests were performed on both oven-dried and saturated samples. The stress rate was applied within the limits of 0.5-1.0 MPa/s. The tests were repeated at least five times for each rock type and the average value was recorded as UCS (Table 2)

4.4 Block punch index (BPI) test

BPI tests were conducted on the discs having a diameter of 42 mm and a thickness of about 10 mm (ISRM, 2007). The tests were carried out on both oven-dried and saturated samples. The results were corrected to a

specimen diameter of 50 mm. The tests were repeated at least five times for each rock type and the average value was recorded as BPI (Table 2).

Table 2. Average values of the UCS and BPI_c values.

Rock code	Dry rock UCS (MPa)	Saturated rock UCS (MPa)	Dry rock BPI_c (MPa)	Saturated rock BPI_c (MPa)
1	8.5	3.4	3.5	2.0
2	18.5	9.7	7.8	5.9
3	27.4	17.0	7.4	4.9
4	16.5	14.3	7.5	4.1

23	7.9	2.2	1.8	1.0
24	8.8	3.6	2.8	2.1
25	25.7	12.9	5.0	4.3
26	18.8	8.0	7.0	4.9
27	23.9	16.1	6.6	4.2
28	46.7	28.0	9.8	7.0

5 EVALUATION OF THE RESULTS

As shown in Table 2, dry rock UCS values vary from 2.2 MPa for the Avanos/Nevsehir sample to 46.7 MPa for the Basakpinar/ Kayseri sample. Saturated rock UCS values vary from 1.4 MPa for the Mustafapasa/ Nevsehir sample to 28.3 MPa for the Gulluce/ Nigde sample. Dry rock BPI values vary from 1.3 MPa for the Avanos/Nevsehir sample to 12.0 MPa for the Gulluce/Nigde sample. Saturated rock BPI values vary from 0.7 MPa for the Karayazi/Nevsehir (dark pink) sample to 8.1 MPa for the Gulluce/Nigde sample.

The test results presented in Table 2 were analyzed using the method of least squares regression. Several types of relationships were investigated (e.g. linear, logarithmic, exponential, power) and the equation of the best-fit line, the 95% confidence limits, and the correlation coefficients (r) were determined for each regression.

The power law function better correlates the relation between *UCS* and BPI for both dry rocks and saturated rocks (Figs. 2 and 3). Regression analysis was repeated for the combined data of dry and saturated rock and a power law relation was found again between the two parameters (Fig. 4).

As stated above, the UCS-BPI conversion factor of 5.1 was suggested by Sulukcu and Ulusay (2001) for a wide range of rock

types. However, it was indicated in some recent studies (Mishra and Basu, 2012; Yesiloglu-Gultekin et al., 2013) that this conversion factor may not be valid for individual rock types. Similarly, pyroclastic rocks tested in this study showed a different trend with the suggested relation. As shown in Fig. 4, the UCS-BPI conversion factor is found as 3.0. This value is fairly lower than the suggested conversion factor of 5.1.

Another important result of this study is that the relation between UCS and BPI is best represented by the power law function, not by the linear function. The correlation coefficients of power law functions are higher than that of linear functions for each case such as dry, saturated and both dry and saturated rocks.

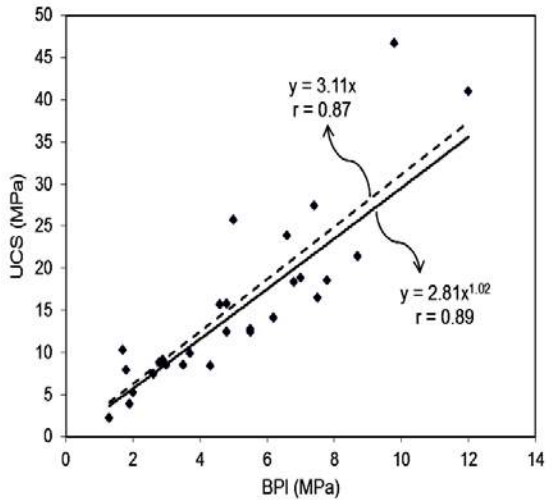

Figure. 2. The relation between UCS and BPI for dry rocks.

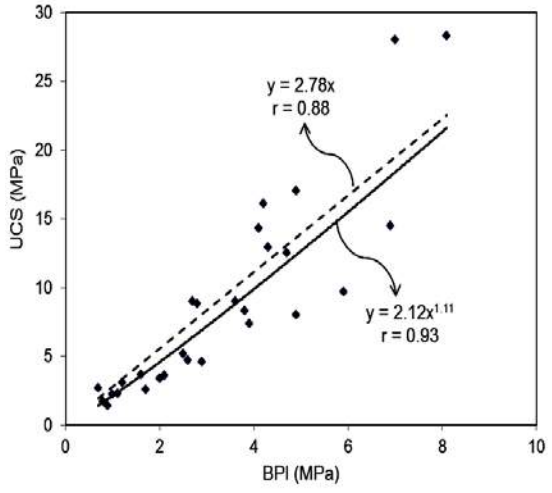

Figure 3. The relation between UCS and BPI for saturated rocks.

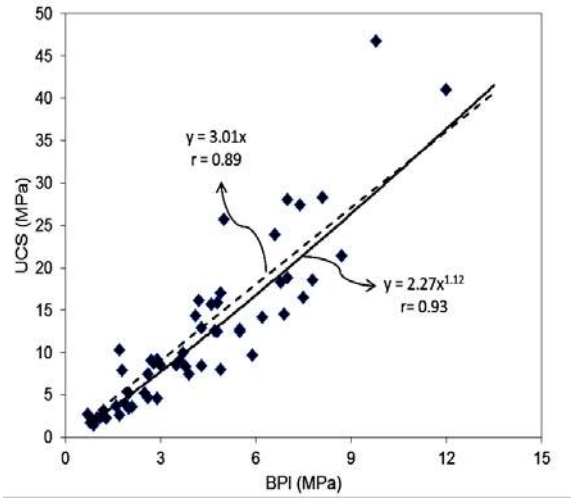

Figure 4. The relation between UCS and BPI for both dry and saturated rocks.

6 CONCLUSIONS

Twenty eight different samples of pyroclastic rocks were tested and the relation between UCS and BPI was investigated by using regression analysis. A UCS-BPI conversion factor of 3.0 was obtained by linear regression analysis for the tested rocks. This conversion factor is fairly lower than the suggested value of 5.1. The nonlinear regression analysis also indicated that the correlation coefficients of power law functions are higher than that of the linear functions for each case.

It is concluded that the UCS-BPI conversion factor is lower than the suggested general conversion factor for the evaluated pyroclastic rocks and the UCS-BPI relation is best represented by the power law function. Further research is necessary to check whether the results are valid for all types of pyroclastic and soft rocks.

ACKNOWLEDGEMENT

This study has been supported by the Turkish Academy of Sciences (TUBA), in the framework of the Young Scientist Award Program (EATUBA-GEBIP/2001-1-1).

Thermo-Mechanical Behaviour of Rocks from the South African Platinum Mines

G. O. Oniyide, H. Yilmaz
School of Mining Engineering, The University of the Witwatersrand, Johannesburg, South Africa

ABSTRACT This paper presents the results of the study on the impact of temperature on the behaviour of selected rocks from the South African platinum mines. These mines are influenced by increasing temperatures due to high temperature gradient. The rock samples from the platinum mines were tested under varying confinements (10 to 30 MPa) and temperatures (20 to 140 °C) using servo-controlled testing machine. The results of the laboratory tests show that increasing temperature results in reduction of yield strength and Young's modulus. Relationships between temperature and strength as well as the elastic modulus were established. These relationships would assist in the proper use of input parameters in numerical modelling exercises using the temperature option. The future design of deeper and warmer platinum mines would also hugely benefit from the knowledge of rock behaviour generated under high temperature and stresses.

Keywords: Temperature testing, rock strength, platinum mines

1 INTRODUCTION

Increasing depth of mining in underground mines brings about the challenges related to heat, in-situ stresses and logistical issues. Heat associated problems have mainly focused on the side effect of heat on workers' health (heat-stroke), increasing production costs as a result of higher cost of ventilation due to cooling and refrigeration. The effect of increasing temperature with increasing depth on the behavior of rock has not been given much consideration.

The platinum mines are in the Bushveld Igneous Complex (BIC), which is located in the northern part of South Africa. The BIC is the world's largest layered intrusion. It is about seven to nine kilometers thick and is divided into eastern, western and northern limbs. Its upper critical zone hosts the world's largest deposit of platinum group elements (PGE), (Schouwstra and Kinloch, 2000). Geological exploration information revealed the possibility of the platinum mines going for ultra-deep mining in future. Schouwstra and Kinloch (2000) stated that the Merensky Reef has been traced for 300 km around the entire outcrop of the eastern and western limbs of the BIC, and to depths of 5 km and beyond.

Gold mines in South Africa are generally deeper than the platinum mines, however, the latter has higher temperature gradient, which makes the platinum mines to be much warmer as the depth of mining increases. Biffi et al (2007) made a comparison of the geo-thermal gradient of the Witwatersrand Basin complex known by its gold mining and the BIC and reported that a virgin rock temperature of 40°C will be reached at an approximate depth of 650 m in the BIC as compared to a depth of about 1800 m in the West Witwatersrand Basin complex. The study of the effect of temperature on the rock behaviour would be beneficial to both gold and platinum mines, however the main focus of the research is on the platinum mines due to their higher temperature gradient. Donoghue (2004) stated that the virgin rock temperatures (VRT) and air temperatures increase with depth, due to the geothermal gradient and auto-compression of air column. Figure 1 shows the comparison of the VRT,

while Figure 2 shows the VRT for the mines in BIC.

Cawthorn (1999) proposed adapting the knowledge from deep mining on the gold-bearing Witwatersrand mines to platinum mines. He, however, noted that higher temperatures would be an additional factor that would influence the platinum mines as they go deeper. Therefore, in consideration of possible problems that would result from high stresses and high temperatures in deep platinum mines in the future, investigation of the influence of these parameters on the rock behaviour becomes necessary from rock engineering perspective.

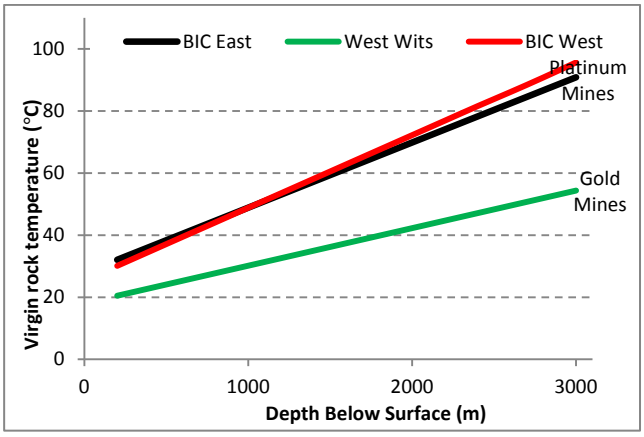

Figure 1. VRT against depth below surface (adapted from Biffi et al, 2007).

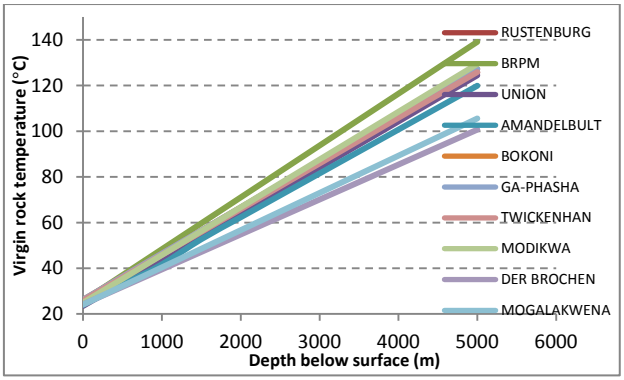

Figure 2. VRT against depth for platinum mines in BIC.

2 EXPERIMENTAL SET-UP AND ROCK TESTING

The rock samples tested were 36mm diameter cores that were obtained from Bafokeng Rasimone Platinum mine (BRPM) located in the western limb of the BIC. The samples are norite (N), leuconorite (LN), mottled anorthosite (MA), chromitite (CR), pyroxenite (PX), vari-textured anorthosite (VTA) and anorthosite-chromitite (ANCR).

MTS 793 servo-controlled testing machine, which is a stiff testing machine, was used for the triaxial compression tests at various temperatures. The MTS triaxial cell is designed for conducting tests with thermal option. The machine assembly consists of a fixed crosshead mounted on two rectangular columns which are bolted to the base, providing a high loading capacity in a stiff frame. Once the triaxial cell is inserted into the test space, the loading frame applies axial stress to the specimen inside the cell.

The load cell (Force transducer) has a maximum loading capacity of 2600 kN, which is accurate to within ±0.5% of the calibrated range. The triaxial cell has a confining pressure capacity of 140 MPa. The heating elements embedded on the cell allows tests to be done as high as 200 °C. The triaxial cell, when lowered onto the base plate forms a sealed pressure chamber for the specimen and extensometer assembly.

The tests are aimed at replicating the environment that the rocks would be exposed to in the platinum mines, where the VRT would increase as the mining depth increases. The tests are also intended to provide information on the post-peak behaviour of the rocks obtained. This information is very important in understanding the process of specimen deformation, starting from the stage of crack initiation to complete failure. The test results would provide insight into the residual strength of the in-situ rock mass.

2.1 Sample Preparation

The specimens were prepared according to ISRM (1999) standard for uniaxial and triaxial compressive strength testing with a length to diameter ratio of 2.5. The ends of the specimen were cut and ground parallel to each other and at right angle to the longitudinal axis. The disparity between the perpendicular ends of the specimen to its longitudinal axis was not more than 0.05 in

50 mm. The specimen (Figure 3) is jacketed in heat-shrink teflon material to prevent confining fluid from getting in touch with the rock specimen during heating and loading.

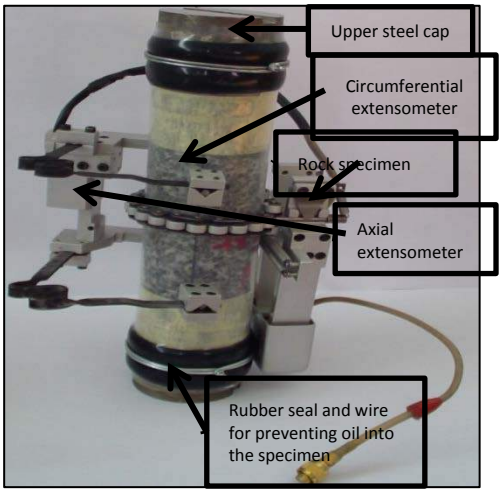

Figure 3. Prepared specimen for testing.

2.2 Temperature Control

The main objective of performing the tests was to study the response of the BIC rocks under increasing temperatures (20 °C, 50 °C, 90 °C, and 140 °C) and confinements (10 MPa, 20 MPa, and 30 MPa). The specimens were heated at the rate of 2 °C /minute until the desired temperature was reached. And then, the temperature was kept constant for one hour to allow for even distribution of heat in the triaxial cell and through the specimen.

2.3 Loading of Test Specimens

The axial stress and the confining pressure are simultaneously increased until the desired confinement is reach at rate of 0.5 MPa/minute. The control mode is then switched to axial strain control and the specimen was loaded at an axial strain rate of 0.001mm/mm/s until reaching approximately 70% of the expected peak force. Since most of the tested specimens are brittle, the axial strain control mode can only be used in the elastic region of the stress-strain curve. At 70% of peak force, the control mode was switched to circumferential strain control at a rate of 10^{-6} mm/mm/s, until the applied load dropped to 50% of peak force in the post-failure region. The control mode was then returned to axial strain control until the completion of the test.

The use of circumferential strain transducer as the feedback has been known (ISRM, 1999)) as the most sensitive means of detecting specimen failure. However, it should be noted that when a trial test was conducted with circumferential strain as the control mode at 70% of the expected peak stress, the test was terminated unsuccessfully. Then, dual compensation control, that is, using a combination of displacement and circumferential strain as the feedback mode, was used.

The machine displacement, in-built-calculated stress, temperature, confining pressure, axial and circumferential strain were continuously captured in a data file at all stages of testing. Five tests were done for each rock type. The test data were then processed to evaluate the Young's modulus at 50% of the peak strength, E_t, as the slope of tangent line of axial stress-axial strain curve.

3 RESULTS AND DISCUSSION

In this paper, the effect of temperature on the behaviour of rocks is analysed only at confining pressure of 10 MPa for ease of comparison. Table 1 shows the averages of Young's modulus of the rocks tested at 10 MPa confinement and increasing temperatures. Figure 4 shows the stress-strain behaviour of norite tested at 20°C, 50°C, 90°C, 140°C and at each temperature confining pressures of 10 MPa, 20 MPa and 30 MPa were applied.

Table 1. Average values of Young's modulus (GPa) at 10 MPa confining pressure with increasing temperature.

Rocks	Temperature			
	20 °C	50 °C	90 °C	140 °C
CR	58.5	56.2	53.8	51.7
LN	78.4	76.6	73.5	70.7
MA	87.1	84.7	82.9	79.9
N	79.6	77.7	74.3	71.1
PX	121.0	118.6	114.8	112.9

It is clearly seen in Table 1 and Figure 4 that increasing temperature results in the reduction of the Young's modulus and peak strength. The ambient temperature is approximately 20 °C at which the samples are tested initially, while 50 °C, 90 °C, and 140 °C correspond approximately to the VRT in the platinum mines at 1073 m, 2835 m and 5037 m below surface respectively. It should be noted that the test results between ambient temperature and increased levels of temperature vary considerably.

Table 2 shows the influence of temperature on the strength and Young's modulus in terms of percentage reduction in the strength and Young's modulus magnitudes as the temperature increases from 20°C to 140°C. It can be seen that 17.3% and 9.4% reductions in the strength and Young's modulus are significant. The reductions are rock type dependant with Chromitite having the highest percentage reductions. This knowledge is of particular importance since the Chromitite is the main reef body where the mining operations are concentrated. Therefore, designs based on rock engineering principals have to take the influence of temperature on rock behaviour into account, particularly in areas with high geothermal gradient .

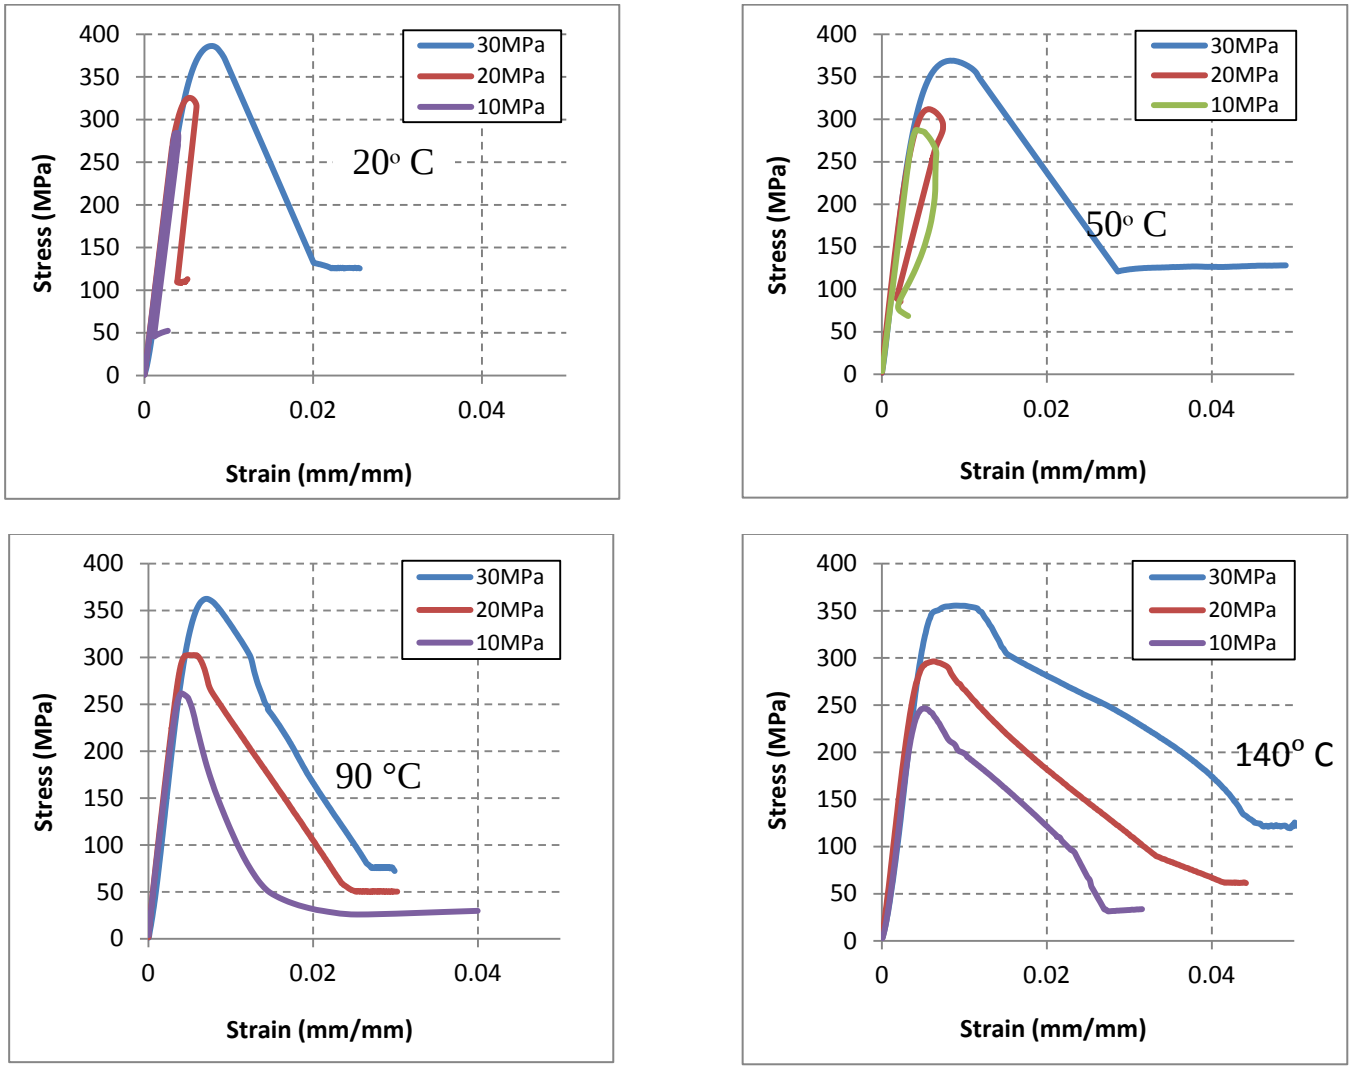

Figure 4: Influence of temperature on triaxial compressive strength and post-failure behaviour between 20°C to 140°C.

Table 2: Reduction in strength and Young's modulus of rocks due to temperature increase from 20°C to 140°C.

% REDUCTION in	CR	LN	MA	N	PX	Average
Strength	20.7	15.4	18.5	13.3	18.9	17.3
Young's modulus	11.7	9.8	8.3	10.7	6.7	9.4

3.1 Regression Analyses

Three specimens were tested per rock type per temperature at 10 MPa confining pressure and the averages of Young's modulus were used to produce the data points on the graph in Figure 4. The selected temperatures were 20 ºC, 50 ºC, 70 ºC, 90 ºC, 110 ºC, and 140 ºC. Figure 4 shows that the values of the gradient "m" range between -0.058 and -0.100. The correlation coefficients "R^2" range between 0.95 and 0.99, which means that there is strong correlation between Young's modulus and temperature.

Therefore, the data provided in Table 1 and Figure 5 is utilised to develop a simple linear regression model (y = mx + c) between temperature and Young's modulus considering that the temperature will increase as mining goes deeper. The ambient Young's modulus (E_{amb}) becomes the constant "c". The gradient "m" is evaluated for each rock type in Figure 5. Therefore, the following general equation can be written to estimate the Young's modulus for a particular rock subject to increasing temperatures:

$$E_t = -m\,(T - T_{amb}) + E_{amb} \qquad (1)$$

where ; E*t* is the temperature dependent Young's modulus (GPa)
T is any temperature between 20 ºC and 140 ºC ($T \geq T_{amb}$)
T_{amb} is the ambient temperature (in this case 20 ºC)

It should be noted that E_{amb} is the Elastic modulus taken from Table 1 at 20 ºC and not the zero intercept provided in Figure 5. The "m" value is rock type dependent. For example, norite (N) has E_{amb} magnitude of 79.6 GPa (Table 1) and m value of -0.074 (Figure 5). Further research is required to check the sensitivity of "m" value to confinements other than 10 MPa.

Although the ambient temperature used in Equation 1 is 20 ^oC, it is assumed that specimens tested at 20 ^oC ± 5 ^oC would still be accommodated. This is based on the information provided by Kruger and Shongwe (2004), who reported that the average annual temperature of South Africa for 1960 to 1990 and 1991 to 2003 as 18.18 ^oC and 18.48 ^oC respectively. This temperature given is that of outdoor. It implies that the ambient room temperature used in in equation 1 falls within acceptable range.

The comparison of the Young's modulus determined from actual laboratory testing and the one estimated using equation 1 is given in Figure 6. Only two of the rocks are provided as examples in Figure 6. The percentage difference between the laboratory determined values and the ones calculated from equation 1 is negligible as shown in Figure 6 and Table 3.

Table 3. Percentage difference between laboratory measured and calculated Young's modulus.

	50 ºC	**70 ºC**	**90 ºC**	**110 ºC**	**140 ºC**	**Absolute average**
CR	-0.97	-0.50	-1.12	-1.92	0.52	0.84
LN	0.26	-1.36	-0.44	-0.44	0.17	0.45
MA	-0.81	-0.51	-0.17	-0.39	-0.30	0.36
N	0.42	0.01	-0.19	-0.37	0.48	0.25
PX	-0.21	-0.41	-0.98	-1.12	0.52	0.54
VTA	0.76	0.42	-0.58	-0.03	0.61	0.40
ANCR	-0.37	0.73	0.11	0.04	-0.18	0.24

Note: Negative sign denotes underestimation, while positive denotes overestimation.

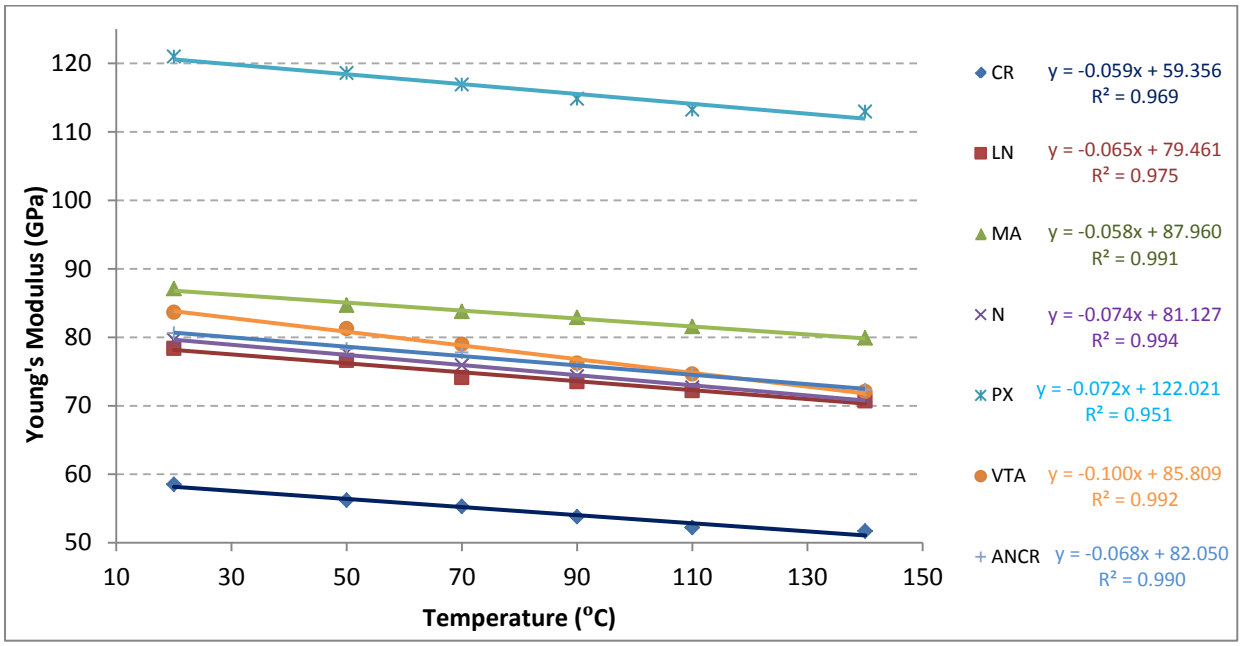

Figure 5. Young's modulus and temperature relationship for various rock types.

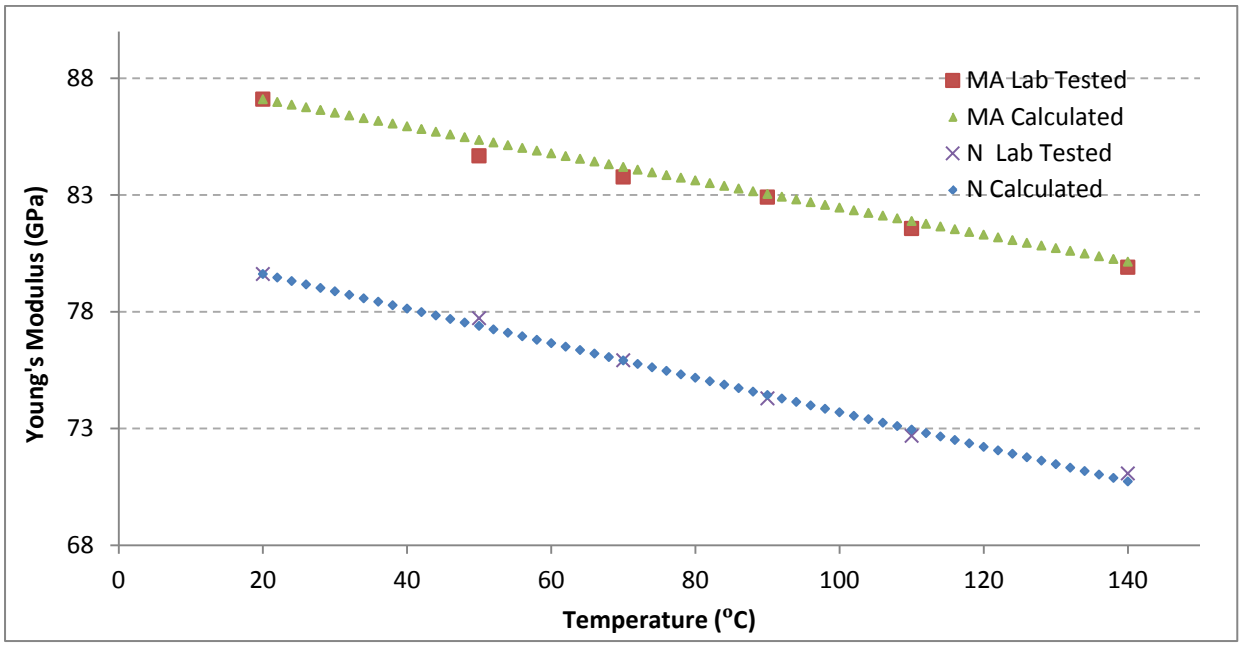

Figure 6. Comparison of Laboratory tested and calculated Young's modulus for two rocks.

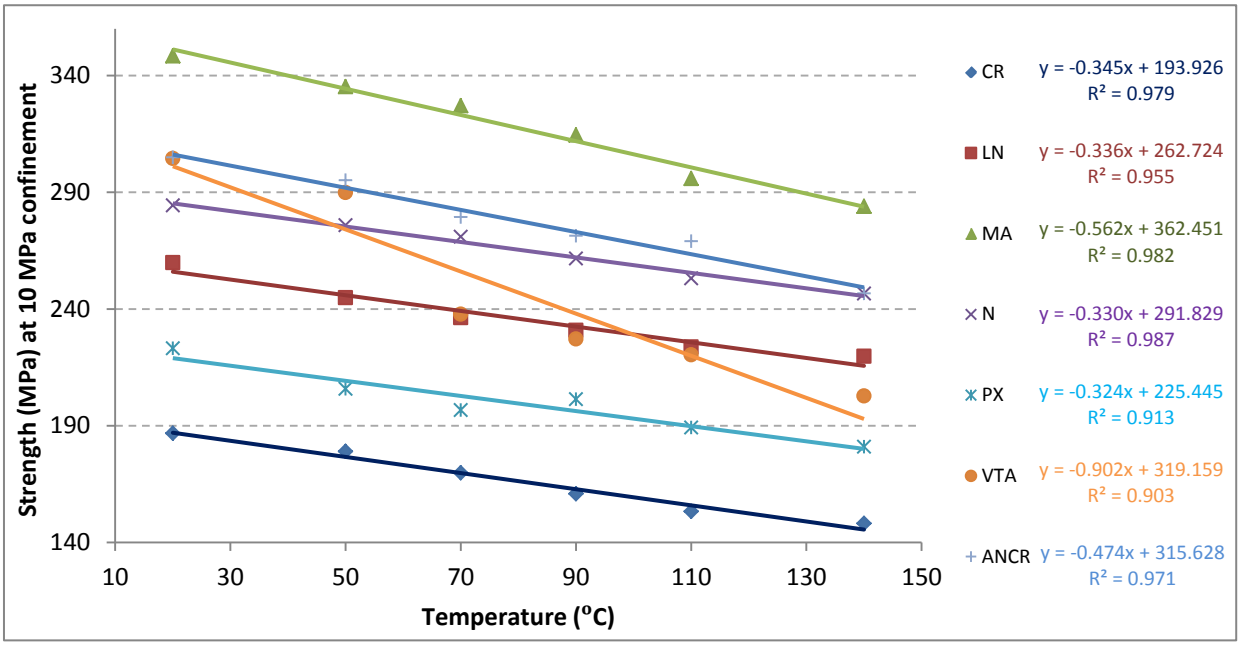

Figure 7: Strength behaviour against temperature at 10 MPa confinement.

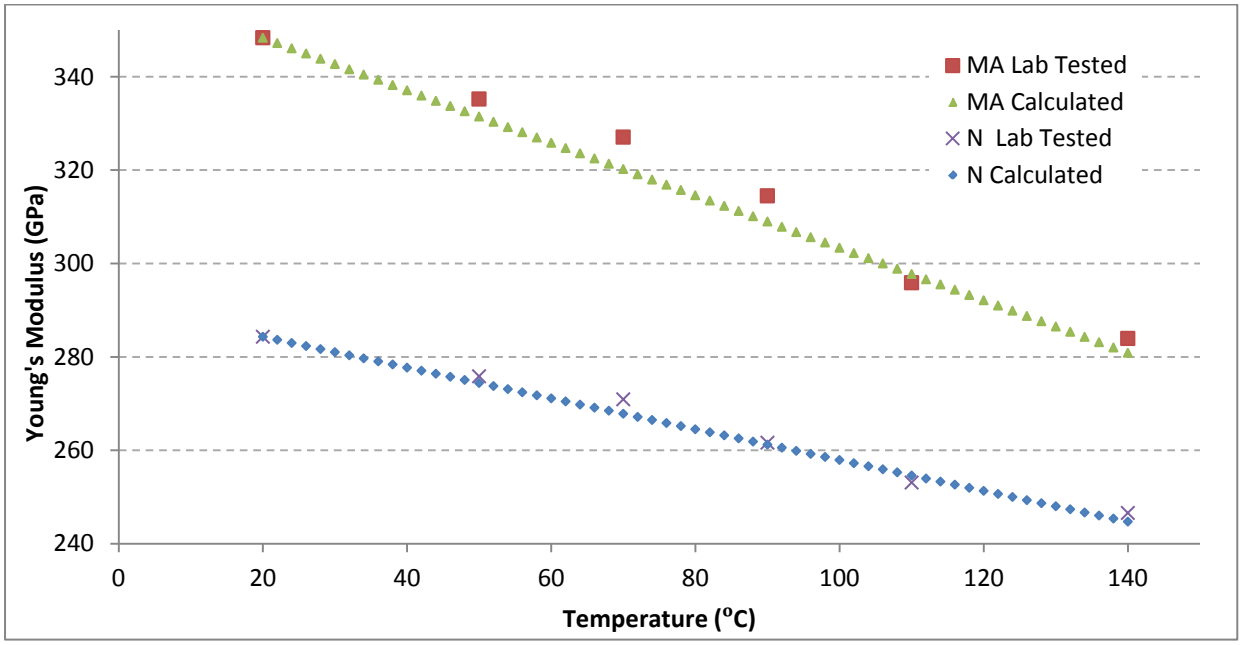

Figure 8. Comparison of Laboratory tested and calculated strength for two rocks.

The percentage difference for all rock types for the temperature range is between -1.92% and 0.76%. The highest percentage difference in absolute terms occurs with CR and the lowest is with ANCR.

Following similar steps as explained for temperature-dependent Young's modulus, a linear regression model (equation 2) was also established for temperature-dependent peak strength from the plot in Figure 7.

$$\sigma_t = -m(T - T_{amb}) + \sigma_{amb} \quad (2)$$

where; σ_t is the temperature dependent strength (MPa)
T and T_{amb} are as explained in equation 1
σ_{amb} is the strength measured at ambient temperature

The comparison of the laboratory-measured strengths and the one estimated from Equation 2 is given in Figure 8, while Table 4 shows the percentage differences. The variation between the laboratory values and the ones derived from the proposed equation 2 is again negligible, except for that of VTA. This variation could be attributed to the inconsistencies in the mineralogical composition of VTA or the presence of internalmicro-cracks.

Table 4: Percentage difference between laboratory measured and calculated strength

	50 °C	70 °C	90 °C	110 °C	140 °C	Absolute average
CR	1.48	0.19	-1.09	-1.57	1.89	1.04
LN	-2.03	-2.89	-2.39	-2.63	0.10	1.67
MA	1.12	2.09	1.75	-0.64	1.07	1.11
N	0.51	1.14	0.15	-0.60	0.75	0.53
PX	-3.68	-5.19	0.44	-2.53	-1.79	2.27
VTA	4.32	-9.01	-6.14	-1.21	3.39	4.01
ANCR	1.50	-0.66	-0.13	2.50	-0.56	0.89

It is suggested that equation 1 and 2 is used for determining the corresponding reduction in Young's modulus and strength respectively with respect to virgin rock temperature as input values for numerical modelling and for subsequent underground rock engineering design.

3 CONCLUSIONS

The South African Platinum mines are going deeper. There would be problems associated with increasing stresses, and mining cost with regards to ventilation, ore transport. An additional problem would arise due to the influence of increasing temperatures on rock behaviour. This paper, in fact, shows that the strength and Young's modulus of the rock types involved in platinum mining undergo reduction with increasing temperatures. The equations to assist the estimation Young's modulus and strength with respect to increasing virgin rock temperatures are proposed. Future rock engineering designs should bear the findings presented in this paper into account particularly when the numerical modelling and the subsequent excavation and support design is done.

ABSTRACT There are a plenty of research have proclaimed that real options valuation (ROV) method is a promising technique for valuing the mineral resource industry in the face of uncertainties. However, it is apparently that this method is rarely used in mining company. This is due to its complexity in solving mathematical mixed integer programming problems (MIPP). Furthermore, there is no exact of existing tools which offer the ease of the quick calculations and reliable results for making flexible alternative decisions. Thus, this article presents the integration of ROV approach and system dynamics (SD) modeling method for developing the dynamics decision making tools (DDMT), for open pit mine planning projects. With the use of SD makes it possible to solve the interdependent variables as well as path-dependent activities. This paper illuminates the conceptual models as well as a roadmap towards developing better decision making tools.

Keywords: ROV, DDMT, SD

1 INTRODUCTION

1.1 Background

Mine planning is a difficult task. Even for small operations, it involves reasoning with complex variables and the practical difficulties of mining. It is also about predicting and planning the future in an unpredictable physical of economic environments. Planning affects everyone in the organization. Company executives are demanding more reliability and stability in cost and revenue forecasts from their operations. Management desires to explore ways of being more cost effective. Miners and contractors need more useful plans and realistic targets. Planners have to describe the method that will translate business into implementable plans [16]. A decision making process involves formulating options, predicting their outcomes and evaluating these against some objectives. This process is cyclically repeated until either the objectives are met or there no more time to consider more options or refine existing options.

It is undeniably that there are commercial software's for planning process, such as MineSight, Surpac, XPAC, and Vulcan, etc. Nevertheless, such software's have quite complicated functions and needed sophisticated experts to carry out the given tasks. Moreover, it is very time demanding processes and it takes many steps to generate single results, which cannot take onboard for making a strategic decision. More in actual

fact, such commercial software's do not have functions to tackle the uncertain conditions during the period of operations in life-of-mine. Martinez [10] suggests that it is of paramount importance for doing more research and development for building new tools that can account for uncertainty and risk in mine project evaluations. Ford and Sobek [4] built a product development project model that uses real options concepts to manage product design risk. Barghav and Ford [2] examined the relationship between project management quality and the value of flexible strategies. Johnson et al. [7] used an SD model to value flexibility in a large petrochemical project. These papers provide examples of how real options logic can be incorporated into SD models; yet they analyze projects with a single option and they do not focus on formalizing an algorithm to estimate the market value of projects with complex option structures using SD models.

Singh [14] proposes capacity expansion planning model for coal mining for Hunter Valley Coal Chain in Australia. The author attempts to solve the mixed integer programming (MIP) models using the commercialized software. Huh et al. [6] considers capacity planning under demand uncertainty using a network optimization based heuristic to determine the sequence and timing for purchasing and retiring machines required to manufacture different products. Sontamino and drebenstedt [15] developed decision making tools for evaluating the feasibility to open coal mines in Thailand. It is clear that there is lack of research which incorporating real options into SD methods. Particularly, there is no studies intent to develop dynamic decision making tools that can handle the uncertainty in open pit mining ventures.

The objective of this research is to develop a better decision making tool that provide user-friendly interface, quick calculations, and generate reliable results. It hopes to build tools which can advocate mine planners that under what conditions the mines should expand its capacities in order to capture the upside potential of favourable market, and at what conditions the mine should maintain, shrink, or shutdown its operations to avoid downside impact and loses. The tools will allow mine planners to input sets of data such as the target of saleable products per year, the target of total productions per year, mining capacity, milling rate, metal price, mining costs, processing costs, among others. This paper should hold an attention of those involved in helping mine operations improve outcomes from investments opportunities by managing uncertainty and risk.

The remainder of this paper is organized as follows: section 2 provides a problem formulation. Section 3 presents methods which applied in this research. In this section, the scope is outlined in order to confine the limit of studies in a certain horizon. Section 4 summarizes the key ideas and roadmap towards developing DDMT. The last section 5 is the conclusion which will provide final remark and highlight the future works of this study.

1.2 Problem Framing

There are existing tools have been used in financial decision-making such as the payback period, the discounted cash flow (DCF) and its alliance net present value (NPV), the internal rate of return (IRR) and the wealth growth rate. These tools are useful and meaningful in evaluating normal projects closely related to regular business where the number of assumptions made is usually very small and where the cost of capital is usually selected as a hurdle rate. It is arguable that in situations where a significant number of assumptions have to be made, two problems can emerge namely: (1) The risk involved is underestimated leading to a potential financial disaster; (2) A good opportunity is lost because the approach used in evaluating the project is too conservative. The reason that current techniques cannot solve the mine evaluation problems appropriately is those techniques have been developed in isolation.

The question arose afterward is that: Is the scenario analysis reflects the reality? It turns out that there are no definite answers for the above question. Johnson et al. [7] infers that

real option theory attempts to answer these questions: what are the future alternative options?; when should we choose between available options to maximize values based on the evolution of conditions?; how much is the right to take an alternative worth at any given time?. Very often in mining industry, project evaluators and decision makers will resort to previous experience and rules of thumbs in determining mining and processing capacity; rather than supporting these decisions with proper analysis. This could lead to operating inefficiencies and inaccuracies. Thus, this study will build the tools with package of the triggering conditions to support the decision makers for making a strategic decision based on best options that fit for operational and management's flexibility.

2 LITERATURE REVIEW

2.1 Real Options Valuation (ROV)

A real option is the right but not the obligation to undertake certain business initiatives, such as deferring, abandoning, expanding, staging, or contracting a capital investment project.

Brennan and Schwartz [1] and McDonald and Siegel [11] were the first economists who came up with the idea to incorporate option valuation techniques when making investment decisions. A few years before that, Myers [9] had already proposed the concept to see investment opportunities as growth options, and had attached the name real options to it. Since then a lot of studies have been published about real options and their applications in the economy. Yet, it still lacks of research conducting a study to incorporating this technique into valid tools for mine evaluation purposes. Dimitrakopoulos [3] summarize the main findings of previous work in real options applications to valuing mining investments.

- The trigger metal price for developing a mine estimated by the ROV is greater than the breakeven price determined by the conventional NPV method.
- The value of a project estimated by the ROV is greater than that estimated by the NPV method. In other words, NPV tends to undervalue mining investment.
- ROV approach is better than NPV in dealing with uncertainty and operating flexibility.
- The different between the ROV and the NPV estimates represents the value of operating or management flexibility, and different depends on the uncertainty level and the project profitability.
- The ROV and the NPV method differ fundamentally in the way the discount future cash flows and in the way they deal with managerial flexibility.

2.2 Fundamental Of System Dynamics

System dynamics (SD) is a methodology and mathematical modeling technique for framing, understanding, and discussing complex issues and problems. In the system dynamics methodology, a problem or a system is first represented as a causal loop diagram. A causal loop diagram is a simple map of a system with all its constituent components and their interactions. By capturing interactions and consequently the feedback loops, a causal loop diagram reveals the structure of a system. By understanding the structure of a system, it becomes possible to ascertain a system's behavior over a certain time period [17].

Richardson [13] reviews the core of SD methods and summarize that the system dynamics approach involves:

- Defining problems dynamically, in terms of graphs over time.
- Striving for an endogenous, behavioral view of the significant dynamics of a system, a focus inward on the characteristics of a system that themselves generate or exacerbate the perceived problem.
- Thinking of all concepts in the real system as continuous quantities interconnected in loops of information feedback and circular causality.
- Identifying independent stocks or accumulations (levels) in the system and their inflows and outflows (rates).
- Formulating a behavioral model capable of reproducing, by itself, the dynamic problem of concern. The model is usually a computer

simulation model expressed in nonlinear equations, but is occasionally left unquantified as a diagram capturing the stock-and-flow/causal feedback structure of the system.

- Deriving understandings and applicable policy insights from the resulting model.
- Implementing changes resulting from model-based understandings and insights.

3 METHODOLOGY

This research employs the SD method to allow real options techniques to unlocking the true value of managerial flexibility when applying it in valuing mineral resource investment project. Likewise, the binomial lattice will also perform alongside with Monte Carlo simulation in order to capture the upside potential and downside risk of options values. In this study, the DDMT will be developed using VensimDSS version6.0b alongside with C++ programming language. With the use of SD makes it possible to solve interdependent variable of mixed integer programming problem.

3.1 Real Options Framework

Real options are appealing to a company's management because it copes with future uncertainty and provides them flexibility.

The framework proposed in this paper is specifically devised for open pit mine planning tasks. Figure 1 depicts the framework used in this study. It is worthwhile to emphasize that real option methods can be useful tools for mining firms if they clearly understand its potentials to deal with uncertainties as superior to the traditional discounted cash flow valuation methods. Besides, the real options method should not only be known by its management level of mining ventures but it should be also engage to mining engineers as to allow them to get the idea on how to confront with the operating problems and solve it effectively. The following steps are guiding principle through the use of DDMT.

1) Base-case mine design, which is built using current mine design techniques and used to identify main cash flow drivers;
2) Determining the sources of risk and uncertainty, by incorporating geological uncertainty and metal price uncertainty into mine planning and design;
3) Using system dynamics to structure the real options valuation (ROV) model, integrating binomial lattice to visualize the options value as well as capturing upside potential and downside risk.
4) Establish financial model and run discrete event simulations using least square Monte Carlo [8]; performing sensitivity analysis to lock up the effects of uncertainty and risk.
5) Ranking the available options based on its value and the indicators of upside and downside.
6) Making final selection based on operational and managerial flexibility.

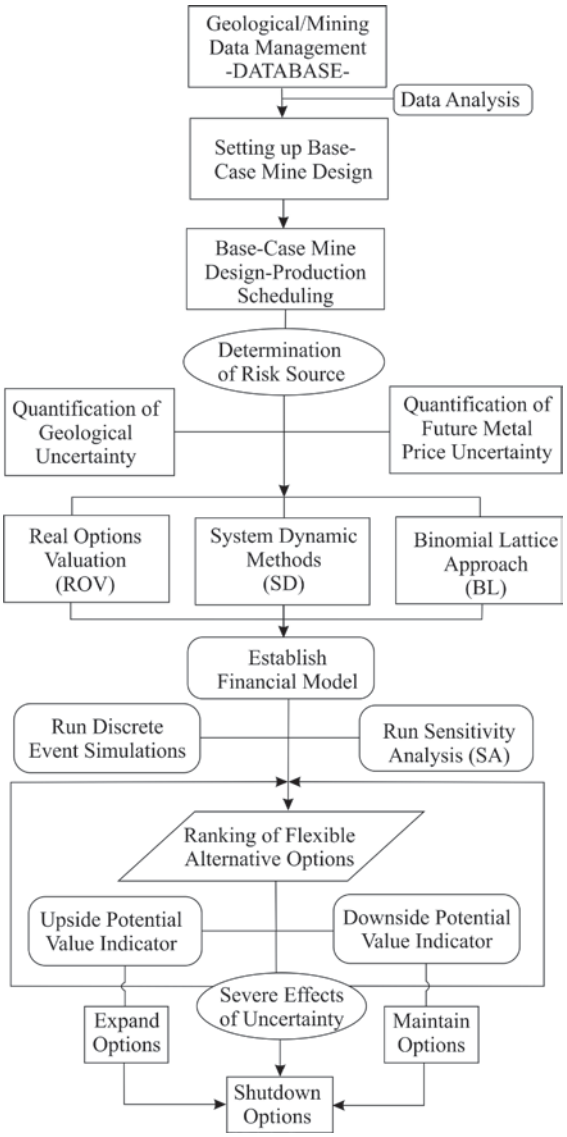

Figure 1. Schematic diagram depicting the framework for dynamics decision making tools

3.2 Prototype Of Dynamics Decision Making Tools (DDMT)

Decision-making can be regarded as the cognitive process resulting in the selection of a belief or a course of action among several alternative possibilities. Figure 2 shows the key influential variables economic feasibilities, technical measurements, and resource portions.

The DDMT model consists of major elements such as objective functions, decision variables, bounds, types, assumptions, constraints. The following passages are described for each of those elements.

- Objectives function: the objective function is to maximize the discounted NPV before tax of mining venture and minimize risk embedded in mine valuation process.
- Decision variable: the sets of inputs which resulting the highest NPV.
- Bounds: defined the upper and lower limits for the variables.
- Types: defines whether the variable is discrete or continuous types. Discrete variables are those that can only take on a finite number of values. Continuous variables that can take on an infinite number of possible values.
- Assumptions: capturing the uncertainty and risk of data inputs to model using probability distributions.
- Constraints: constraints restrict decision variables by defining their relationship among them. The major constraints refer to market conditions, operating efforts, and technical matters.

Decisions are usually triggered by internal and external conditions. In circumstance cases, decision can be made as quick as to rescue projects from the horrific impact which resulting from risk and unforeseen incidents. For example, metal price falling, pit wall sliding, concentrator in predicament, among others. This paper focuses on decisions that triggered by three main triggering conditions, namely economic, resource and technical conditions as shown in Figure 2. These decisive criteria based upon the ability of management flexibility to execute the options as well as availability of data.

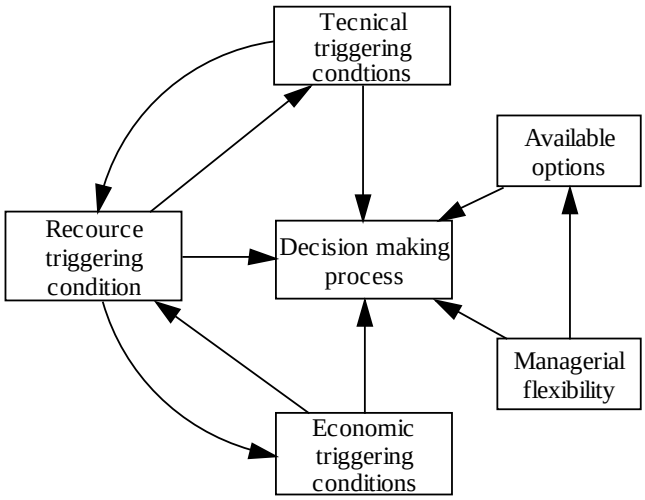

Figure 2. Decisive triggering condition for DDMT

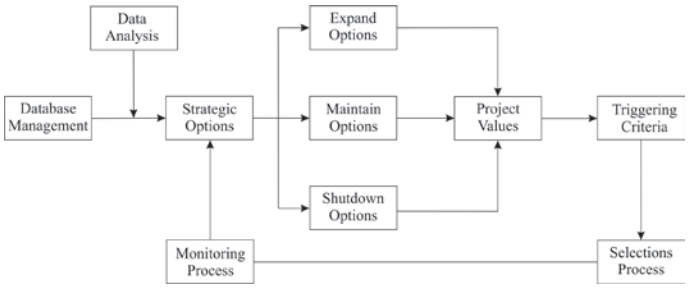

Figure 3. Decision process of options model for DDMT

Figure.3 illustrates the decision process diagram of options model for DDMT which represents the interrelationships between available options i.e., expand options, maintain options and shutdown options. These strategic options are assumed interchangeable during periods of operations. It is visibly shown in figure 3 that the strategic options will be chosen if only the calculated project value met the objective functions which defined above. It is important to note that the options must be executable against the triggering criteria. Then the selection process is performed one at a time to make a final decision on the way to take the options to action, this process will be repeated as to measure the outcome in short-term of implementation.

3.3 Conceptual Model Of DDMT

In this section, the conceptual models of dynamic decision making tools will be presented. It is very interesting to demonstrate the integration of real options valuation logics into system dynamics model. As shown in figure 4, it is apparently that options defined production capacity, putting different operating options resulting in different production capacity, and also option values.

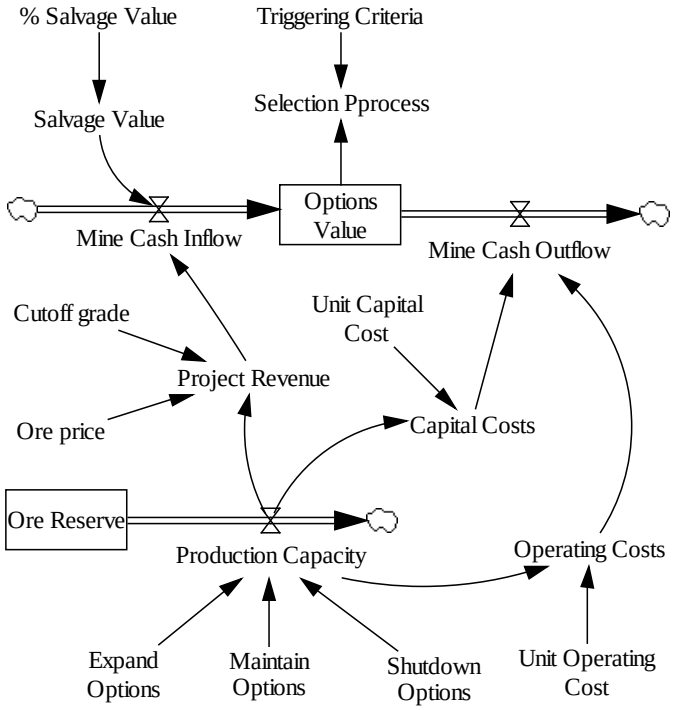

Figure 4. Prototype integration of ROV into SD model

However, switching options not only depend on its value but also rely on the ability of managerial flexibility. For example, if mining firms decide to expand its operations in times of rising metal price, the mining firm shares may be a superior to alternative physical economic investments. In other words, by executing options the mine operators are capable to yielding higher returns. In other way around, when the time of metal price falling consecutively, the mine might need to consider shutting down their operation temporarily or permanently. In this context, temporary closing is theoretically feasible but not seemingly executable for some reasons in real practice. In equilibrium market, the mining firms may possibly maintain their operating capacity, as mine operators believed that at the stability of metal price will lead them to generate higher profits than in volatile environments. In detail, the following sections provide an explanation of option models which proposed to build-in dynamic decision making tools.

3.3.1 Expansion options concept

When demand turns out to be high in line with the favourable of future market conditions, then the expansion options can be regarded as favourite choice for mining operation. Table 1 elucidates the expansion planning models which proceed in phases, where each phase is broken into stages. In doing so, we can define the marginal costs of each stages as well as marginal revenue. The idea behind is to minimize the risk which associate with infrastructure enhancements; especially in delivery of major mining and concentration equipments. The expansion capacity of both mining and processing will progressively increase as the construction of new infrastructures progresses. Table 1 tabulates the indicative stages of expansion options model. In this framework, there are three of capacity developments phases will be developed in the specified time periods, symbolize *t*, where *t* is in *T*, which represent total time of each development phase.

It is of paramount importance to note that this paper assumes there are no delays in delivery of expanded equipments, also any hindrances in construction of the support facility and infrastructures.

Table 1. Hierarchy phases of expansion options model

Stage	Timing	Description
Initial capacity development	t_0, $t \in T$; t=0,1..,T;	(a) Development of the pre-mine infrastructure and establishing the new open pit mine to deliver the target capacity of the first stage (b) Development of off-site infrastructure associated with initial mining development and concentrator plants (c) Acquiring mining equipments, i.e., shovels, trucks, concentrator and metallurgical plants, etc.
Intermediate capacity development	t_1-t_{t+1}, $t \in T$; t=0,1..,T	(a) Construct off-site facilities, concentrator plant and metallurgical plant to extract and process up to target of saleable products (b) Expansion of existing smelter to allow smelting the target concentrates (c) Develop new expanded infrastructure to support the increased capacity of the expanded of mining and metallurgical plants
Full capacity development	t_1-t_{t+1}, $t \in T$; t=0,1..,T	(a) Expansion of open pit mine, concentrator, and hydrometallurgical plants to extract and process to achieve target saleable products. (b) Fully constructed the expanded facilities to allow mining and processing achieved target saleable products

3.3.2 Maintain options concept

When market is in equilibrium state, the maintain option is reserved for a mining project. This is due to the fact that there is no gain nor loses from exercising other options. However, the producers consider that price stability can lead to higher returns than a volatile price that fluctuates in response to short-term variations in demand and supply. This is seemingly the case, since there is a strong implication between commodity price volatility and market performance, as well as mining project value. Haque et al. [5] unveils a study that when volatility increases, the risks associated with the commodity price increases and investment returns decrease, and project values typically decrease. The numerical results of his study suggest that the mine should run their project when the commodity price volatility lies either below the average or at the average volatility levels. This is probably arguable outcomes because if the mine has strategic options and the ability of management to handle uncertainty; then the mine would have gain its value and eventually profitable. In this paper, the maintain option is considered as the standby options, for when the market conditions turn out to be positive , mining firms can plan to expand their operations in order to capture the advantage from the upside potential of investments opportunity. If otherwise, the mine operators should hold their production capacity consistently.

3.3.3 Shutdown options concept

Once the triggered conditions turn out to be adverse, the abandonment option is one of the most common strategies considered in project evaluation [12]. In mining, the strategy consists of having the flexibility of closing and abandoning the open pit mining project permanently if market conditions or mineral resources decline severely. This strategy normally incurs costs for mine closure and land reclamation, while it also relies on secondary markets that are the salvage value from selling capital equipments and other assets. It is oftentimes closing a mine leads toward additional costs. For instance, reclamation costs, tailings and waste rocks treatment costs, among others. In

his conceptual model, it is evidently described that when the metal price is consecutively falling, the gross revenue generated cannot copes all the costs incurred. It is thereby causing the negative NPV. In the meantime, if the resource is radically depleting where there are no newfound ore deposits, then the mine must consider to shutdown its operation prior to the effect of erratic adversity. This kind of options would be valued if only the manager decide to execute it in advance.

4 SUMMARY

This study steps toward developing a dynamics decision making tool for open pit mine planning projects. The main idea is to build tools, which offer flexible alternative options i.e., expansion options; maintain options, and shutdown options based upon the availability of information and inputs data. It accordingly aspires to design a tools with simple features, users-friendly, quick computations, and easy-handy to setting up in operating systems of computers. Figure 5 showing a roadmap to develop DDMT(s). There are four main tasks, which linked by the connector lines, the arrow heads denote the predecessors must be done before proceed to successors. The different symbols in each connector heads represent mission of each task. The circle connector head linked between task I and task II, denote the initial stage to framing the scope and determine the constituents of tools. The rectangular connector head coupled from task II to task III indicate that thereafter finished conceptual models and its components; then proceed to design the architecture of DDMT. It includes sketch up the graphical user interface (GUI), formulate the toolkits with function guideline and the drafting the help for users. The final task is connected by the line with triangle connector head, represent methods and technologies will assemble in the DDMT.

The next stage is to synthesize those elements of four tasks (I+II+II+IV), into one package of application. The DDMT will be generating through the development process, called ‘assembling’ enactment. The final work is to testify the validation of DDMT application.

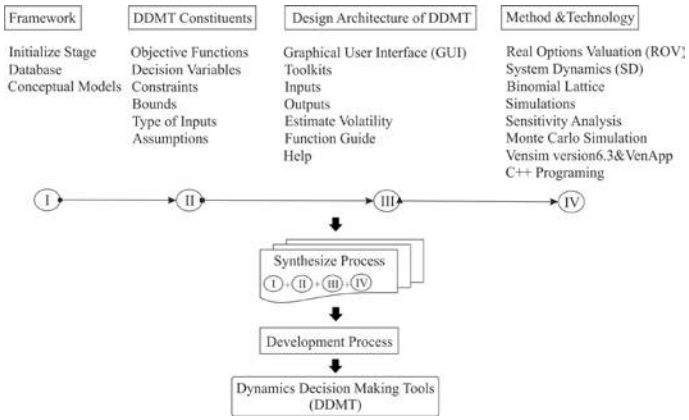

Figure 5. Diagram showing a roadmap to build DDMT

5 CONCLUSION AND FUTURE WORK

The article has presented the prototype of a dynamics decision making tools (DDMT), for open pit mining planning projects. It has pioneered an integration of real option valuation approach into system dynamics modeling methods. The tools will offer a power to mine planning engineers in valuing projects under uncertainties. The benefit of using DDMT is that it will prompt decision makers to realize the value of managerial flexibility or options premium, which can be obtained from the variation of uncertainties. It is hoping that the successfully combination of real option logics into the prototype of SD model will be extended to create a better decision making tool for solving mine evaluation problem in effective ways.

The ongoing work of this research would be continuing to shape the form of DDMT into a useful and interactive application. The future work is formulating comprehensive framework and robust triggering conditions to reinforce the decision making process. Also, considering the actual number of input variables in application is substantially important. The DDMT will be developed in the ways that it can assist mining firms to improve its management to change the way the mine runs.

ACKNOWLEDGEMENT

The author gratefully acknowledged for the financial support from German Academic Exchange Service (DAAD), granted code A/12/96777. Likewise, thanking Institute of Mining and Special Construction Engineering, TU Bergakademie Freiberg for supporting a sound environment for conducting this research.

Determining Refuge Chamber Location in Underground Tunnel Using 3D Computer Modelling

C. Doğruöz, M. Özdemir
Dumlupınar University, Mining Engineering Department, Turkey

A. Nieto
Penn State University, Energy and Mineral Engineering Department, USA

ABSTRACT Refuge chambers for underground mines can provide air, food, water, and supplies to miners in the event of an emergency. This paper presents an initial approach to prepare the area and install a refuge chamber located in an arched sectional underground tunnel. The proposed model was developed in order to clearly define the dimensions and safety specifications needed to properly install a refuge chamber in a given underground arched section. Rock bolt holes were designed based on simulated data to emulate roof and lateral forces created by the layers of rock above the arched section of the tunnel in question. This model can be modified based on the specific characteristics of the host rock mass and the local geology. In this study, tunnel design and refuge chamber utilization were designed in conjunction to confirm consistency of the refuge chamber geometry vs. the dimension of the tunnel section. The model was carried out using 3D computer modeling. Per our conclusions, when designing and developing a new underground mine, or opening a new underground section in already active mines, it is important to determine and define, during the early stages of the mine design, the specific location and geometry needed to deploy and install refuge chambers to comply with safety regulations and specifications.

Keywords: Refuge chamber location, refuge chamber in tunnel

ÖZET: Yeraltı madenciliğinde kullanılan yaşam odaları madencilerin kullanabilmesi için temiz hava, yiyecek, su temin etmekte ve acil durumlarda barınak olarak kullanılabilmektedir. Bu makalede yaşam odalarının konulacağı alanların önceden belirlenmesi ve yaşam odalarının kemer kesitli tünellerde konumlandırılması dizayn edilerek çalışılmıştır. Oluşturulan modelde, yaşam odalarının konumlandığı alan, iş güvenliği ve formasyon açısından yeraltında kemer kesitli tünellerde en uygun lokasyonlara konumlandırılması amaçlanmıştır. Tünellerin tavan kısımlarına açılan kaya saplamaları delikleri ile tavan kayaç katmanları belirlenerek kayaç formasyonları kemer kesitli tünellerde dizayn edilmiştir. Bu model spesifik kayaç karakteristikleri ve kayaç kütlesi ile jeolojik katmanlar belirlenerek geliştirilebilir. Bu çalışmada, yaşam odası geometrisi ile tünel boyutları arasındaki tutarlılık hedeflenerek tünel içerisinde yaşam odası dizaynı uygulanmıştır. Bu model, 3 boyutlu bilgisayar uygulaması kullanılarak oluşturulmuştur. Sonuç olarak, yeraltı madenciliğinde tünel dizaynı yapmadan önce yaşam odalarının yer tespitinin yapılması, iş güvenliği düzenlemeleri ve yaşam odalarının tüneller içerisinde önceden konumlandırılması açısından önem arz etmektedir.

Anahtar kelimeler: Yaşam odası lokasyonu, tünellerde yaşam odası

1 INTRODUCTION

After several underground mine accidents occurred around the world, the need for refuge chambers has been given markedly more attention. However, the utilization of refuge chambers alone remained inadequate. There are many safety parameters to consider for underground mines before constructing refuge chambers. Only after other safety measures are applied, should refuge chambers become a significant focus. In this study, a horseshoe sectional tunnel was designed by using a mining software program and rockbolt holes were placed based on assumptions. The main purpose of this study was to determine the proper location of refuge chambers. In addition, these refuge chambers were monitored in tunnels together with the rockbolt holes.

In underground mining, enforcement of refuge chamber laws needs to be improved and new approaches should be developed to increase the effectiveness of mine safety. Toward that goal, 3D views of underground mine planning and modelling should be a part of safety legislation. There are different scenarios of underground mine accidents and disasters such as mine explosions, mine collapses, and gas emission problems. In addition to aforementioned hazards, psychological factors of miners, escape techniques, and refuge chamber locations gain more significance for mine safety.

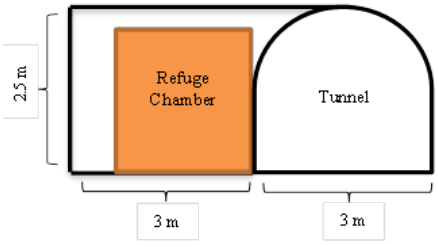

Figure 1. Cross sectional area of tunnel with refuge chamber

Within tunnels, it is important to find the most accessible location of refuge chambers for miner safety. Zhang and his colleagues have developed a model using the finite elements method. The correct dimensions for a refuge chamber are 3.2 m in length and 2.6 m in height (Zhang et al., 2014).

In this study, an underground tunnel has been designed and the rockbolt holes have been located at the roof of the tunnel. The tunnel has been developed as a horseshoe section and the roof rock layer formations have been added. The length of our tunnel section is 3 m in length, 2.5 m in height and the room in which the refuge chamber is located at 2.5 m. After modelling the tunnel, the possible refuge chamber location has been determined and designed into the tunnel. Figure 1 shows the cross sectional area of the tunnel with refuge chamber. In this study, the models and designs are defined based on possible operational scenarios. Moreover, a cross section of the horseshoe tunnel has also been studied in this article.

2. REFUGE CHAMBER UTILIZATION IN MINE ACCIDENTS

Mine explosions and mine disasters lead to new approaches to mine safety and health. After these unexpected accidents, miners psychological conditions become very significant during the escape from mines (Margolis et al. ,2011). Qunanian suggested that psychological factors for miners during emergencies such as reducing anxiety and improving morale are important considerations for using refuge chambers (Qunanian, 2007). According to Qunanion, psychological conditions regarding emergencies such as decreasing concern and increasing morale are significant parameters for using refuge chambers.

Gas and coal dust explosion has been one of the serious accidents to coal industry for many years, as in many cases miners can not have enough time to escape from high temperature and toxic gases (Brnich, M. J., Jr.(2010). In general, refuge chambers are designed to protect miners for up to 96 hours under worst conditions. (Zhang, et.al. 2014)(Safety,2008). The importance of refuge chambers is varying for each mine safety authorities to improve design and plan guidelines (Brnich and Kowalski-Trakofker, 2010).

In terms of heavy casualties are occured by underground mine accidents each year in China which are mainly due to underground miners poisining and suffocation that caused by the spread of toxic fumes in operation of accident (Mingju et. al., 2009, Keguan et.al.,2010).

In 2010, State Administration of Work Safety and State Administration of Coal Mine Safety reported the construction of a complete refuge 'six systems' and according to their notification, mine institutions must deal complete refuge system including underground monitor system, perfect positioning, underground miners, positioning system, emergency escape system, compressed air self rescue system, water supply system and communications network (Li, 2012).

According to Li (2012), emergency refuge system of refuge chamber, one of the 'six systems' of safety refuge chamber, is emergency chamber for miners to reduce damage caused by mine disasters while existing power supply is not guaranteed (Li LT,2012).

Permanent refuge chambers are fundamentally set in shaft station and near emergency exit of mining area, the distance of working face away which is based on specific situations in coal mine. In general, it is a part of emergency shelter for the complete coal mine or mining area, and it's service life time is over 10 years. Permanent refuge chambers should be determined in stable rock formations avoiding geologic tectonic zone, high temperature zone, stress anomaly locations and flooding threatened locations in order to fix that is not affected by mining operations during it's service life time (Meng et al., 2011).

Non–flammable materials should be utilized to increase the strength of roadway in 20 meters distance of is and its roof should be completed. Morever, the access route of refuge chamber safe area for the roadway does not need to be straight, and it can arrange various curve roads in order to decrease the shock wave hazard caused by gas and coal dust explosion (Hu, 2010).

The refuge chamber systems are made up by permanent refuge chamber, temporary refuge chamber and rescue capsule and they are also a refuge and transfer station to survive for the miners in disasters. A whole refuge chamber system increase the probability of being rescued for the miners in disasters, apply easy first-aid dressing for the seriously injured, and acquire self-help in reserve, decreasing loses and casualties. Thus, it is specifically significant to make safe and rational design (Meng et al, 2011).

3. REFUGE CHAMBER LOCATION IN UNDERGROUND TUNNELS

When locating a refuge chamber in an underground tunnel the walls should most definitely be smooth and rigid. Before processing continuous tunnel work, being well organized and determining the refuge chamber sight beforehand is most significant. Therefore, planning and designing the tunnel and refuge chamber simultaneously before commencing the mining operation is indispensable. Manufacturers produce the refuge chambers according to their customer's requests and demands. For that reason, each refuge chamber can be different sizes and dimensions. During the mining operations in underground, whether the tunnel coordinates, lengths and heights are well known, determining the refuge chamber location becomes easier, reliable and safer.

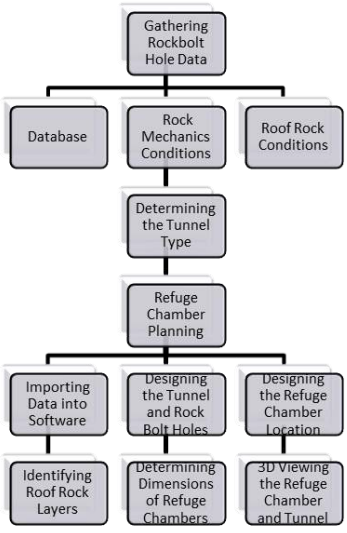

Figure 2. Flow sheet of designing and modelling tunnel and refuge chamber location in underground

As stated in the above and displayed in figure 2, planning the location design of refuge chambers most certainly needs to be well organized. In this process, there are important steps to create a 3D view of underground refuge chambers.

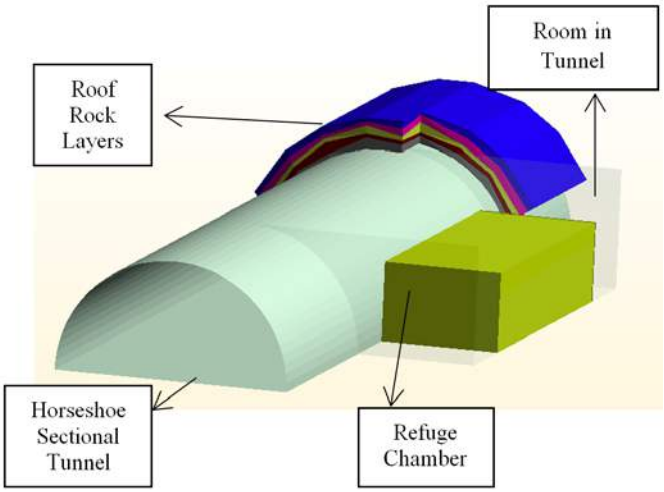

Figure 3. Model view of tunnel and roof rock characterization with refuge chamber

Each mine field show different characteristics of underground processes in terms of their depths, elevations and operational methods. Due to these reasons, placing the refuge chambers into the safest and best places depends on the refuge chambers dimensions and tunnel parameters. As shown in figure 3, the refuge chamber is positioned in the room of the tunnel.

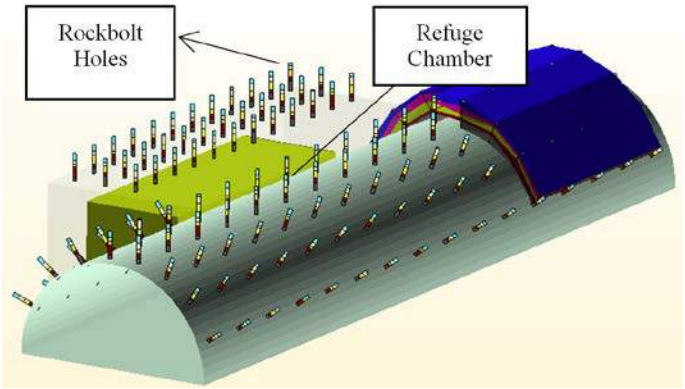

Figure 4. Refuge chamber and rockbolt holes showing roof rock layers in tunnel

Roof rock layers of tunnels give us additional information about the rock strengths or rock mechanical parameters and in knowing this information helps us find out the best place of refuge chambers in the underground. In case that the roof rock structure is weak and brittle, refuge chambers should obviously not be located in these areas.It is better to place these chambers in stronger and more durable areas. Drilling the rock bolt holes and measuring the levels of rock mass layers are the first steps of the modelling operation. After obtaining the data, rock mass properties are drawn by using mining software programmes. Figure 4 shows us the rockbolt holes and rock layers at the top of tunnel.

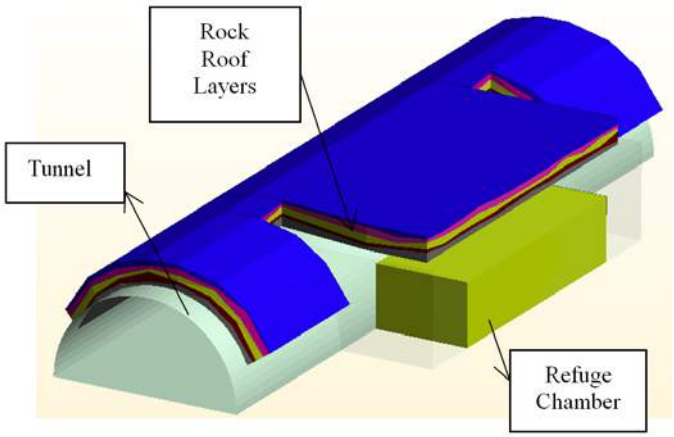

Figure 5. Refuge chamber and rock formations in underground tunneling

Through the use of cross-sectional methodology in mining software programmes, it is easier to create the rock layers and see the details of the tunnel with refuge chambers. The main purpose of this study is to view the refuge chambers in the underground. In Figure 5 it is seen that the tunnel and refuge chamber is together with the roof rock characteristics. Once the design of the tunnel and refuge chamber is completed, estimations and operations can be viewed and managed easily using the 3D view technique.

4. CONCLUSION

Refuge chamber utilization in underground mining is very significant and needs to be investigated in detail. When designing and developing a new underground mine, it is important to determine and define the specific location during the early stages of the mine design. In this study, underground tunnels and roof rock mass characteristics of

tunnels have been created. The main objective of the study is to install the refuge chambers inside the room of tunnels and forecast the next steps in operation. There are different approaches about how to find out the best place for refuge chambers and it depends on the operational method of the mines. This study presents an initial approach to prepare the area and install a refuge chamber located in an arched sectional underground tunnel. Tunnel design and refuge chamber utilization were designed in conjunction to confirm consistency of the refuge chamber geometry vs. the dimension of the tunnel section. Rock bolt holes were designed based on simulated data to emulate roof and lateral forces created by the layers. This model was designed by using computerized 3D modelling. All the coordinating data is based on possible geological assumptions. Therefore, any of the underground mining scenarios can be designed and developed using this computerized modeling. As a recommendation, the model can be developed and different underground mining types can be modified.

Long Term Planning In Open Pit Mines In Presence Of Commodity Price Uncertainty

M. Rahmanpour, M. Osanloo
Department of mining and metallurgy, Amirkabir University, Tehran, Iran

ABSTRACT Mine planning is a multidisciplinary procedure based on which the profitability of the mining operation is guaranteed in a changing and uncertain conditions. Many factors affect the preciseness of mine plans and cause deviations in reaching the predetermined objectives. Long-term production planning in open pit mines is defined as a precedence-constraint knapsack problem. This paper deals with price uncertainty and considering different price scenarios, it determines 9 different and mutually possible mine plans. Price variations throughout the mine life are modeled using the Generalized Autoregressive Conditional Heteroskedasticity (GARCH) and Geometric Brownian Motion (GBM) methods. Finally, using the concept of value at risk, the most profitable and the less risky plan is selected as the optimum mine plan. The model is applied in a small hypothetical iron ore deposit.

Keywords: Open pit mine, commodity price uncertainty

1 INTRODUCTION

The aim of mine planning is to develop a yearly extraction plan which guides the mining operation to the highest Net Present Value (Dagdelen 2007; Yarmuch and Ortiz 2011). This plan considers the constraints such as blending requirements, block sequencing, and pit slope (Caccetta and Hill 2003). Thus, determining the extraction sequence of mining blocks through the mine life is referred to as mine planning (Johnson 1968). The mine plan affects the economy and the payback period of mining operations. Mine planning is a procedure based on which the profitability of the mining operation is guaranteed in a changing and uncertain conditions (McCarter 1992). Mine plans are normally classified into long term, medium term, and short term plans.

In a sustainable mining operation, environmental, economical and social aspects of mining and its reclamation should be considered in mine planning procedure (Osanloo 2012). The essential data required for mine planning are geological, geo-mechanical, hydrological, economic, environmental, infrastructures, and the knowledge of mining engineering. These data contribute more or less on the mine planning procedure and mine plans. The characteristics of future mining activities and also inherited uncertainty of the data (such as commodity price, ore grade, mining costs, and recoveries) highlighted the importance of mine planning under the conditions of uncertainty. These issues and mainly the price uncertainties motivate the study of the factors that affect mine planning and their management.

Open pit mine production planning is a multi period precedence-constraint knapsack problem and it normally fit into the MILP framework (Osanloo et al. 2008; Newman et al. 2010). This problem is defined on a spatial representation of the mining area called block model (Figure 1) (Hustrulid et al. 2013).

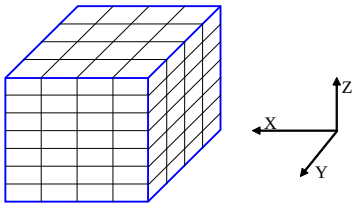

Figure 1. Simplified representation of a block model.

Considering the exploration-drilling pattern, geological condition, and the size of mining equipments to be used, the size of the blocks in a block model will be determined. After determining the block dimensions, the geological characteristics of each block are assigned using any available estimation techniques (Journel and Kyriakidis 2004). Then, considering the economic parameters such as selling price, operating costs, and overall recovery one could calculate the economic value of each block.

Using a block model, the aim of mine planning is to determine whether a given set of blocks should be mined or not, if so, at which time it should be mined, and once it is mined, then, how it should be processed to maximize the net present value of the operation (Dagdelen 2007). Once a block is mined, one could determine different destinations or processing methods for that block. Conclusively, the act of determining the time and extraction sequence of blocks through the mine life is referred to as mine production planning (Johnson 1968). The problem of production planning in open pit mines is studied by many researchers (Dowd and Onur 1992; Tolwinski and Underwood 1996; Denby and Schofield 1996; Kumral 2003; Ramazan and Dimitrakopoulos 2004; Menabde et al. 2007; Boland et al. 2008; Dimitrakopoulos and Ramazan 2008; Elkington and Durham 2009; Sattarvand 2009; Bley et al. 2010; Kumral 2010, Groeneveld and Topal 2011; Murakami et al. 2011; Gholamnejad and Moosavi 2012; Lamghari and Dimitrakopoulos 2012; Moosavi et al. 2014). These studies aimed to maximize the net present value of the operation while satisfying all the operational constraints.

There are two optimization approaches to solve the production-planning problem in open pit mines named deterministic and uncertainty based approaches (Osanloo et al. 2008). In deterministic models, all the inputs are assumed to have fixed known real values (such as Tan and Ramani 1992; Akaike and Dagdelen 1999; Zhang 2006; Elkington and Durham 2009; Cullenbine et al. 2011). However, the assumption of input's certainty is not always realistic and some data such as ore grades, future product demand, future product price, and production costs can vary throughout the mine life. Researchers (Albach 1976; Rovenscroft 1992; Smith 2001; Godoy and Dimitrakopoulos 2004; AbdelSabour et al. 2008; Abdelsabour and Dimitrakopoulos 2011 to name a few) have developed various models based on mixed integer linear programming, meta-heuristics, heuristics and simulation, chance constraint linear programming, and stochastic programming to determine the mine plan in uncertain condition.

In this paper the price uncertainty and its affect on mine planning is studied. To do so, a simple integer linear programming model is formulated to determine the production planning and mining sequence of block.

2 DESCRIPTION OF THE METHOD

Mineral price is a key factor in mine planning and it seems as the heart of any mining project. Mineral price has a volatile and changing nature. The mineral or the commodity price affects the mining cut off grade, mineable reserve, mine size, and mine life. Any long term change in commodity price will affect cutoff grade and amount of mineable reserve. For example in case of price fall, the ultimate pit limit shrinks, cutoff grade increases, low grade ore blocks will be classified as waste, amount of mineable reserve decreases, and it will change the long term and short term plans of the mine. It must be noticed that short term changes in commodity price will affect the short term plans (Tulp 1999). In these conditions, short term plans must be changed cautiously because short term gains may cause other problems in long term plans (Hall 2009-a).

This paper studies the effects of price uncertainty on mine planning and aims to minimize the risks of price changes throughout the mine life. The procedure of the study is as Figure 2.

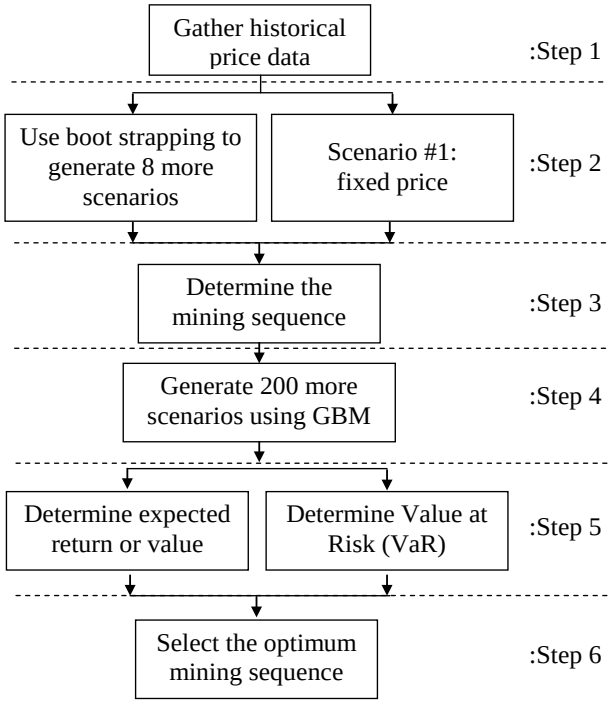

Figure 2. The procedure of determining the optimum mining sequence.

2.1 Bootstrapping

According to Figure 2, in the first step the historical changes in mineral price are collected in order to simulate the future possible price forecasts. In the 2nd step, the bootstrapping method is applied to determine 8 scenarios for future price trends and changes. Bootstrapping is a sampling method. Assuming a given data set of historical mineral prices, the yearly or monthly returns (i.e. rate of monthly/yearly price change in each period) are calculated. In order to forecast future mineral prices or to generate a new sequence of prices for a mineral, the individual returns are randomly chosen from historical returns. The main advantage of this method is that, it does not need any assumptions on the distribution of the returns and the empirical distribution of the returns is inherited in the sampling procedure. Using the method, 8 different scenarios are generated for the iron ore price (Figure 3).

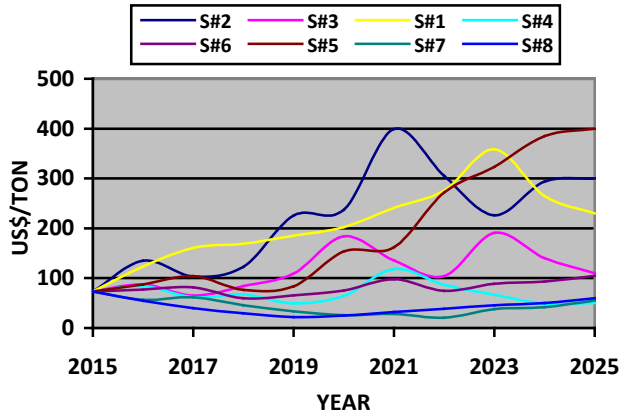

Figure 3. Simulated iron ore price using bootstrapping.

Another scenario with the assumption of fixed price throughout the mine life is made in order to have a bench mark to compare the results with the traditional approaches. Thus, at the end of the 2nd step, 9 price scenarios are determined for price changes in the next 10 year.

2.2 Mathematical Model Of Block Sequencing

In the 3rd step, the optimum block sequencing should be determined for each price scenario. An integer linear programming model of long-term production planning and block sequencing in open pit mines is formulated and it is given in equation 1. This model determines the time of extracting and processing method of each block to maximize the NPV of total operation.

Objective function:

$$\text{Max} \sum_{b\in B}\sum_{t\in T}\sum_{m\in M} c_{bmt}\, x_{bmt} \quad (1a)$$

Subject to:

$$\sum_{t\in T}\sum_{m\in M} x_{bmt} \le 1, \ \forall b \quad (1b)$$

$$MC_t \le \sum_{b\in B}\sum_{m\in M} X_b\, x_{bmt} \le \overline{MC_t}, \ \forall t \quad (1c)$$

$$PC_{mt} \le \sum_{b\in B} X_b\, x_{bmt} \le \overline{PC_{mt}}, \ \forall t,m \quad (1d)$$

$$\sum_{b\in B}(g_b - G^{t,m}_{\max})x_{bmt} \le 0, \forall t,m \quad (1e)$$

$$\sum_{b\in B}(g_b - G^{t,m}_{\min})x_{bmt} \ge 0, \forall t,m \quad (1f)$$

$$\sum_{t=1}^{t'}\sum_{b'\in P_b}(x_{bmt} - x_{b'mt}) \le 0, \ \forall b\in B, \forall t' \in \{1,...,T\} \quad (1g)$$

$$x_{bmt} = 0 \text{ or } 1, \ \forall b,t,m \quad (1h)$$

The notation of the model is as follow:

B	is the set of all blocks in the block model
P_b	is the set of blocks that overlays or precedes block b
t, t'	are the time index
T	is the mine life or number of the periods to be planned
M	is the number of possible destinations or processing alternatives
c_{bmt}	is the discounted economic value of block b mined at time t and sent to destination m
x_{bmt}	is the decision variable and it is equal to 1, if block b is mined at time t and sent to destination m and it is equal to 0, otherwise
$MC_t, \overline{MC_t}$	is the Min and Max mining rate at time t respectively
X_b	is the amount or tonnage of rock in block b
g_b	is the grade of commodity in block b (it is normally presented in percentage of the total tonnage in each block)
$G_{\min}^{t,m}, G_{\max}^{t,m}$	is the Min and Max acceptable grades at destination m at time t respectively
$PC_{mt}, \overline{PC_{mt}}$	is the Min and Max processing capacity at destination m at time t respectively

In equation 1a, the objective function of the model is defined as maximization of the discounted economic value or the NPV of the mining operation. Constraint 1b ensures that if block b is to be mined then it could only be mined once and sent to destination m at time t. Constraints 1c and 1d ensures that the total amount of rock mined and processed at time t does not exceed the prescribed lower and upper bounds on mining and processing capacities, respectively. Constraints 1e and 1f ensure that the average grade of material sent to each destination is within the prescribed lower and upper bounds. Constraint 1g is known as slope or proceeding constraint. This constraint ensures that wall slope restrictions are obeyed and block b can only be mined if all the overlaying blocks are removed beforehand. The model in equation 1 is programmed and solved using CPLEX 12.5.

According to the procedure (Figure 2), in step 2, 9 different price scenarios are generated for the mineral. The term c_{bmt} in the objective function is a function of mining time and the mineral price in that period. This term is embedded into the model using the generated scenarios.

At the end of this step, 9 different mine designs are generated for the ore deposit. The block sequencing in these plans is different from each other due to different and variable mineral prices in each period. The next step is to select the optimum block sequencing for the deposit. To do that, a simulation based approach is applied which will be described in the next subsection.

2.3 Geometric Brownian Motion

"Geometric Brownian Motion" or simply GBM is one of the most common methods for price modeling and scenario generation (Erlwein et al. 2012). In this method, the stock or the mineral price is modeled as a wiener process and it is a function of return and volatility of the mineral price (Equation 2) (Hall 2009-b).

$$S_t = S_0 \exp\left(\left(\mu - \frac{\sigma^2}{2}\right) + \sigma W_t\right) \quad (2)$$

Where, S_0 and S_t is the current mineral price and the mineral price in period t. The wiener process W_t is defined in equation 3.

$$W_t = z_t\sqrt{t},\ z_t = N(0,1) \quad (3)$$

In equation 2, μ is the return of the mineral price and it is calculated using equation 4.

$$\mu = Ln\left(\frac{S_t}{S_{t-1}}\right) \quad (4)$$

In this paper, the volatility of the mineral price in equation 2 is calculated using the Generalized Autoregressive Conditional Heteroskedasticity (GARCH) method. In this method, the volatility of the mineral price is

a function of its previous conditions and it is calculated using equation 5.

$$\sigma_t^2 = \gamma V_L + \alpha u_{t-1}^2 + \beta \sigma_{t-1}^2$$
$$\gamma + \alpha + \beta = 1 \quad (5)$$

In this equation, the term V_L is the long term variance or volatility of the mineral price. The parameters γ, α, β are defined such that they maximize the model in equation 6.

$$\sum_{i=1}^{t} \left(-\ln\left(\sigma_i^2\right) - \frac{u_i^2}{\sigma_i^2} \right) \quad (6)$$

Then, the GARCH model could be applied to estimate the future volatility of the mineral price (Equation 7).

$$E\left(\sigma_t^2\right) = V_L + \left(\alpha + \beta\right)^t \left(\sigma_0^2 - V_L\right) \quad (7)$$

Using the model in equation 6, the volatility of iron ore price in the coming years is estimated (Table 1).

Table 1. Estimated volatility of iron ore price.

Year	$E\left(\sigma_t^2\right)$
2015	0.26
2016	0.26
2017	0.27
2018	0.27
2019	0.27
2020	0.27
2021	0.27
2022	0.27
2023	0.28
2024	0.28
2025	0.28

Combining the result of Table 1 and equation 2, and using the GBM method, it is possible to simulate more scenarios for future prices. The result of 100 simulations is shown in Figure 4.

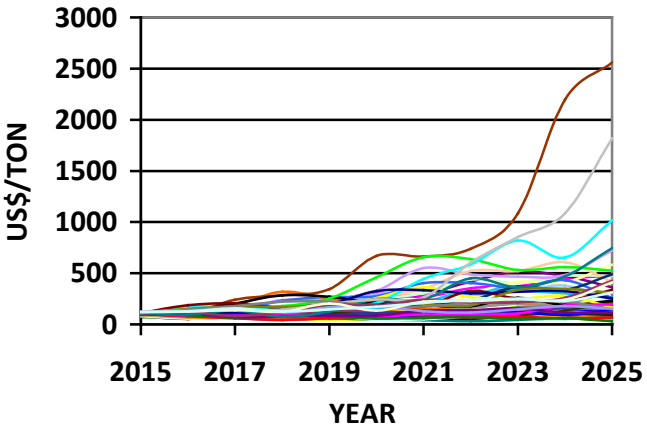

Figure 4. Simulated iron ore price using GBM.

2.4 Value At Risk And Expected Return

In the 5th step of the procedure given in Figure 2, the expected value (i.e. expected return) and the value at risk of each mine design should be determined.

In this step, the aim is to provide the answer of these questions, (1) what is the distribution of the mine value at the end of its life?, and (2) with 1 percent probability, what is the maximum loss at the end of mine life?.

Value at risk (VaR) is a measures of the worst expected loss under a normal market condition which is calculated for a specific time period at a given confidence level. VaR answers the questions like "with a probability of x%, how much can I lose over a pre-set horizon" (Benninga 2008). It means that VaR (1%) is the 1% quintile point of the probability distribution function of mine value.

3 RESULTS

The procedure described in Figure 2 is applied in a hypothetical iron ore deposit. As stated, 9 different mining plans are generated for this particular case considering the price scenarios generated via bootstrapping. After that, using the price scenarios generated by GBM method, the probability distribution of net present value of the mining operation is determined. Figure 5 represents the

cumulative probability distribution of the net present value (NPV) for plan #1.

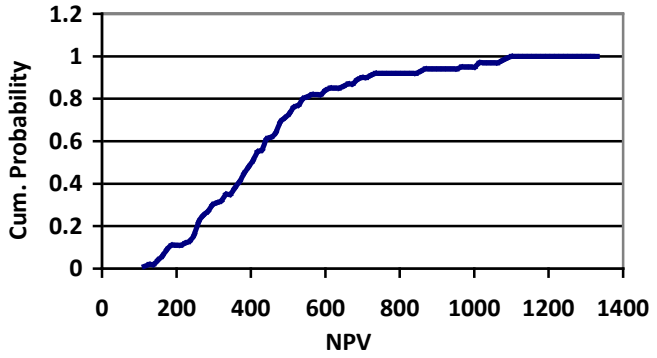

Figure 5. Probability distribution of the NPV for plan #1.

The result shows that plan#2 has the highest expected NPV compared with other plans (Figure 6). Also, considering the value at risk of each mining plan, the plan #8 has the lowest VaR (1%) among the other plans (Figure 7).

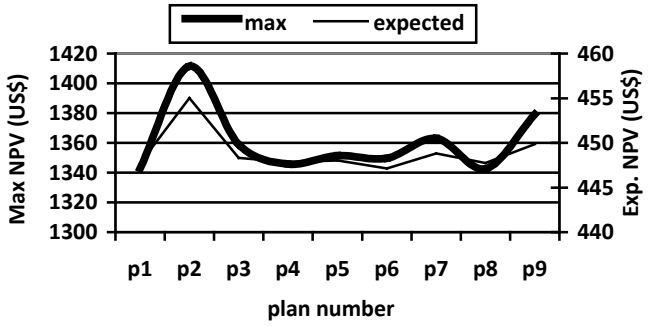

Figure 6. Maximum and expected NPV of mine plans.

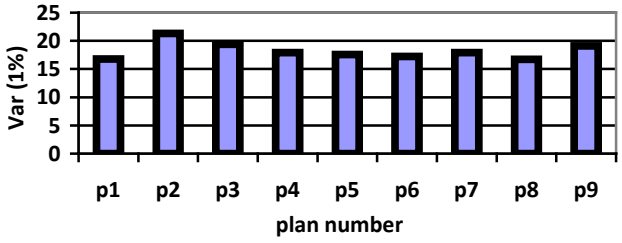

Figure 7. VaR (1%) of NPV for mine plans.

The amount of VaR in case of plan #8 is about 10.77% of the initial capital cost. The expected NPV and also the maximum possible NPV of the plan #8 is also the lowest among other plans. However, considering VaR, this plan will be comprehended as the optimum mining sequence in this example.

4 DISCUSSION

The procedure presented here is applied in a hypothetical iron ore deposit. The results should be validated using a real case data set. However, the procedure seems to be applicable in real world problems.

Following the procedure presented here, 9 different optimal mine plans were generated. These plans were analyzed in the presence of mineral price uncertainty. According to the results, the plan #8 is suggested as the optimum mining sequence in this case. Analyzing the price scenario based on which the mine plan is optimized; one could see that, in this particular scenario, the mineral price has a falling trend compared to the other scenarios. This will cause high grade ore blocks to be mined early in time in order to gain the maximum possible NPV.

The main limitation of the presented procedure is the determination of initial price trends and scenarios. The scenarios based on which the mine plans are determined are given in Figure 2. It means that there is a need to carefully determine the initial price trends. In this paper the bootstrapping method is applied to generate some price scenarios such that they are a representative sample of future price outcomes.

5 CONCLUSIONS

VaR is capable of determining the worst expected loss under a normal market condition and it helps the mine planner to determine the optimum mine plan under the uncertainty of mineral price.

The main conclusion is that, those mine plans determined based on the falling price scenarios has the lowest VaR compared with other plans.

Measuring Mine Planning Software Utilisation for Decision-Making Strategies in the South African Iron Ore Mining Sector

B. Genc and C. Musingwini
University of the Witwatersrand, Johannesburg, South Africa

ABSTRACT Mine planning software has and continues to contribute to the development of the South African mining industry. As mine planning software usage continues to be more widespread, it is imperative that a methodology to evaluate mine planning software utilization for enhanced decision-making strategies in South Africa is established. This paper institutes this new methodology to measure mine planning software utilisation in the South African iron ore mining sector. An existing online database available on the website link http://db.mining.wits.ac.za was developed prior to this study in September 2012 (initial data collection date) to show the mine planning software providers, their corresponding software solutions as well as the software capabilities and information on the number of licences. The outcome of this development and implementation was published in the *Journal of the Southern African Institute of Mining and Metallurgy* in 2013. In 2014, the dataset was updated with additional and new information.

The methodology for the evaluation of utilisation of mine planning software in various commodity sectors was developed on the basis of three variables, namely, commodity, functionality, and time factor, as a key evaluation criteria. Even though the calculations can be done on any commodity in a similar manner, in this paper, calculations were only performed on one commodity, namely iron ore which is one of the most significant minerals in South Africa. The work presented in this paper is part of a Ph.D. research study in the School of Mining Engineering at the University of the Witwatersrand.

Keywords: Iron ore mining, mine planning software utilisation, database, and South African mining industry

1 INTRODUCTION

Mine planning software plays a vital role in every stage of mining operations, even before the actual mining commences. Gibbs (1994) stated that mine planning software had changed radically in the five years prior to 1994. This statement is still valid today, twenty years after it was made. The South African mining industry adopted mine planning software usage and it is imperative that a methodology to evaluate mine planning software utilization for enhanced decision-making strategies in South Africa is established. This paper outlines the development of a new methodology to define and measure mine planning software utilisation in the South African iron ore mining sector. Although the calculations can be done on any commodity, in this paper, calculations were only done on the commodity iron ore as iron ore is not only one of the most significant commodities in the South African mining industry, but also iron ore generated almost 18% of the mining income during 2013 in South Africa (Statistics South Africa, 2014).

An initial dataset showing the mine planning software providers, their corresponding software solutions as well as the software capabilities and information on the number of licences was collected and compiled in 2012 in an online database. The database development and implementation was published in the *Journal of the Southern African Institute of Mining and Metallurgy* in 2013 (Katakwa, et al., 2013). In 2014 the database attracted more software providers to be the part of the dataset and using the updated dataset, a methodology was developed to measure mine planning

software utilisation for iron ore in order to inform decision-making strategies for utilisation of the iron ore sector's software.

2 SOFTWARE UTILISATION

Utilisation is an important factor as it is often associated with the level of productivity in the South African mining industry. According to the Oxford English Dictionaries (2014), the root of the word of utilisation comes from the word "utilise", meaning "make practical and effective use of". Hence software utilisation can be defined as the effective use of mine planning software but in general, utilisation is associated with the overall equipment effectiveness which is one of the key performance-based metrics. Overall Equipment Effectiveness (OEE) is not only one of the most widely used metrics to determine performance against capability of the equipment but also it is commonly used as a key performance indicator (KPI) in Total Productive Maintenance (TPM) and Lean Manufacturing programs for measuring production efficiency (Vorne Industries, 2008). Detailed information regarding the overall equipment effectiveness was documented by Genc et al. (2014).

The fact is that OEE is designed for measuring equipment utilisation which can be defined as *hardware utilisation*, there is a need to define *software utilisation*, which can be used to establish a framework towards defining strategic mine planning software utilisation.

Some researchers tried to define software utilisation using the number of techniques available such as system-user interaction data to understand how often the software is being used as well as in which degree it is being used. (El-Ramly & Stroulia, 2004). But this approach cannot be used to measure mine planning software utilisation by considering the size of the whole South African iron ore sector and user privacy. Due to these reasons, a methodology was developed in such a way that utilisation of the various mine planning software that is used in iron ore mining sector could be measured. The next section defines this measurement framework.

3 UTILISATION FRAMEWORK

Software utilisation can be defined by associating many-to-many, one-to-many and many-to-one relationships between entity types. In this association, the relationship between software vendors, commodity, functionality and time factor were used to develop the following terminology:

$$\{C_i, F_l\} \rightarrow S_{k=\{i,\,l\}} \tag{1}$$

Where S_k is the software that performs tasks on commodity (i) and functionality (l). In the market usually there is more than one software specifically designed for commodity (i) and functionality (l). Genc et al. (2014) gave a detailed explanation about the terminology which defined utilisation: $u_{i,l}^{(m)}$ is the utilisation of the software that performs task on commodity (i) and functionality (l) by using software (m) and

$$u_{i,l}^{(m)} \in [0,1]$$

Furthermore, the utilisation formula can be extended by considering time factor (t) to the following:

$$u_{i,l}^{(m,t)} = f_{i,l}^{(m,t)}.w_{i,l}^{(m,t)}$$

where $f_{i,l}^{(m,t)}$ is a quantity factor that relates to the software that performs a specific task on commodity (i) and functionality (l) using software (m) at a specific time (t) and $w_{i,l}^{(m,t)}$ is the weighing factor, which will handle the missing data related issues and/or other factors such as market capitalisation of the companies. For instance $f_{i,l}^{(m,t)}$ can be defined as the total number of sites. For example, if the market capitalisation of the software companies X and Y are 5 million USD and 100 million USD respectively, but if both companies have a software solution having the same functionality, then the weighing factor of the small company will be higher than the other software company. Furthermore, the price of the mine planning

software as well as support availability plays an important role when considering the weighing factor.

As the software utilisation is already defined in a generic way previously, however, the software utilisation can also be defined in a specific way, i.e. the relative utilisation (*r*). Relative utilisation can be considered as a weighed software utilisation and can be formulated as:

$$r_{i,l}^{(m,t)} = u_{i,l}^{(m,t)} / \sum_{n=1}^{M} u_{i,l}^{(n,t)}$$

Calculating relative utilisation leads to weighed market impact of the software utilisation. However, calculating relative utilisation, three variables were used to generate the results, namely:

- commodity (*i*),
- functionality (*l*),
- time factor (*t*).

For example, the following results were calculated for only one commodity (*i*) namely iron ore using six different functionalities (*l*) namely (Katakwa, et al., 2013):

1. "Geological data management
2. Geological modelling and resource estimation
3. Design and layout
4. Scheduling
5. Financial valuation
6. Optimisation"

Six functionalities listed by Katakwa et al. (2013) originated from the Open Group's Business Reference Model which categorises not only the functionalities of mine planning software, but also mine value chain stages and mining methods (The Open Group, 2010). The Open Group's Business Reference Model illustrates how the various software solutions interact with each other, although this classification can be debateable. For example, Mine 2-4D software that is used in mine scheduling is often used in conjunction with the Enhanced Production Scheduler (EPS) as it cannot produce a schedule without the use of EPS. Figure 1 shows the names of available mine planning software and their functionalities along the mining value chain.

The time (*t*) factor has two timestamp indicators showing different data collection dates namely:

- September 2012, t=1
- April 2014, t=2

By using all three variables, the weighed software utilisation, hence the market impact of each participating mine planning software was calculated. The dataset were extracted from the updated database and the programming language GNU Octave was used for the data analysis and the calculation of the software utilisation per functionality for the selected iron ore commodity using two different timestamps as mentioned previously.

It is important to note that if $f_{i,l}^{(m,t)}$ is 0; it means either the subject software does not support the specific functionality or the subject software does not support the specific commodity. Furthermore, when calculating $u_{i,l}^{(m,t)}$ and $w_{i,l}^{(m,t)}$, the value is set to 1 as at this stage of calculation the weighed software utilisation did not have any impact on the calculation of the relative software utilisation. The software_id which is a unique identifier of each particular software are not named in this research work, and have been numbered randomly

4 RESULTS

In this section, mine planning software utilisation for commodity (*i*) iron ore was calculated. Six functionalities (*l*) with two timestamps (*t*) were used for the calculations and the results for each functionality with two timestamps were presented as tables and figures, respectively. Accordingly, the total number of {6(*l*) x 2(*t*) = 12} tables for iron ore were created. After generating the tables, pie charts were created for each table for easy interpretation of the results. Consequently, using the functionality list, the remaining tables and figures were created in a similar manner.

The following software providers participated in this study: Geovia, MineRP Solutions, Sable, RungePincockMinarco, Maptek, Cyest Technology and CAE Mining. Note that data on CAE Mining was only made available in the April 2014 dataset. The results presented here do not cater for neither the mining methods nor the type of mine whether it is a surface or an underground operation.

4.1 Geological Data Management Software Results For Iron Ore

Table 1 shows the market impact of the individual software for commodity iron ore using the functionality, Geological Data Management, as at September, 2012 while Table 2 shows the same results using the second timestamp, i.e. April 2014. Figure 2 illustrates the graphical representation of both tables. Note that $f_{i,l}^{(m,t)}$, $w_{i,l}^{(m,t)}$, $u_{i,l}^{(m,t)}$ and $r_{i,l}^{(m,t)}$ in column headings in Tables 1 to 11 were defined in section 3.

When comparing the diagrams in Figure 2, there is a difference between the two pie charts; Although Surpac is still the leader with a 50% market impact, CAE Mining's Geological Data Management Solution software with a 31% market impact in the April 2014 chart is clearly visible.

4.2 Geological Modelling and Resource Estimation Software Results For Iron Ore

Table 3 shows the market impact of the individual software for the commodity iron ore using the Geological Modelling and Resource Estimation functionality as at September, 2012 while Table 4 shows the same results using the second timestamp, April 2014. Figure 4 illustrates the graphical representation of both tables.

When comparing the diagrams in Figure 3, similar to the previous results, there is a huge difference between the two pie charts; Surpac is once again the leading software with a 47% market impact in the April 2014 chart. Studio 3 - Geology have a 41% market impact in this field.

4.4 Scheduling Software Results For Iron Ore

Table 7 shows the market impact of the individual software for the commodity iron ore using the Scheduling functionality as at September, 2012 while Table 8 shows the same results using the second timestamp, April 2014. Figure 5 illustrates the graphical representation of both tables.

When comparing the diagrams in Figure 5, there is not much difference between the two figures; Xpac and MineSched software still has the biggest market impact with 38% and 25%, respectively in the Scheduling software field.

Table 7. Scheduling functionality software utilisation for iron ore as of September 2012

4.5 Financial Valuation Software Results For Iron Ore

Table 9 shows the market impact of the individual software for the commodity iron ore using the Financial Valuation software functionality as at September, 2012 while Table 10 shows the same results using the second timestamp, April 2014. Figure 6 illustrates the graphical representation of both tables.

Figure 6 indicates that Whittle is still the leading software with a 75% market impact in the iron ore sector when it comes to the Financial Valuation software. NPV Scheduler (CAE) is in the second place with a 25% market impact in this field.

Table 9. Financial Valuation functionality software utilisation for iron ore as of September 2012

m	software_id	$f_{i,l}^{(m,t)}$	$w_{i,l}^{(m,t)}$	$u_{i,l}^{(m,t)}$	$r_{i,l}^{(m,t)}$

4.6 Optimisation Software Results For Iron Ore

Table 11 shows the market impact of the individual software for the commodity iron ore using the Optimisation functionality as at September, 2012 while Table 12 shows the same results using the second timestamp, April 2014. Figure 7 illustrates the graphical representation of both tables, Table 11 and Table 12.

When comparing the diagrams in Figure 7, there is a noteworthy difference between the two pie charts; Studio 3 – Geology has emerged as a new leader with a 47% market impact in April 2014, which is followed by Whittle with a 40% market impact in the Optimisation software field.

Table 11. Optimisation functionality software utilisation for iron ore as of September 2012

m	software_id	$f_{i,l}^{(m,t)}$	$w_{i,l}^{(m,t)}$	$u_{i,l}^{(m,t)}$	$r_{i,l}^{(m,t)}$
1	1	0	1	0	0

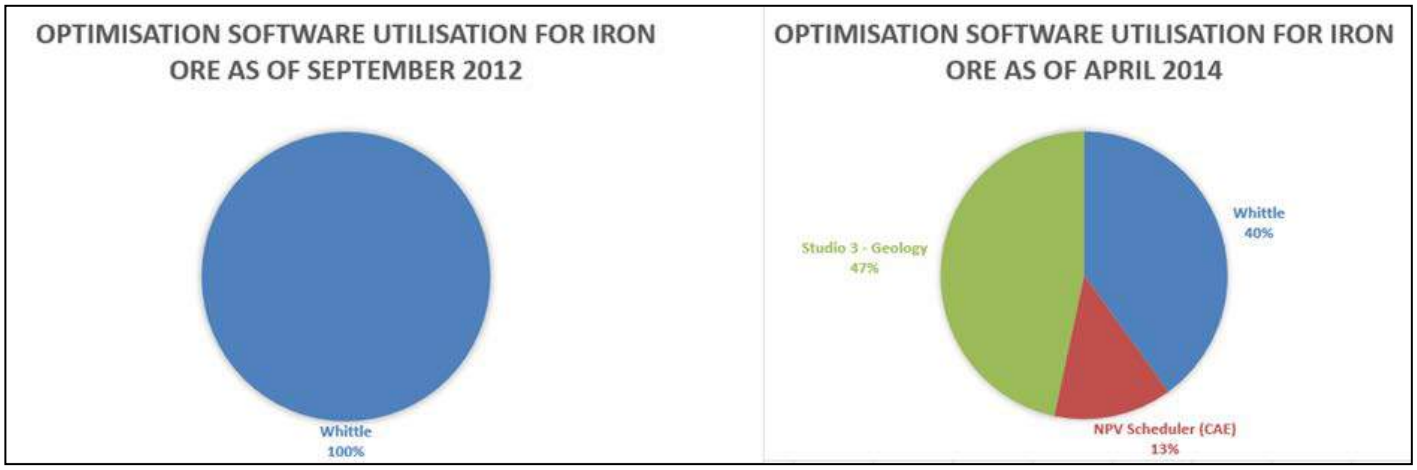

Figure 7. Optimisation functionality software utilisation for iron ore

5 CONCLUSION

The South African mining industry makes use of mine planning software in every stage of the mining operations. To gain maximum benefit from these operations, efficiency within the mining sector needs to be improved. To improve efficiency, a methodology to evaluate mine planning software utilisation for enhanced decision-making strategies was developed by calculating mine planning software utilisation with two time-stamps. Through these informed decision-making strategies, the South African mining industry is now in a position to choose the leading software solutions, which will lead to improved production efficiencies. A methodology for the evaluation of mine planning software for measuring utilisation in the South African iron ore mining sector was developed. In this framework, three variables, namely, commodity (i), functionality (l), and time factor (t) were used to calculate the results. It is important to note that data on CAE Mining was only made available in the April

2014 dataset. When comparing the results, the GEOVIA and CAE Mining market impact is visible in the iron ore sector.

This methodology provides an opportunity for all involved parties to strategically position themselves within the very highly contested mine planning software market.
